Prion diseases in animals include *scrapie* of sheep and goats, *bovine spongiform encephalopathy* (BSE), *chronic wasting disease* (CWD) of deer and elk, *transmissible mink encephalopathy* (TME), *feline spongiform encephalopathy* (FSE), and *exotic ungulate encephalopathy* of captive wild ruminants. Human prion diseases include *kuru; Creutzfeldt–Jacob disease* (CJD), which has four types, sporadic CJD, familial CJD, iatrogenic CJD, and variant CJD (vCJD); *Gerstmann–Straussler–Scheinker disease* (GSS); and *fatal familial insomnia* (FFI). The inherited prion diseases of humans are all of dominant inheritance and all are associated with coding mutations of the *PRNP* gene. Interest in the TSEs has increased greatly for several reasons. First, the discovery that these diseases may result from an infectious protein agent that is lacking nucleic acids contradicted the central dogma of modern biology that all living organisms use nucleic acids to reproduce. Second, the appearance of BSE in Great Britain and other parts of the world, and its presumed relationship to vCJD, triggered both scientific and public interest in these diseases. Despite extensive work on prions, our understanding of their pathogenesis and etiology is incomplete.

The *protein-only hypothesis* is currently the most accepted hypothesis for the pathogenesis of prion diseases. This hypothesis states that: (1) PrP^{Sc} is the etiologic agent of TSEs and other prion diseases; (2) the transformation of α-helical PrP to its misfolded β-pleated sheet isoform, the PrP^{Sc}, requires either a genetic predisposition or requires the help of unknown protein cofactors (protein X) that act as a molecular chaperone for this conversion; (3) PrP^{Sc} triggers the PrP gene (*PRNP*) to produce more PrP^{Sc} (self-replicating protein); and (4) PrP^{Sc} can be infectious itself and can be transmitted to other hosts and cause disease (transmissible protein). There is a species barrier to transmission of the TSE agent, but it is not complete. Less-accepted theories for the etiology of prion diseases include the virion or virus hypothesis, and the autoimmunity/allergic hypothesis, which states that TSEs could be autoimmune diseases resulting from ingestion of feedstuffs contaminated with certain bacteria, e.g., *Acinetobacter* spp., that show molecular mimicry between bacterial components and CNS tissue. *Spiroplasma mirum*, a cell-wall-deficient bacterium, has also been proposed as a trigger for TSEs.

The mechanism by which PrP^{Sc} causes nerve cell degeneration is complicated and several mechanisms have been proposed including: (1) mechanical destruction of nerve cell membranes from the excessive accumulations; (2) lysosomal accumulation of PrP^{Sc} may trigger apoptosis by release of cathepsin D into cytosol; and (3) PrP^{Sc} may be a direct neurotoxin. There are multiple strains of prions in scrapie of sheep, the strains distinguished by biological properties in defined strains of mice determined especially by incubation periods and lesion profiles, and the nature and patterns of neuropathological changes. In sporadic disease in humans, different strains or types of the agent are beginning to be related to clinical phenotypes, and in some of the diseases in animals, additional to scrapie, there is evidence for strain variation. The agent of BSE is exceptional in being, so far, monotypic. Prions have unusual resistance to physical and chemical agents and this unusual resistance makes inactivation of prion infectivity very difficult.

The pathogenesis of these diseases is further complicated by genetic variation among hosts whereby homozygosity at particular codons is known to confer susceptibility to the natural or experimental disease and heterozygosity confers survival advantage, although this is expressed mainly as prolonged incubation time. In heterozygotes, the outcome of exposure may be further modified by other polymorphisms. For example, sheep carry two alleles of the PrP gene and five different allelic variants. Sheep breeds that are homozygous for the variant VRQ/VRQ (valine (V) at codon 136, arginine (R) at codon 154, glutamine (Q) at codon 171) are the most susceptible to scrapie, whereas sheep with the ARR (alanine (A)) variant are most resistant and do not develop overt disease.

The transmission of prions between individuals or species in spontaneous disease remains a mystery, except for kuru for which there is strong evidence for ritualistic cannibalism, and vCJD for which there is compelling evidence of oral transmission from BSE. It is noteworthy that all cases of vCJD and kuru are homozygous for methionine at *PRNP* codon 129. The oral route is probably important for BSE, vCJD, and TME. The mode of transmission of scrapie and CWD remains unclear.

There are *no gross abnormalities* in the brain other than those expected in older animals with a wasting disease. Some elements of the histological picture are consistently present but variable in their neuroanatomical distribution and degree of expression. The most consistent pattern involves the medulla oblongata. Inflammatory change is absent. *Spongiform change is an important identifying feature.* It consists of small rounded vacuoles in the neuropil sometimes extending into neurites. The vacuoles in the neuropil may become confluent. The extracellular space is normal. The vacuoles are of variable distribution in cerebral gray matter and may be diffuse or clustered. The pathogenesis of the spongiform change is not known.

Neuronal vacuolation has long been the identifier for scrapie. It is a feature of the natural and experimental prion diseases of animals noted above. The vacuolation may occur in the soma, perikaryon, or neurites, but may not be accompanied by the spongy change described above. The empty vacuoles may be single, multiple, or in chains. Loss of neurons is difficult to assess and neuronophagia is absent. Descriptions of abnormal numbers of dark neurons may not be significant.

Astrocytic hypertrophy and hyperplasia varies in severity. Astrocytic nuclei may be paired or densely packed and may be without increase of fibers. Astrocytosis usually involves gray matter affected by spongiform change and may spread to adjacent white matter.

Although frequent and readily detected in kuru and in vCJD of humans, *amyloid plaques are sparse or absent in the animal diseases.* They may be difficult to demonstrate in hematoxylin-eosin-stained sections but are well demonstrated with Congo red and especially the periodic acid-Schiff method. The pathogenic prion isoform is subject to limited proteolysis to produce a smaller molecule, PRP27-30, which is protease resistant and deposited as intraneural amyloid in neurons and neuropil and around neurons and blood vessels.

Electron-microscopic examination of detergent extracts of infected brain reveals characteristic fibrils, termed "*scrapie-associated fibrils*" (SAF), which have PrP^{sc} as their major component. In many cases, plaques of this material may be present in the neuropil, as histochemically detectable amyloid deposits, and it can be detected more sensitively by specific immuno-staining as "scrapie immunoreactive amyloid." Cerebrovascular amyloidosis is also usually demonstrable in ovine scrapie.

Scrapie was the first prion disease to be recognized and described, around 1732 in the UK, and is endemic worldwide, except in Australia and New Zealand where it has been eradicated. The precise route of transmission is unclear but the disease spreads in an infectious-like pattern with rapid lateral communicability in a contaminated field. Infection mostly occurs around the time of birth, and probably via ingestion, but the question of vertical modes of transmission remains unclarified. The likelihood of ewe-to-lamb transmission is highly significant, in that a ewe could give birth to and infect several lambs before showing clinical signs. The scrapie agent can infect goats sharing the pasture with affected sheep; natural spread to species other than goats grazing the same pasture is not reported.

As discussed above, sheep breeds differ in their susceptibility to scrapie. The morbidity of the natural disease is low, except in some closed stud flocks, and clinically affected animals are usually in the 2–5-year age group. There is a long incubation period, and the disease, once clinically manifest, is progressive and ultimately fatal in from 10 days to several months. The agent proliferates initially in the lymphoid tissues and lower intestine, but may take up to 2 years to reach the nervous system. A further 2 years may lapse before clinical signs appear. The methods of spread of the agent between both cells and organ systems are still enigmatic, although there is good evidence that the nervous system is first infected via the splanchnic nerves, which carry the agent to the thoracic spinal cord. Once within the central nervous system, the presence of the agent seems to be of no consequence until it reaches "clinical target areas," where the expression of PrP^{Sc} in select neurons could presumably lead to progressive dysfunction.

Both clinical signs and pathologic changes are somewhat variable but, in general, affected sheep are initially alert but excitable, tremble when excited, and may have seizures. Later, paresthesias may appear, manifested as agitated rubbing against posts and trees, and nibbling at the feet and legs when lying down, behavior that gave rise to the colloquial name "scrapie." Self-trauma can cause extensive loss of wool

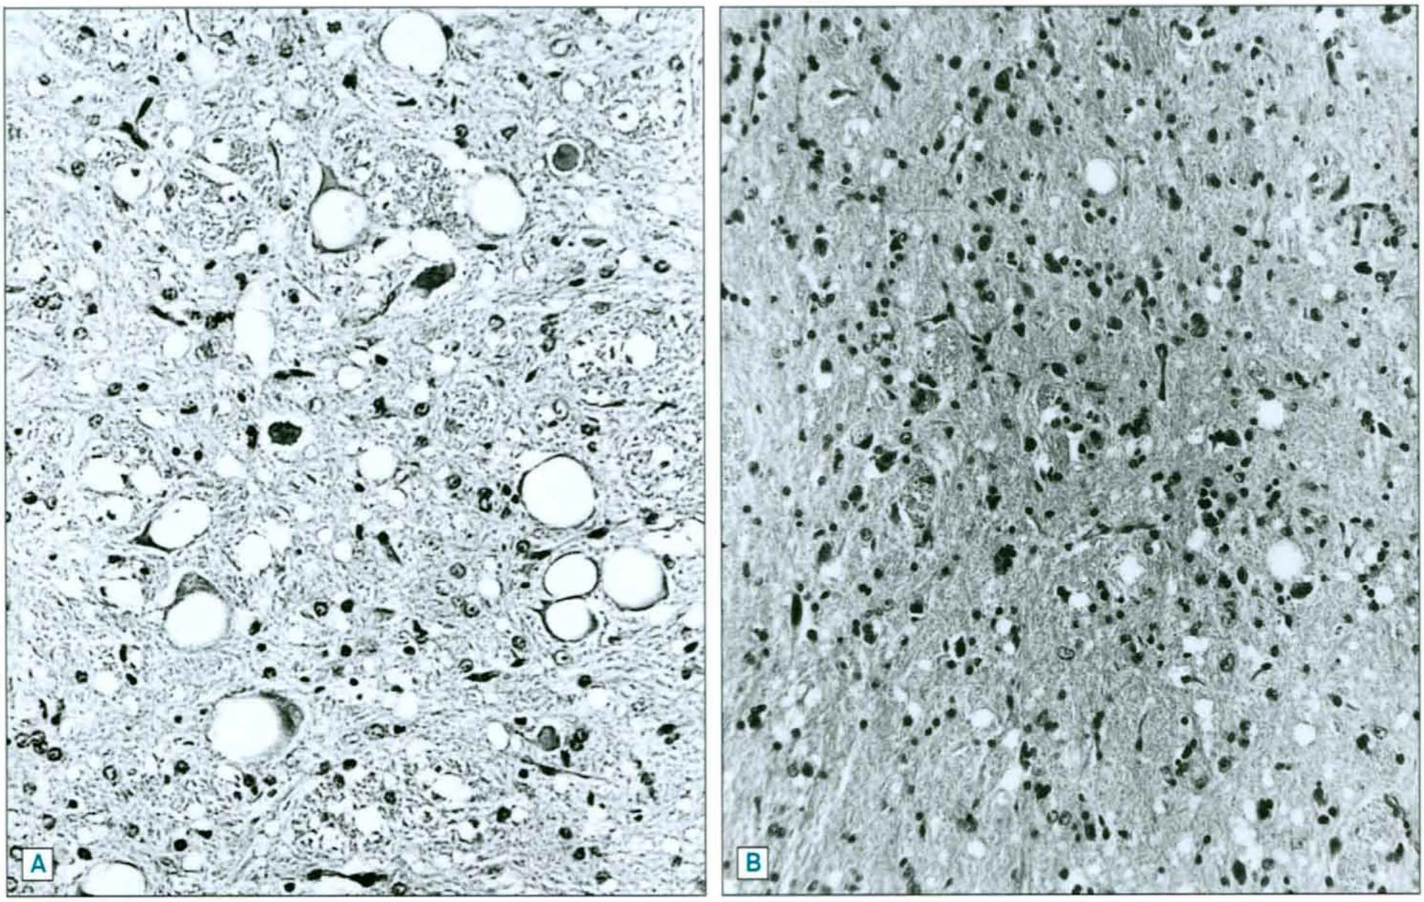

Figure 3.99 Scrapie in a sheep. **A.** Vacuolated neurons in the brain stem. **B.** Vacuolated neurons, loss of neurons, and gliosis in the medulla.

and abrasions of the skin. There is also progressive dysmetria and emaciation, and finally paralysis and death.

Apart from emaciation and self-trauma, there are no significant gross lesions, and no inflammatory changes. The most characteristic finding is the presence of *large intraneuronal vacuoles* in the medullary reticular, medial vestibular, lateral cuneate, and papilliform nuclei. The neuronal vacuolation may however be present throughout the brain stem and spinal cord (Fig. 3.99A). The vacuoles contain no stainable material and may considerably distort and displace the normal organelles. Although the vacuolated neurons do not generally appear degenerate in any other way, shrunken and apparently degenerate neurons may be found in mesencephalic, medullary, and deep cerebellar nuclei, and in the intermediolateral nucleus of the spinal cord. In late stages, neuronal loss may be evident, as well as diffuse fibrillary astrogliosis present mainly in the mesencephalon (Fig. 3.99B) and the molecular layer of the cerebellum. These lesions are bilaterally symmetrical, and the cerebral cortex is rarely involved (see Fig. 3.12A, B). *Spongy vacuolation of the neuropil* in gray matter is due to vacuolation of neuronal processes, but it is seldom a feature of the natural disease in sheep.

Bovine spongiform encephalopathy (BSE) causes cattle 3–6 years of age to become apprehensive, hyperesthetic, and dysmetric. The animals display fear and aggressive behavior, with progressive gait disturbances leading to frequent falling. Eventually, frenzied episodes or recumbency necessitate euthanasia. The origin of the rogue prion is still undetermined; however, ingestion of feed contaminated with infectious prion is the most likely origin for BSE. This contamination may have come from bone and meat meal from scrapie-infected sheep carcasses; however the BSE agent is different biologically than any of the known scrapie strains. Another source suggested is feed contamination with the remains of humans infected with CJD. Sporadic and genetically determined TSEs have not been detected in cattle. BSE is basically a food-borne epidemic; lateral or vertical transmission is highly unlikely. *The pathologic features of BSE resemble those of scrapie*. Scrapie-associated fibrils and immunoreactive amyloid are demonstrable. *Vacuolation of neuronal cell bodies and processes* is particularly prominent in the dorsal vagal, medullary reticular, vestibular, solitary, spinal trigeminal, and red nuclei, and is accompanied by moderate degrees of *spongiform change in neuropil*. The severity of neuropil and neuronal somatic vacuolation varies independently among anatomic locations, and the latter is sometimes accompanied by ceroid-lipofuscin granules. Occasional necrotic neurons and axonal spheroids may be present, as may mild astrogliosis.

Transmissible mink encephalopathy (TME) has caused high levels of morbidity and mortality in ranch mink in North America and northern Europe including Finland and Russia. The source of TME infection was not determined, but contamination of feed materials by the scrapie agent was suggested. The agent was experimentally pathogenic to a variety of wild carnivores, sheep, cattle, and primates. Neuronal vacuolation is sparse in this disease, which exhibits *spongy* *degeneration and astrocytosis* of parallel intensity. Neuronal vacuolation is mainly in brain stem. The lesions are especially well developed in the neocortex and amygdala, corpus striatum, caudodorsal thalamus, and medial geniculate bodies. The pathologic profile may differ between countries, perhaps due to strain differences of the agent or genotype of the captive mink.

Chronic wasting disease (CWD) of cervids affects mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginianus*), Rocky Mountain elk (*Cervus elaphus nelsoni*), and perhaps other cervids in several states in the USA and in western Canada. Although CWD was first diagnosed in the 1960s in captive cervids, it is now prevalent and possibly increasing among free-ranging and wild susceptible species and is considered to be the only TSE that occurs in free-ranging animals. The source of infection is unknown, but the disease is likely spread horizontally by ingestion of material contaminated with the CWD agent. CWD PrP^{Sc} is widespread not only in the CNS but also in various lymphoid tissues, including gut-associated lymphoid tissue (GALT). The presence of PrP^{SC} in GALT led to the presumption that PrP^{Sc} could be shed in feces causing pasture contamination and a health hazard to other animals or humans. Affected animals show slow progressive weight loss, dullness and depression, polydipsia and polyuria. Deer may show swallowing difficulty and esophageal dilation. Spongiform change, neuronal vacuolation, gliosis, and amyloid deposition are especially well developed in the olfactory tubercle, cortex hypothalamus, and vagal nuclei. Amyloid plaques are more frequently demonstrated in deer than in elk.

Feline spongiform encephalopathy (FSE) has been observed in domestic cats and captive felids in zoos. FSE was likely transmitted to captive felids by ingestion of BSE-infected cattle carcasses, and to domestic cats by ingestion of pet food contaminated with the BSE agent. The lesion pattern emphasizes the spongy change in deep laminae of cerebrum, the corpus striatum, thalamus, medial geniculate body, and cerebellar cortex. Neuronal vacuolation occurs mainly in medullary neurons but is not pronounced.

Transmissible spongiform encephalopathy of captive wild ruminants Several zoo members of the family Bovidae, e.g. nyala, Arabian oryx, and a bison, developed TSE at the time of the BSE epidemic in UK in association with ingestion of BSE-contaminated meat and bone meal.

Spongiform encephalopathy in nonhuman primates Lemurs and a rhesus macaque in France developed TSE naturally. The disease was likely a food-borne infection from ingestion of primate food containing BSE-contaminated beef.

Laboratory **diagnosis** of TSEs can be achieved by immunohistochemistry or by rapid tests such as ELISA or Western blot.

Bovine citrullinemia

This fulminating neurologic affliction of newborn Holstein-Friesian calves results from a blockade of urea cycle metabolism caused by *deficiency of arginosuccinate synthetase*. The enzyme deficiency leads to hyperammonemia and citrullinemia, and is due to an *autosomal recessive* genetic defect. Increased cross-breeding and screening of sires for the defect have reduced its prevalence to insignificant levels. Citrullinemia has also been reported in dogs.

Calves are affected within the first week of life, the clinical features being depression, head pressing, stupor, convulsions, terminal coma, and death. There are no gross neural lesions, but microscopically there is mild to moderate spongy vacuolation of the deep laminae of the cerebral cortex. *The spongy change is due to astrocytic swelling.* Hydropic astrocytes have enlarged vesicular nuclei, but their cell bodies and processes are vacuolated and give rise to the spongiform appearance of the neuropil, the creation of perineuronal spaces, and the enlargement of pericapillary spaces. The astrocytic reaction is believed to represent a stress on these cells in their attempts to detoxify ammonia. Astrocytes play a major role in ammonia detoxification via utilization of glutamine synthetase and glutamate dehydrogenase activities. In spite of the marked degenerative changes in astrocytes, other elements of the tissue remain morphologically normal, but neuronal function is obviously grossly disturbed.

Affected calves also have pale yellow-ochre discoloration of the liver, which is correlated microscopically and ultrastructurally with hydropic degeneration of hepatocytes.

Neuronal vacuolar degeneration of Angora goats

A scrapie-like neuronopathy is described in young Angora goats in Australia (where scrapie is not present), and is presumed to be genetically determined. Animals become ataxic at about 3 months of age, and progress to severe paresis. No significant gross lesions are present, but there is spectacular vacuolation of large neurons in the red nucleus and other brainstem nuclei, and in the spinal motor neurons. Some Wallerian changes are present in the brain stem, spinal cord and peripheral nerves.

Focal spongiform encephalopathy of dogs

A disease was originally described in **Bull Mastiffs** as familial cerebellar ataxia with hydrocephalus, but the main pathologic feature is spongy vacuolation of several gray matter nuclei. Clinical signs emerge between 6 and 9 weeks of age, and include ataxia and visual impairment, and a number of other variable deficits. An autosomal recessive genetic defect has been proposed.

Macroscopically, there is moderate to severe dilation of the ventricular system. Microscopically, bilaterally symmetrical spongy vacuolation and gliosis are evident in all three deep cerebellar nuclei, the posterior colliculi and, to a lesser extent, the lateral vestibular nuclei. The vacuolation is accompanied by axonal spheroids, but nerve cell bodies appear normal. Some of the vacuoles appear to involve myelin sheaths, but the lesions are essentially confined to the gray matter, and the cytologic basis of the vacuolation is not precisely defined.

Similar vacuolating lesions of these gray matter areas have been described in **Saluki** dogs.

Spongiform encephalopathy of unknown etiology and characterized histologically by neuronal vacuolation is recognized in **Rottweiler** dogs. The condition usually starts at 8 weeks of age and is characterized clinically by progressive laryngeal paralysis, tetraparesis, and cerebellar ataxia. Vacuolated neurons are prevalent in the cerebellar roof nuclei, nuclei of the extrapyramidal system, dorsal nerve root ganglia, myenteric plexus, and other ganglia of the autonomic nervous system.

A hereditary polioencephalomyelopathy of **Australian Cattle Dogs** is characterized histologically by neuronal, neuropilar, and astrocytic vacuolation, particularly in the ventral horn of the spinal cord, cerebellar, and brain stem nuclei. An autosomal recessive trait affecting the astrocytic mitochondria is suspected.

Alaskan Husky dogs can develop a hereditary familial encephalopathy (*Alaskan Husky encephalopathy*) similar to Leigh syndrome in humans and to the multifocal symmetrical myelinolytic encephalopathy of Simmental calves described above. Clinical signs usually start before 1 year of age and include seizures, ataxia, blindness, and behavioral abnormalities. Lesions are more prevalent in the basal nuclei, thalamus, midbrain, pons, and medulla oblongata, and include bilateral symmetrical malacia, status spongiosus, gemistocytic astrocytosis with marked intracytoplasmic vacuolation, gliosis, vascular hyperplasia, and mild infiltration of mixed inflammatory cells, with relative neuronal sparing. Similar but milder lesions occur in the cerebellar ventral vermis and the base of cerebral sulci. Neuronal sparing and marked astrocytic vacuolation suggests a role for astrocytes in the pathogenesis of this condition.

INFLAMMATION IN THE CENTRAL NERVOUS SYSTEM

Brain and infection

Organs defend against invading infectious organisms either by innate or adaptive immunity. Innate immunity is composed of resident components, e.g., pulmonary alveolar macrophages, or recruited components, e.g., neutrophils. Unlike parenchymatous organs, the brain depends solely on resident innate immunity to recognize and clear pathogens. In other words, under normal nondisease conditions, the brain does not rely either on adaptive immunity or the recruited components of innate immunity for defense. Innate immunity in the brain is diverse and composed of structural units, e.g., blood–brain barrier (BBB), plus cellular and chemical components.

The structural units that separate vulnerable brain cells from the blood stream are the **blood–brain barrier (BBB)** and the **blood–cerebrospinal fluid barrier (BCSFB)**, which is present at the choroid plexuses. The BBB is made up of endothelial cells lining the blood capillaries, pericytes embedded in the capillary basement membranes, and the foot processes of astrocytes. The endothelial cells of the BBB differ from other body endothelial cells, first by having significantly fewer endocytotic vesicles, thereby limiting the amount of transcellular flux, and second, they are connected by both *adherens junction* (e.g., cadherin) and *tight junction proteins*; the latter significantly reduce paracellular flux. Also, BBB endothelial cells are rich in several transport systems that selectively transport essential nutrients to the brain or harmful material back into the blood (efflux transport proteins). One of the most important efflux proteins is *P-glycoprotein*. Inhibition of P-glycoprotein increases the tissue invasiveness of *Listeria monocytogenes*. In addition to these protective properties of the BBB, the CSF side of the BCSFB is also rich in tight junctions, which restricts movement to the CSF. *The ability of organisms to breach these barriers determines their neurotropism*. Neurotropic viruses and bacteria have developed several strategies to breach or to cross these barriers. For example, several neurotropic viruses bypass the BBB and invade the brain via axons (e.g., *Rabies virus*); intracellular bacteria (e.g., *Mycobacterium bovis*) invade the brain as Trojan horses, hidden in infected leukocytes; and finally some bacteria have a direct cytotoxic effect on the endothelial cells of the BBB (e.g., *Histophilus somni*).

The cellular part of the brain's innate immunity is composed of perivascular **dendritic cells, microglia**, and **astrocytes**. These cells are rich in *pattern recognition receptors*, which bind directly and nonspecifically to *pathogen-associated molecular patterns*. For example, all three cell types are rich in *macrophage mannose receptor*, which is a lectin receptor that recognizes "nonself" sugars on the cell wall of gram-negative and gram-positive bacteria, parasites, and yeasts. Microglia cells also express several *tool-like receptors,* e.g., TLR 2 and 6, which have a major role as bridges between innate and adaptive immunity. Activated microglia express several receptors important for phagocytosis, e.g., CR3 and CR4; recognition of pathogens is followed by phagocytosis, largely by microglial cells and to a lesser extent by astrocytes. Finally, glial cells release several *cytokines* and *antimicrobial peptides*, for example, interleukin-1β, tumor necrosis factor-α, and the antimicrobial peptide *cathelicidin*. Inflammation of the brain starts once an infectious agent overcomes the resident innate immunity and recruiting begins of different components of adaptive immunity (leukocytes and humoral immunity), which are more specific and more effective but also more destructive.

Inflammation in the central nervous system

Inflammation of the brain is **encephalitis**, of the spinal cord **myelitis**, of the ependyma **ependymitis**, of the choroid plexus **choroiditis**, and of the meninges **meningitis**, qualified as **leptomeningitis** when it involves the pia-arachnoid and as **pachymeningitis** when it involves the dura. This is the area of neuropathology that is of most veterinary importance because it embraces many of the transmissible highly fatal infections of animals, because even the sporadic infections are common, and because there is always a pressing need for the pathologist to separate the inflammations into general or specific etiological categories. Most of the specific infectious diseases to be described in this chapter are caused by agents that demonstrate a remarkable or specific neurotropism. These are, however, only a segment of the list of agents that commonly, occasionally, or rarely involve the CNS (Table 3.1); neurologic lesions are also discussed with systemic infections elsewhere in these volumes.

Inflammatory processes in the CNS are basically the same as those in other tissues, but they derive some specific features from the special responsiveness and anatomic arrangements of the CNS. It is important to recognize the criteria of inflammation in the CNS and then to presume from that, as far as is possible, the nature of the infecting organisms because opportunities to intervene clinically are brief and the time frame for clinical intervention is less than required for definitive microbiological diagnosis.

The problem is not only one of why and how the CNS, of known high vulnerability to infection, is so frequently spared in systemic diseases; it is also one of why and how it is infected hematogenously. There is presently no better knowledge of why four out of five cases of Glasser's disease will have meningitis than why one of five will not, even though in the one case the pathologic syndrome is otherwise fully developed.

Infections that, in other organs or tissues, may be inconsequential and even asymptomatic frequently cause death or permanent disability when they involve the nervous system. There are several contributing factors, the most important of which is the *indispensability of most portions of the CNS.* The nervous tissue cannot reconstitute itself, but it may, if the lesion develops slowly, manage a considerable degree of functional compensation. Vascular responses may be more of an impediment than a help in the reaction to inflammation, because they lead consistently to edema and brain swelling that spreads the consequences of the inflammation far from the active focus. Vascular proliferation and fibrous tissue encapsulation may develop only when the inflammatory reaction involves the meninges and the larger blood vessels because these are the only source of reticulin and collagenous tissue. Investigation continues into how viruses spread in nervous tissue; bacteria and fungi can spread rapidly and extensively in the fluid of the ventricular system and meninges. Spread of infection from the ventricular fluid to the periventricular veins occurs readily across the ependyma, and spread from the meninges to the brain, or vice versa, can occur via the Virchow–Robin spaces. The special drainage of CSF is such that exudate rich in fibrin and cells is drained very poorly.

The structure of nervous tissue and meninges limits the anatomical types of inflammation that may occur. **Fibrinous inflammation** is confined to the meninges and larger perivascular spaces. Fibrin is usually indicative of a bacterial infection, but there are exceptions. Fibrinopurulent, largely fibrinous, exudate is caused by the mycoplasmas; fibrinous exudation is typical of the meningeal reaction in malignant catarrhal fever of cattle, and it is occasionally observed in organomercurial poisoning of swine and cattle. **Hemorrhagic inflammation** is not common except as examples of symptomatic purpura in infections such as porcine erysipelas and infectious canine hepatitis and in the infarcts of embolic infections. Hemorrhage is characteristic of helminthic infections, but these lesions are perhaps better regarded as traumatic malacias. **Suppurative or granulomatous inflammation** is the usual response to bacterial or mycotic infections. Viral infections are characterized by **nonsuppurative inflammation**, which is described in more detail later; it is typically composed of neuronal degeneration, perivascular cuffing by mononuclear cells, and focal or diffuse glial proliferations.

Applying these broad criteria, there is seldom much difficulty in deciding on the class of the infecting agent. *There is occasionally some difficulty in distinguishing between the reactions to degeneration and to viral infections.* While suppuration does not occur in either of these processes, early infiltration of neutrophils occurs in acute degenerations, such as the malacias, and a few neutrophils can be found migrating in affected gray matter in the first stages of many cases of viral encephalomyelitis. Acute demyelinating processes are associated with, and probably stimulate, perivascular cuffing. The cuffs tend to be quite distinct from those in viral infections by being relatively very thick (up to ten or more cells thick) and to be composed of pure populations of lymphocytes. *If there are proliferated adventitial cells with plasma cells or other leukocytes mixed in the cuffs of lymphocytes, then the cuffs are likely to be a response to infection.* Only three diseases in animals are caused by viruses and characterized by demyelination and these, namely canine distemper, leukoencephalomyelitis of goats, and visna of sheep, have their own distinguishing characteristics. A possible fourth is so-called "old dog encephalitis." Glial responsiveness occurs in a variety of degenerative and viral lesions, but *glial nodules are characteristic only of an infectious process*, usually viral but occasionally rickettsial or bacterial.

Bacterial and pyogenic infections of the nervous system

Epidural/subdural abscess and empyema

The brain and spinal cord are protected against direct penetration of infection by the skeletal encasement and by the dura mater; the dura is almost impermeable to inflammatory processes. However, infection of the epidural space or the bony encasement with pyogenic bacteria and occasionally fungi can occur and may lead to localized *abscessation* or to the collection of suppurative material in the epidural or subdural space without forming a discrete abscess (*epidural or subdural empyema*). Infection may be hematogenous from *distant sites of infection* (e.g., septic valvular endocarditis, lung abscess), *direct extension* (e.g., osteomyelitis, middle ear and tympanic bullae, eye, paranasal sinuses, ethmoid cells), *trauma* (e.g., bite wounds especially in cats), or by *direct incidental injection* (e.g., contaminated spinal needle). Most cranial epidural abscesses arise by direct extension from one of the paranasal sinuses. Spread from the middle ear and through the cribriform plate is usually directly to the leptomeninges and brain. Occasionally, epidural suppuration is observed to have tracked from a retropharyngeal or nodal abscess through cranial foramina. Epidural suppuration about the base of the brain usually does not become encapsulated.

Tail biting in pigs, docking of lambs, and tail fracture in cats are common etiologies for spinal epidural abscesses that develop either secondary to local venous bacterial invasion or by direct extension from septic osteomyelitis. In cattle, spinal epidural abscesses are usually secondary to osteomyelitis of the vertebral bodies, are more prevalent at the lumbosacral area, and are usually caused by *Arcanobacterium pyogenes* or *Fusobacterium necrophorum*. Migrating grass awns can cause osteomyelitis and epidural abscess in the thoracolumbar regions in dogs. Common bacterial etiologies for epidural abscess or empyema in dogs and cats include *Streptococcus*, *Staphylococcus*, *Brucella*, *Pasteurella*, *Bacteroides*, and *Fusobacterium*, and in horses include *Actinobacillus* and *Streptococcus*.

Clinical signs vary according to the area affected, and can range from mild pain and restlessness to blindness and ataxia. Epidural abscessation at the lumbosacral area in ruminants may lead to circling, which can be confused with encephalitic listeriosis. Spinal epidural abscesses usually cause compression malacia of the cord, if the osteomyelitis from which they originate does not first lead to pathologic fracture with displacement.

Subdural abscessation is seldom observed, but can result from local penetration, perhaps most frequently from the paranasal sinuses. Extension can occur from epidural abscesses or, because subdural suppuration is prone to cause local phlebitis, it may give rise to epidural suppuration. Subdural infection is liable to spread widely via the veins or after penetrating the outer layer of the arachnoid. Spread is also permitted by the slowness with which leptomeningeal fibrous tissue develops to encapsulate the reaction.

Leptomeningitis

Leptomeningitis can be classified according to *etiology* (e.g., bacterial, mycotic), according to *duration* (e.g., acute, chronic), and according to the *type of exudates* (e.g., fibrinous, purulent). Classification by type of exudate is very useful, not only because it indicates the expected histologic lesions, but also clinically because it indicates the possible etiology. *Purulent meningitis* is by far the most common meningitis in domestic animals, especially neonates. *Serocellular meningitis* is described later with viral inflammation. *Hemorrhagic meningitis* occurs in septicemic anthrax and very seldom in other septicemias. Purely *fibrinous meningitis* occurs in malignant catarrhal fever, chlamydiosis, and seldom in anything else. *Mycoplasma bovis* is a rare cause of fibrinous meningitis in calves. *Granulomatous meningitis* occurs in systemic infections of this type, such as tuberculosis and cryptococcosis. The nonsuppurative inflammations of the leptomeninges are described with the diseases of which they may be part. They are mentioned here to draw attention to the wide variety of infectious agents that may localize in and produce inflammation of the leptomeninges. We have also mentioned or discussed purulent leptomeningitis with the many specific diseases of which it can be part, but dwell on the purulent process here because it is common, lacks specificity, and is suitable for a "type" description.

Purulent leptomeningitis may arise by direct extension from an adjacent structure. Extension from an epidural abscess or inflammation may result in diffuse leptomeningitis but, in most of the few cases of this origin, the leptomeningitis is local and overshadowed by the brain abscess that usually forms. Leptomeningitis may arise by local extension from a brain abscess, either by direct permeation or by spread in the Virchow–Robin spaces. Such an origin is observed frequently in listeriosis and in association with very large cerebral abscesses, but most cerebral abscesses, which are usually small, track inwards to the white matter rather than out to the meninges. The reverse sequence in which meningitis spreads to the brain and cord is not unusual in granulomatous infections but is distinctly unusual in suppurative infections, and when it occurs it consists of invasion of the surface of the brain by neutrophils (Fig. 3.100A) rather than of abscessation.

Both purulent meningitis and cerebral abscesses are usually of hematogenous origin, but they are seldom concurrent, and one usually finds meningitis alone or abscessation alone. There are occasional exceptions including thromboembolic lesions and leptomeningitis complicated by choroiditis. Septic emboli are prone to localize in the brain but may localize in meningeal vessels (Fig. 3.100B). Although those in meningeal vessels may lead to diffuse suppurative meningitis, they are usually quickly walled off and prevented from spreading (Fig. 3.100C,D). In the other exception, that of choroiditis concurrent with leptomeningitis, encephalitis or cerebral abscesses may develop because choroiditis leads to exudation into the cerebrospinal fluid and the ependyma is virtually no barrier to infection. Even this combination of pathologic processes is unusual and, when choroiditis is complicated by ependymitis and suppurative encephalitis (Fig. 3.100E), there is usually little or no meningitis. Whether encephalitis develops by spread of meningitis may be largely a question of time, but it is not unusual for animals with purulent meningitis to survive for a week, and sometimes much longer. There is ample time for the inflammation to spread throughout the cranial and spinal meninges – and to the brain if it were going to do so – but it seldom does, and *there is seldom anatomic justification for the common diagnosis of suppurative meningoencephalitis.*

In the section on inflammatory diseases of joints and synovial structures, attention is drawn to the frequent concurrence of polyarthritis with choroiditis and leptomeningitis in fibrinopurulent infections. Erysipelas, in which arthritis is a typical lesion, is an

exception in that it may produce septicemic and embolic lesions in the brain but it does not cause suppurative meningitis. Several bacteria, such as streptococci and *E. coli*, cause bacteremia and suppurative meningitis in neonates resulting in an important clinical entity, especially in ruminants and pigs, called **neonatal bacterial suppurative meningitis** (NBSM). Streptococcal NBSM in calves, lambs, and piglets (but not in foals), frequently has a combination of polyarthritis, purulent leptomeningitis, choroiditis and, in calves only, endophthalmitis (Fig. 3.101A, B). In pigs, *Streptococcus suis* types 1 and 2 (see Vol. 1, Bones and joints) cause NBSM that is usually accompanied by polyserositis; *S. suis* meningitis is suppurative in the acute stage, and lymphoplasmacytic in pigs that survive. *Streptococcus pneumoniae* usually produces fulminating septicemia in calves characterized only by very acute splenitis but, if the course of this infection is less fulminating than usual, polyarthritis and meningitis can be found. *E. coli*, another cause of NBSM of protracted course, commonly causes well-developed meningitis and polyarthritis in neonatal calves and lambs, but even in fulminating infections the mild changes of early inflammation can be found in these structures. On the other hand, both coliform and streptococcal infections in calves and piglets may avoid the joints and meninges and localize instead in the choroid plexuses and spread from there to the ventricles and brain, or localize in the brain alone. The coliforms and streptococci behave differently in calves with respect to the eyes; a combination of synovial, meningeal, and intraocular localizations is almost invariably of streptococcal origin (and the lesions can be well developed within 12 hours of birth, or even at birth according to farmers); the coliforms can, but only seldom do, cause endophthalmitis.

Mannheimia haemolytica and *P. multocida* are usually regarded only as causes of fibrinous pneumonia and hemorrhagic septicemia, but they are responsible for localized infections in other locations, including the meninges, in ruminants. When polyarthritis is present in septicemic or pulmonary pasteurellosis, *fibrinosuppurative leptomeningitis* can also be anticipated. Isolated cases and limited outbreaks of pasteurellosis that is entirely meningeal are observed in cattle and sheep, usually young ones. The course is asymptomatic until meningitis develops.

Once infectious agents gain access to the leptomeninges there is little resistance to spread in the meningeal spaces, and the inflammatory process becomes more or less diffuse in most cases. When the inflammatory process, excepting some that are granulomatous, remains localized, it is probable that only the inflammatory reaction, and not the infection, reaches the meningeal spaces. Cerebrospinal fluid is an excellent culture medium for many sorts of bacteria and these spread rapidly in the fluid, assisted to some slight extent by normal flow so that, although meningitis may appear grossly to have a limited distribution, its true distribution can be determined only microscopically.

The apparent gross distribution of meningitis varies somewhat with the cause. Thus in listeriosis, the process is confined largely or entirely to the meninges covering the medulla oblongata and upper cord, and in Glasser's disease and in malignant catarrhal fever the exudate is concentrated over the cerebellum and occipital poles of the cerebrum. In pyogenic meningitis, the basal meninges show the most obvious changes.

In the first day or so of suppurative meningitis before exudation is clearly recognizable, the meninges may be faintly opaque and hyperemic (Fig. 3.101C). After a few days, the appearance of the brain and cord is typical. The basal cisterns that accumulate the most exudate are filled with creamy pus or with gray-yellow fibrinopurulent exudate. The extreme exudation in these cisterns is due in part to their large size but in part also to sedimentation of particulate exudate. The exudate is in the arachnoid spaces and there is little if any on the outer surface of this membrane (Fig. 3.101D). The arachnoid appears stretched. *It is easy to overlook even copious exudates because their color is not very different from that of the brain.* A useful clue is that even the largest basilar vessels and the trunk of the oculomotor nerve are partially or completely buried and obscured by exudate and the filling-in of basal sinuses and grooves obliterates the normal topography. Over the hemispheres the exudate is usually confined to the fissures, where the arachnoid space is wide, and spares the surfaces of the gyri, where the arachnoid space is narrow. There is seldom frank pus over the hemispheres except in cases of unusually long survival.

The severe degree of exudation described above is what is usually seen in animals. In very acute or early cases, the exudation may be considerably less, and detectable only as congestion and cloudiness of the basal meninges extending towards the convexity of the hemispheres as fine gray sleeves about the arteries and veins. On careful inspection by naked eye, almost every case of purulent meningitis can be detected but the microscope may be necessary to confirm some cases.

The brain is swollen in every acute case of pyogenic meningitis, and the swelling is frequently severe enough to cause displacement with coning of the cerebellum. The pathogenesis of the edema and swelling is not known. The edema affects the white matter. It is possible that obstruction of the meningeal orifices of Virchow–Robin spaces by exudate and stasis of flow of meningeal fluid may contribute to the edema. The brain itself is normal except for softness and swelling and the rare cortical infarcts in the cerebrum or cerebellum.

Choroiditis commonly complicates leptomeningitis. It is usually quite obvious when it affects the plexuses of the fourth ventricles, but that affecting the plexuses of the lateral ventricle is not apparent until the ventricles are opened, although it may be expected if cloudy fluid escapes from the third ventricle when the infundibular process is opened. The CSF is cloudy, flakes of exudate overlie the plexuses and float in the fluid, and smeary sediments of pus lie on the walls of the ventricles (Fig. 3.101B). The exudate may be impacted in the aqueduct, occluding it and leading to ependymitis. Internal hydrocephalus then develops rapidly.

Microscopically, purulent meningitis does not differ in its character from pyogenic inflammation in other loose tissues, such as the lung. A few mononuclear cells are mixed with a very large number of neutrophils in the arachnoid spaces (Fig. 3.101E). The amount of fibrin in the exudate varies. There may be some infiltration for a short distance along the Virchow–Robin spaces about veins (Fig. 3.102). The pia mater as a rule remains intact, and it is only in exceptional cases that some microbial activity is observed in the adjacent parenchyma, or the pia is eroded to allow neutrophils to invade the surface of the brain. When the choroid plexuses are involved, they are swollen and infiltrated with leukocytes, many of them mononuclear. The plexus epithelium is eroded and covered by fibrin and cells. The ependyma is also eroded, there is edema of subependymal tissues, and the surrounding veins are infiltrated.

Internal hydrocephalus is a sequel to ependymitis and occlusion of the aqueduct, as a result of which the lateral and third ventricles are

dilated (Fig. 3.103). This condition is a complication of choroiditis, but hydrocephalus may also be a sequel without choroiditis being present. The medullary foramina are frequently occluded as a result of inflammation in the tela choroidea so that CSF cannot escape from the ventricular system to the arachnoid spaces; the hydrocephalus is noncommunicating. Obstruction to the flow of fluid in the arachnoid spaces may occur as a result of brain swelling with impaction in the tentorial incisure, heavy deposits of exudate in the arachnoid space, or as a result of meningeal adhesions and thickenings in chronic inflammations. The hydrocephalus of this pathogenesis is communicating.

Chronic pyogenic leptomeningitis is rarely observed in animals. The process may sterilize itself or be sterilized by antimicrobials, but much of the injury is established in the early stages of the process and, once the diagnosis is evident clinically, *death is the expected outcome*. The early injury is exaggerated by the persistence of exudate even after the infection is controlled because there is no free drainage from the meningeal spaces. Healing occurs only after there has been considerable destruction of the meningeal framework with repair by fibrous tissue. Meningeal adhesions may produce cystic loculations in the arachnoid space, and obliterate the medullary foramen or basal arachnoid space and cause lingering death from hydrocephalus.

In a purulent process, *leptomeningeal vasculitis commonly occurs*. The expected sequelae of venous or ischemic infarcts are seldom observed even in those few cases with vasculitis in which thrombi can be found. This apparent discrepancy is probably due to the rate at which the vascular obstructions develop and on the type and size of vessel. Cases in which suppurative thrombophlebitis of the sagittal or transverse sinuses, or both, can be readily observed may not have venous infarcts in the brain. Thrombosis in the afferent circulation usually involves the smallest of meningeal vessels and usually develops at a rate that allows collateral circulation to develop. Inflammation of larger arteries (Fig. 3.100D) in which the endothelium is dissected from the intima by leukocytes has not been observed to lead to thrombosis.

Septicemic lesions, septic embolism, and cerebral abscess

The brain responds in septic or endotoxemic shock by releasing or controlling the release of several proinflammatory and anti-inflammatory cytokines; this major biochemical role is not always associated with a morphologic change in the CNS. *The CNS is injured to some extent in every episode of septicemia or sustained bacteremia.* The simplest and most common type of injury is inflicted on the venules, especially those of the cerebral white matter and to a lesser extent those of the cerebellar white matter. Injury of this type is not of much significance. There is sludging of leukocytes and probably of erythrocytes in these vessels, associated usually with degenerative and reactive changes in the endothelium. In the symptomatic purpuras, it is frequently possible to find the site of diapedesis in the brain, but not in other organs. Associated with endothelial injury there is often leakage of plasma into the perivascular space and, given time, adventitial proliferation and infiltration of a few lymphocytes or other leukocytes into the Virchow–Robin spaces. Commonly, the injury is more severe, the vessel wall is totally necrotic in its cross-section, and in these lesions a few bacteria may be demonstrable (Fig. 3.104).

Septic embolism in the CNS may be a complication of active endocarditis; the bacteria are usually gram-positive. The bacteria implicated most commonly are *Erysipelothrix rhusiopathiae* in pigs, streptococci in all species, and *Arcanobacterium pyogenes* in cattle.

The toxigenicity and pathogenicity of many infections by gram-negative bacteria in septicemic phase seem to depend largely on the number of organisms present, as has been demonstrated in sheep for septicemic pasteurellosis caused by *Mannheimia haemolytica*. In septicemic pasteurellosis of sheep, in infection of foals by *Actinobacillus equuli*, in infections of sheep and cattle by *Histophilus somni*, and in some coliform infections of calves, the blood literally swarms with bacteria because common to these infections is massive and widespread bacterial embolism. These are the principal infections in which bacterial embolism occurs in the CNS without there being a demonstrable primary focus such as endocarditis, pneumonia, or an abscess. The problem of cerebral embolism in these infections is not solely one of quantitative factors determined by the height of the bacteremia; qualitative factors of unknown nature are also involved.

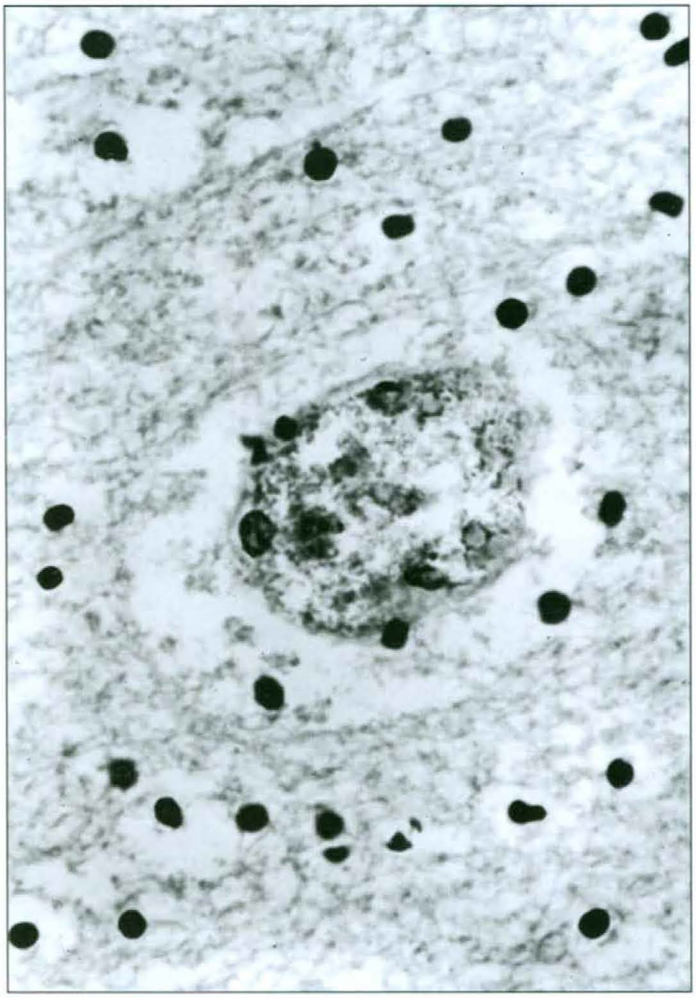

Figure 3.104 Necrosis of cerebral venule in *Escherichia coli* septicemia in a calf.

Septic thromboemboli and **bacterial emboli** lodge in the small cerebral vessels but, whereas thromboemboli tend to lodge particularly in small arterioles, bacterial emboli lodge in capillaries and venules. Consequences depend on the vessels involved, although the consequences are not particularly significant because abscessation occurs in either location. *Arterial emboli frequently cause ischemic infarcts, and venous and capillary emboli cause hemorrhagic infarcts.* The venular lesions also extend rapidly to involve large veins, whereas local spread in arteries does not occur.

Cerebral abscesses may arise in embolism, by direct implantation in wounds, or by direct invasion of the brain from an adjacent structure. Leptomeningitis rarely leads to abscessation, whereas choroiditis commonly leads to periventricular abscess. Abscesses in the spinal cord are seldom sought or observed; they may be hematogenous via arteries or veins (Fig. 3.105), and rarely do they enter through the dura.

Abscesses of hematogenous origin may occur anywhere in the brain, but there are two areas of remarkable predilection – the hypothalamus, and the cerebral cortex at the junction of gray and white matter (Fig. 3.106A, B). *Listeria monocytogenes* is an exception because it always demonstrates an affinity for the reticular formation in the brain stem. There may be only one abscess in the brain, or they may be multiple, especially when due to bacterial embolism. Multiple abscesses of septic thromboembolic origin tend often to be localized in one area of the brain. Some care is necessary in specifying the origin of multiple adjacent foci of suppuration because the *production of satellites*, each of which may be larger than the primary, is a natural attribute of brain abscesses.

Abscesses arising by direct invasion of the brain may develop in any location. There are two common sites of invasion, namely the *cribriform plate and inner ear*, and two somewhat less common, namely the *hypophyseal fossa and the paranasal sinuses*. Hypothalamic abscesses

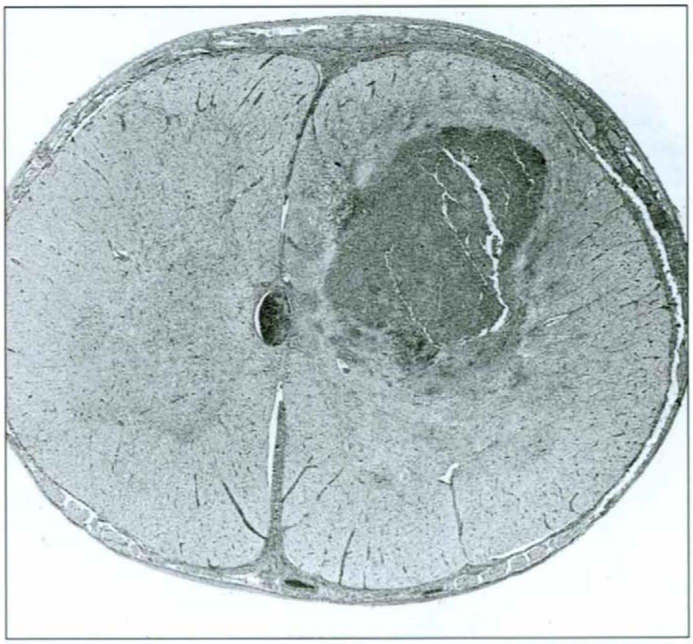

Figure 3.105 Meningitis, tracking abscess in dorsal horn, and ependymitis, complicating docking wound in a lamb.

are observed occasionally in cattle and dogs. At least some of those in dogs are caused by minute foreign bodies migrating with phlebitis through the orbital fissure or foramen rotundum and carrying actinomycetes. The importance of the cribriform plate and internal ear in the development of cerebral abscess is due to the frequency with which infections occur in those locations, that in neither site is there an actual or potential epidural space to protect the brain, and because nerves and vessels enter and leave through both.

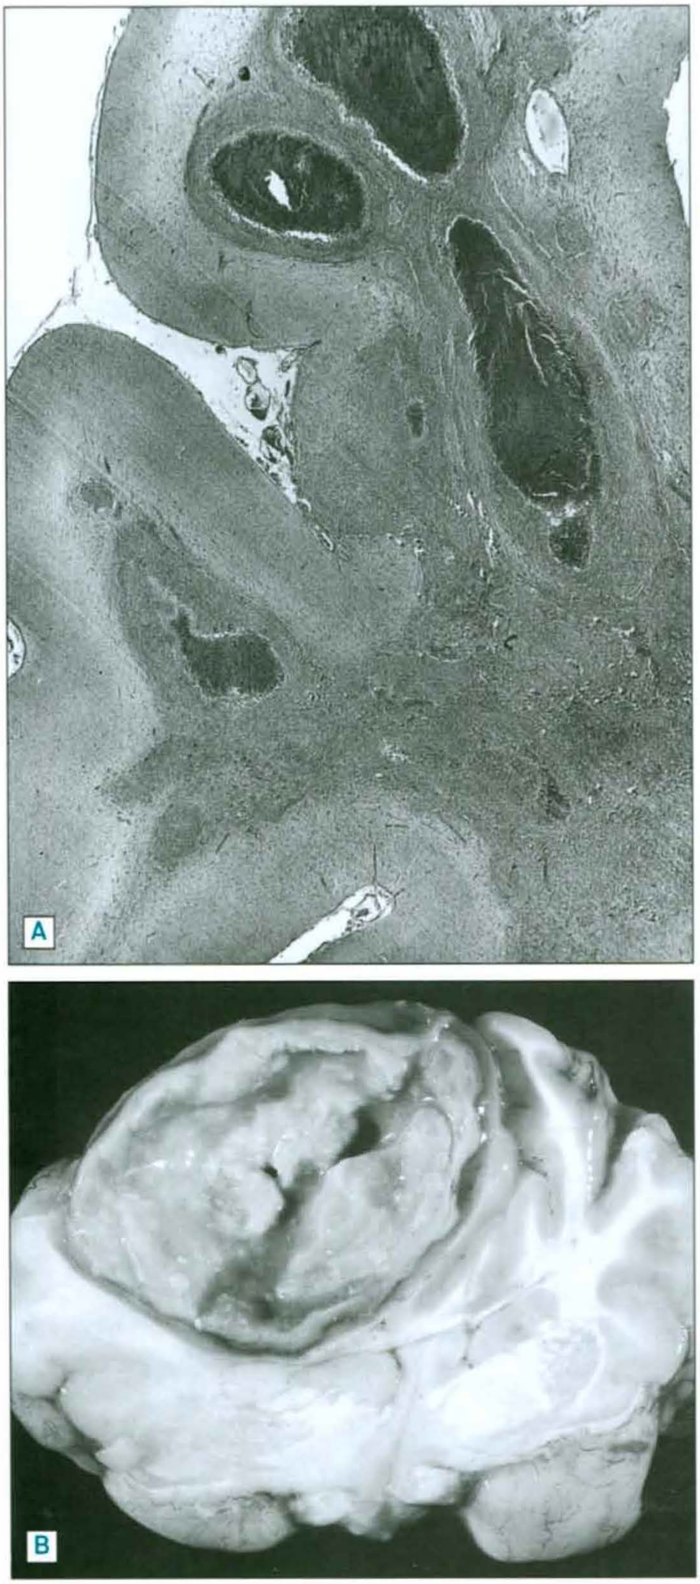

Figure 3.106 A. Hematogenous **abscesses** in cerebrum in a pig. **B. Abscess** distorting left cerebral hemisphere in a goat. *Pasteurella multocida* and *Fusobacterium necrophorum*.

Frontal abscesses of sinus origin occur occasionally in cattle as a complication of dehorning wounds, but abscesses in this site occur most commonly in sheep in which sinusitis, especially in the ethmoid cells, develops as a suppurative complication of myiasis (*Oestrus ovis*). *Arcanobacterium pyogenes* is the organism usually present. The olfactory bulb is destroyed and the first ventricle is opened, infection then spreading to the substance of the hemisphere (Fig. 3.107). There is little tendency to spread into the meninges from the point of entry or to invade the cortical gray matter, although both layers are usually secondarily involved by expansion of the abscess later.

Abscesses commonly develop at about the *cerebellopontine angle* as complications of suppurative otitis media. These are usually problems of pharyngitis, infection spreading via the Eustachian tube to the middle ear and from there to the brain, either by erosion of the bulla or extension along natural foramina.

Cerebellopontine abscesses are rarely, if ever, observed in horses in spite of the frequency of pharyngitis in this species. This exemption of horses may be due to the diversion of exudates from the Eustachian tube to the guttural pouches. Otogenic cerebral infections are very

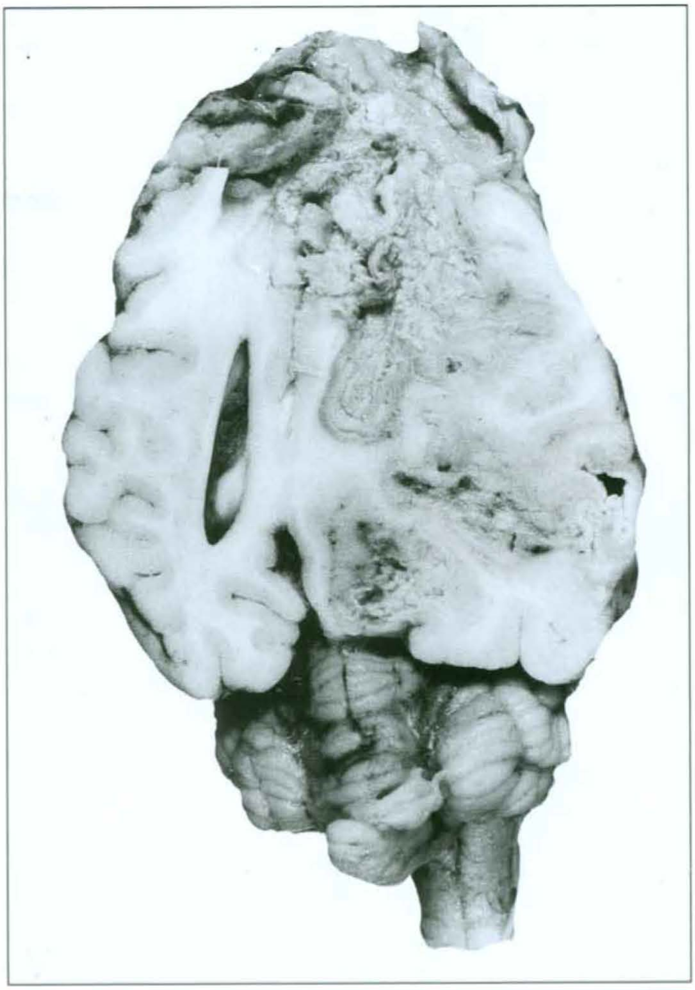

Figure 3.107 Arcanobacterial **abscess** arising from right ethmoid in a sheep.

seldom observed in dogs. Those observed have come via the auditory meatus rather than the Eustachian tube, and the cerebral reaction is nonspecifically granulomatous, usually without pus. Otitis media caused by *Pasteurella multocida* is fairly common as a complication of chronic cases of upper respiratory infection in cats and, when the infection extends to the cranial cavity, it produces diffuse purulent leptomeningitis and not, as expected, a cerebellopontine abscess. Most otogenic infections occur in sheep and swine; a few are observed in cattle, and in each species the outcome is an abscess of the brain.

Otic infections are commonly bilateral so that otogenic abscesses may be also. The usual organism in these abscesses is *Arcanobacterium pyogenes* alone or mixed with *Pseudomonas aeruginosa*, *Pasteurella multocida*, and mixed cocci. Affected pigs usually have several other chronic debilitating infections at the same time so that several animals in the herd may have otogenic abscesses. This pattern of infection in calves is uncommon and sporadic. In sheep on the other hand, the disease may be observed in limited outbreaks and there is an association with grazing on rough, dry, mature summer pastures. The reasons for this association are unknown.

Established abscesses are found much more commonly in the white matter than in the gray, in spite of the fact that they usually begin in the gray. There is no suitable explanation for this tendency to track into white matter, but once within white matter they do permeate along fiber tracts (Fig. 3.108). As a result of this activity, satellite abscesses are to be expected, sometimes chains of them. Connecting purulent tracts may be very thin and difficult to find.

An abscess may begin as an intense accumulation of neutrophils in and around a thrombosed vessel (Fig. 3.109A), or in a focus of septic encephalitis in which neutrophils lightly infiltrate a zone of early softening. The principal differences between a cerebral abscess and an abscess in some other location are the vulnerability of the surrounding nervous tissue to edema, which can destroy it, and the slowness with which encapsulation occurs (Fig. 3.109B). The meninges and larger blood vessels are the only sources of fibroblastic tissue for encapsulation.

In the *early stages*, the abscess cavity contains a liquefying center and the margins are irregular and poorly defined even microscopically. The surrounding brain tissue is edematous and infiltrated by neutrophils. The microglia and vessels are fairly resistant and reactive in a narrow peripheral zone, but the neurons and neuroglia degenerate. Most abscesses develop rather slowly and later become encapsulated. The capsule seems often to be formed more by condensation of vessels around an expanding focus than by proliferating fibroblastic tissue, but both contribute; the result is an irregular capsule thicker on the meningeal than on the ventricular aspect. Most capsules are very distinct and 1–3 mm wide. Their distinctness is due to the paucity of reticulin or collagen spreading out into the surrounding parenchyma or into the abscess cavity. In old abscesses with shrinkage, the core may separate from the capsule, and the capsule may separate extensively from the surrounding cerebral substance. The surrounding tissue is discolored yellow due to edema, the edematous zone often being much larger than the abscess itself. The *microscopic structure of the wall of a chronic abscess* does not differ much from case to case except in the thickness of the capsule. A narrow zone of histiocytes or gitter cells faces the neutrophilic debris. The next zone is a laminated layer of collagenous fibers between which are rows of gitter cells laden with debris. The outer zone is vascular, the vessels being large and usually nonreactive. The surrounding nervous tissue is severely edematous, with degeneration of myelin and fibers. Astrocytes are swollen and reactive about encapsulated abscesses, but it takes a long time for their fibrils to begin to intertwine with capsular reticulin. The veins are heavily cuffed by lymphocytes.

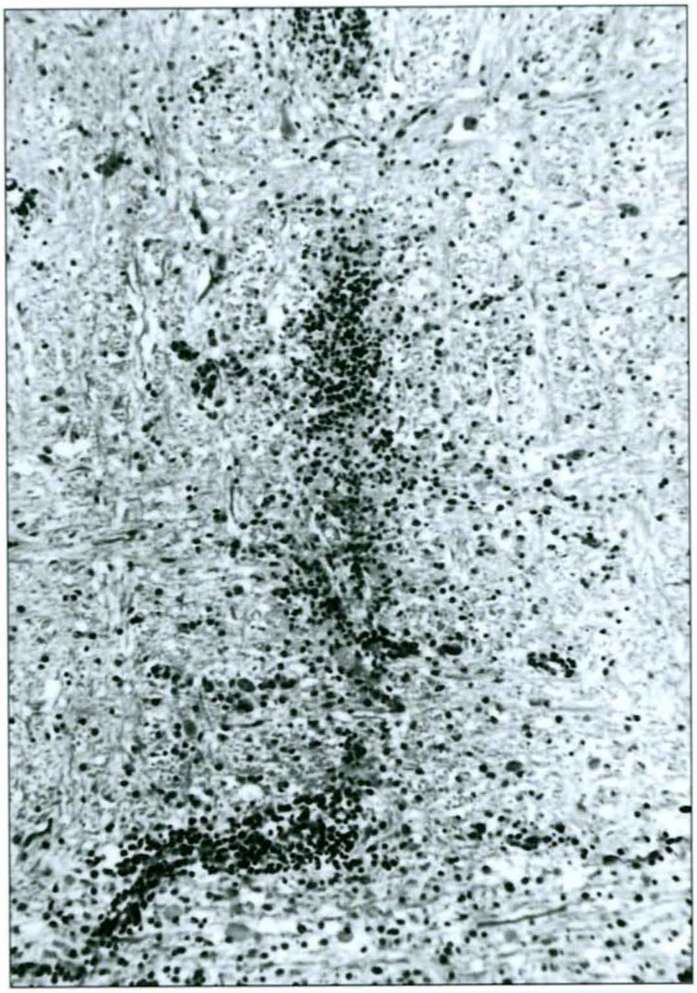

Figure 3.108 Spreading tract in suppurative (streptococcal) encephalitis in a pig.

When abscesses are multiple, death is the outcome after a short course. When they are isolated, they may permit prolonged survival. The course is usually short with medullary abscess, even when small, because it, or more usually the edema it provokes, interferes with vital centers. Abscesses in the hypothalamus or cerebrum may track through the white matter to the ventricles to produce pyencephaly that is quickly fatal (Fig. 3.110A, B, C, D). Large abscesses ultimately expand to the meninges to produce adhesive meningitis. Many abscesses act as space-occupying lesions by virtue of their size or the edema they provoke or both. The consequences of space occupation depend on the site and size of the lesion.

Granulomatous and pyogranulomatous meningoencephalomyelitis

Granulomatous to pyogranulomatous meningoencephalomyelitis is observed in many systemic mycotic (e.g., blastomycosis, cryptococcosis) or algal (e.g., protothecosis) diseases, which are described elsewhere in this book. Granulomatous inflammation can also be caused by bacteria (e.g., *Mycobacterium bovis, Nocardia* sp.) (Fig. 3.111), and migrating helminths or arthropod larvae (see below). The diagnosis and differentiation among these etiologies requires culture or demonstration of the causative pathogen using histochemical or immunohistochemical stains.

Listeriosis

Listeriosis is caused by *Listeria monocytogenes*, a Gram-positive, facultative anaerobic bacillus that is ubiquitous in the environment and can multiply in diverse environmental conditions – it can grow in a temperature range from 4 to 45°C and at a pH range of 5 to 9. It is remarkably viable in the external environment, being able to survive in dried media for several months and in suitably moist soil for ~1 year. The organism is commonly isolated from tissues of normal animals, including tonsils and other gut-associated lymphoid tissue, and in large numbers from the feces of ruminants. *L. monocytogenes* has more than 11 serotypes; almost all animal infections are caused by serotypes 1/2a, 1/2b, and 4b.

Listeriosis is of worldwide distribution, possibly excepting the tropics. The organism has been isolated from diseased mammals and birds of many species and produces septicemia, meningitis, and abortion in humans. In domestic animals, the disease is most important in ruminants. *L. monocytogenes* is an intracellular pathogen of macrophages, neutrophils, and epithelial cells. Important virulence factor include the surface protein *internalin,* which internalizes with *E-cadherin*, an adherans junction protein, to overcome the intestinal, placental, and blood–brain barriers. Also, it relies on another virulence factor, *cholesterol-binding hemolysin*, to lyse phagocytic cell phagosomes and escape to the cytoplasm. The organism proliferates in the host cell cytoplasm and many migrate against the cell membrane to form protrusions that can then be taken up by other cells. It is one of the few organisms known to co-opt the host cell contractile actin to facilitate cell-to-cell transfer.

Listeriosis behaves as three separate diseases or syndromes. They seldom overlap so that each syndrome probably has a separate

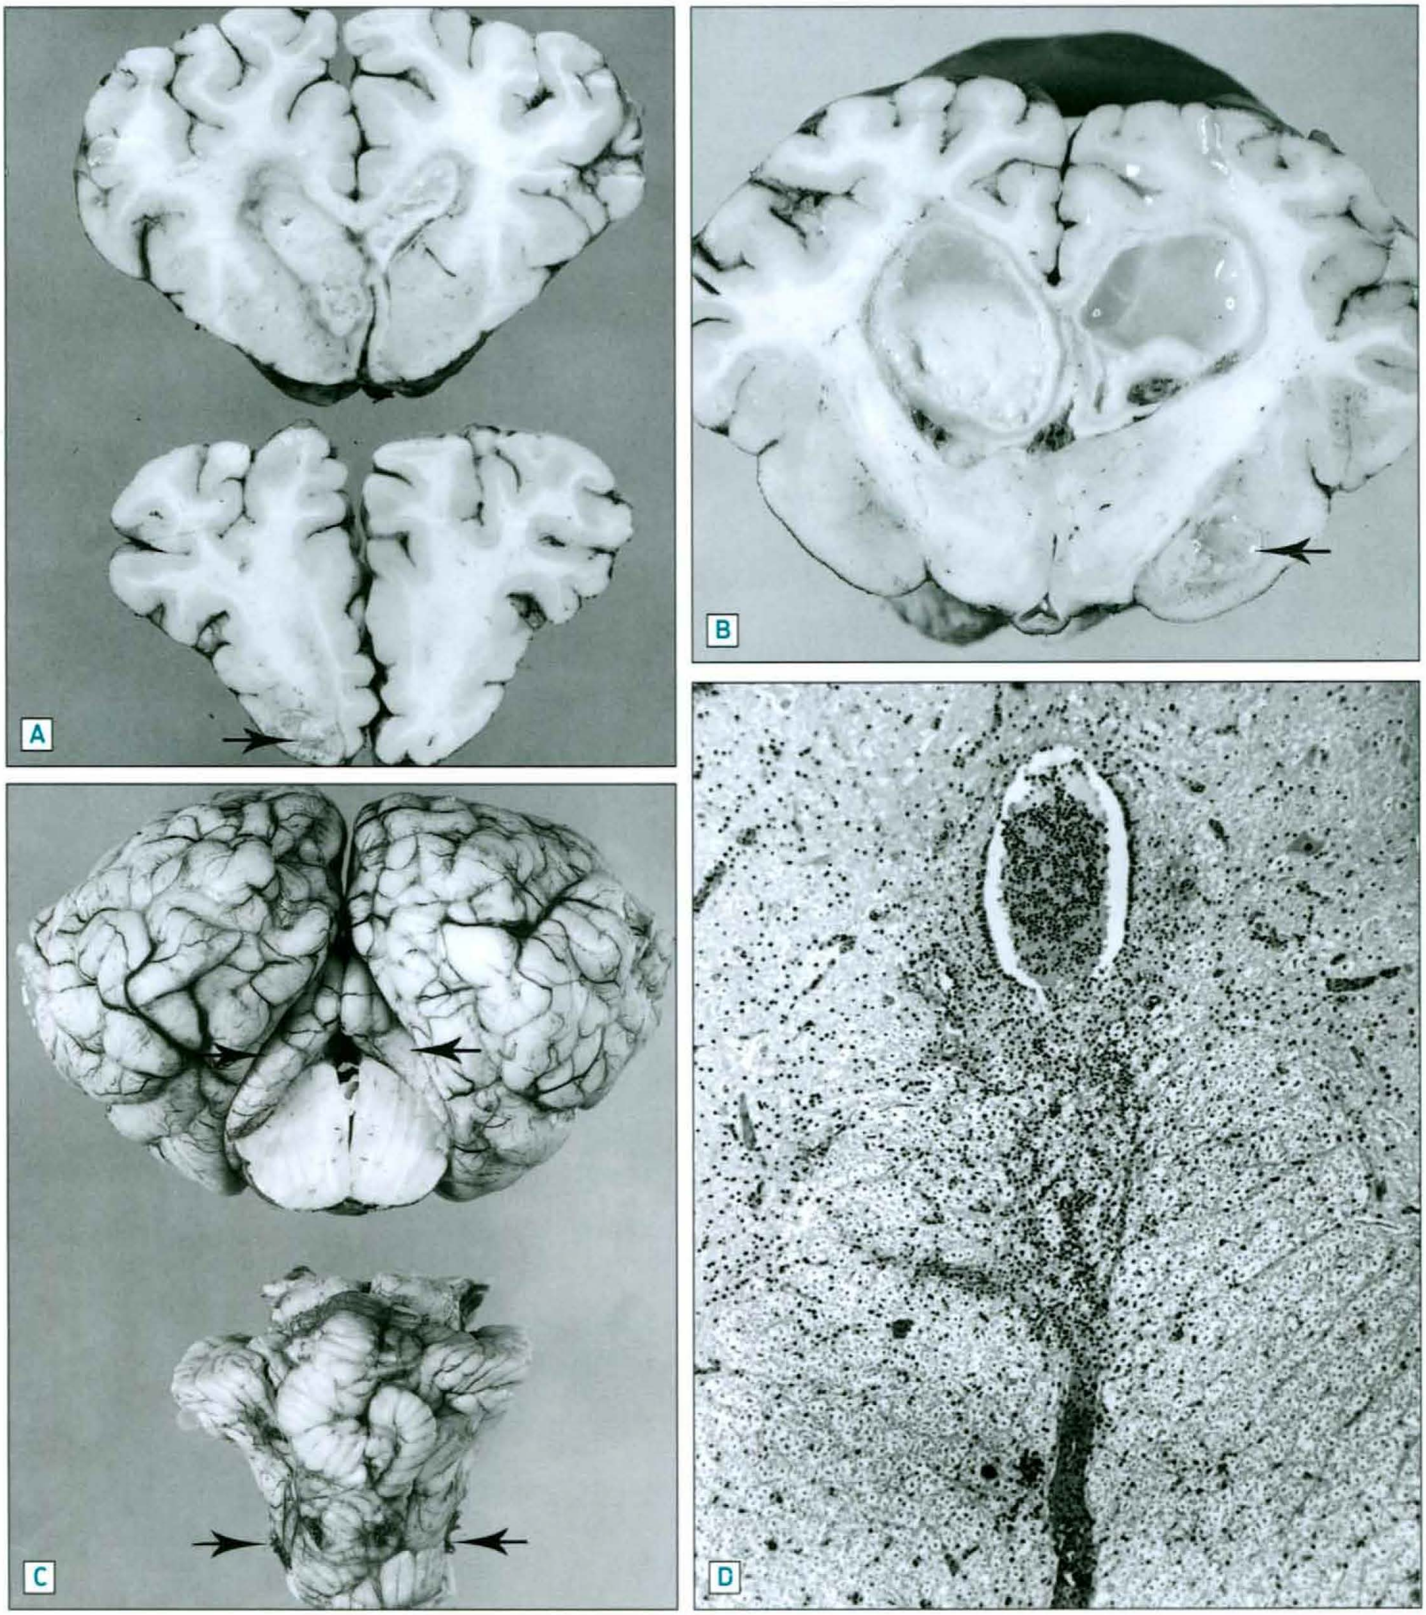

Figure 3.110 Pyencephaly in a calf. **A.** Pus in lateral ventricles (above) and left olfactory ventricle (arrow, below). **B.** Dilation of lateral ventricles by fibrinopurulent exudate (arrow). **C.** Brain swelling with cerebellar coning and hemorrhage (arrows, below) and subtentorial herniation of hemispheres (arrows, above). **D.** Inflammatory exudate in aqueduct.

pathogenesis. *The three recognized syndromes are: infection of the pregnant uterus with abortion, septicemia with miliary visceral abscesses, and encephalitis.* Additional syndromes of clinical significance in ruminants include conjunctivitis, possibly from contaminated silage dust, endocarditis, and mastitis. The uterine infection is discussed with Diseases of the pregnant uterus (see Vol. 3, Female genital system). Aborting ruminants are not usually ill, and abortion is usually late in gestation. The uterine infection is probably hematogenous and the bacteremic phase is asymptomatic, and localization occurs only in the uterus. Infection of the uterine contents can be established quite readily by oral exposure of pregnant animals and by intravenous inoculation.

Septicemic (systemic) listeriosis occurs in aborted fetuses and neonatal lambs, calves, and foals up to 1 week of age and in others that are several months of age, and is characterized by multisystemic bacterial colonization and multifocal multisystemic areas of coagulative necrosis or microabscess formation. The necrotic areas or microabscesses are miliary in distribution, very numerous in the liver, but much less numerous in the heart and other viscera, and characterized by tissue lytic necrosis with infiltration of neutrophils and fewer macrophages. Neonates generally become infected in utero.

Listerial encephalitis occurs almost solely in adult ruminants; its pathogenesis is partially understood. Listerial encephalitis may be sporadic or occur in outbreaks in which the morbidity may be 10% or higher. Outbreaks are usually associated with *heavy feeding of silage*, with disease most likely occurring in winter and early spring when the animals are indoors. This association of outbreaks of cerebral listeriosis with silage feeding is a circumstantial observation, but the association is so common that silage is fed as a calculated risk and removed from the ration when the first case occurs. The association with silage may indicate an acquired susceptibility of the animals or the provision of a growth medium that leads to heavy infection pressure. The organism will multiply in spoiled silage that is incompletely fermented and with a pH of 5.5 or above. Ingested *Listeria* is likely to breach the oral mucosal barrier through pathological or physiological wounds, e.g., erupted teeth wounds. *After invading the oral mucosa, the bacteria invade the trigeminal nerves and travel centripetally via axons to the brain. Listeria* can also breach the blood–brain barrier under experimental conditions; however the specific distribution of listerial encephalitis in the natural disease is inconsistent with a hematogenous infection. In animals, *Listeria has a remarkable affinity for the brain stem*, the lesions being most severe in the medulla and pons and less severe rostrally in the thalamus and caudally in the cervical parts of the spinal cord. Intravenous or oral dosing of pregnant ruminants will regularly produce intrauterine infection but seldom produce intracranial infection and probably never produce encephalitis of the specific distribution. Bacteremias with localization in the CNS regularly cause meningitis, choroiditis, and cerebral abscesses, which is what *L. monocytogenes* does, but only as an experimental hematogenous infection. When a pregnant animal dies of encephalitic listeriosis, the uterine contents are usually sterile.

Conjunctivitis and keratitis follow experimental conjunctival exposure, but this should not imply that the endophthalmitis of the natural disease is produced by local invasion. Rhinitis is clinically apparent in many cases of encephalitic listeriosis, but histological evidence does not support the idea that the olfactory nerves are a route of invasion of the brain. The position with respect to other cranial nerves and the internal ear has not been examined.

The *neurological signs* and lesions of listeriosis in the various ruminants are qualitatively the same, differing only in severity. The signs are combinations of mental confusion and depression, head pressing, and paralysis of one or more medullary centers. Characteristically, there is deviation of the head to one or other side without rotation of the head; when such an animal moves it does so in circles, hence the name "*circling disease*." There is frequently *unilateral paralysis of the seventh nerve* causing drooping of an ear, eyelid, and lips. There may also be paralysis of the masticatory muscles and of the pharynx. *Purulent endophthalmitis*, which is usually unilateral, is often present and has caused listeriosis to be confused with malignant catarrhal fever. The course of the disease in sheep and goats is a few hours to 2 days; survival occurs but usually with neurologic handicaps.

Listeriosis in *swine* is comparable to the disease in ruminants, but is relatively rare. Outbreaks of encephalitis may be observed with lesions of usual distribution in the brainstem. Alternatively, there may be abortion and neonatal death. The usual expression of the disease is visceral with miliary abscesses in the liver and heart.

The patterns of listeriosis in *other domestic species* appear to follow the general scheme but are rarely observed. The encephalitic form in adult horses, the septicemic form in foals, and abortions in mares are reported. Several cases of encephalitis caused by *L. monocytogenes* are reported in dogs.

Gross lesions are usually not observed in the brain in listerial encephalitis. Occasionally, the medullary meninges are thickened by green gelatinous edema, and gray foci of softening may be found in the cross-section of the medulla. The initial lesions are parenchymal; involvement of the meninges, which is almost constant, is secondary to the parenchymal lesions. Mild meningitis commonly affects the cerebellum and cranial cervical cord, and less commonly is found in patches over the cerebrum and down the spinal cord. *The characteristic parenchymal lesion is a microabscess*. It may begin in a tiny collection of neutrophils (Fig. 3.112A), but more usually begins in a minute focus of microglial reaction. The glial nodules may persist as such, the cells taking on the characters of histiocytes, but the tendency is always for the nodules to be infiltrated by neutrophils and for their centers to liquefy (Fig. 3.112B). The focal lesions do not

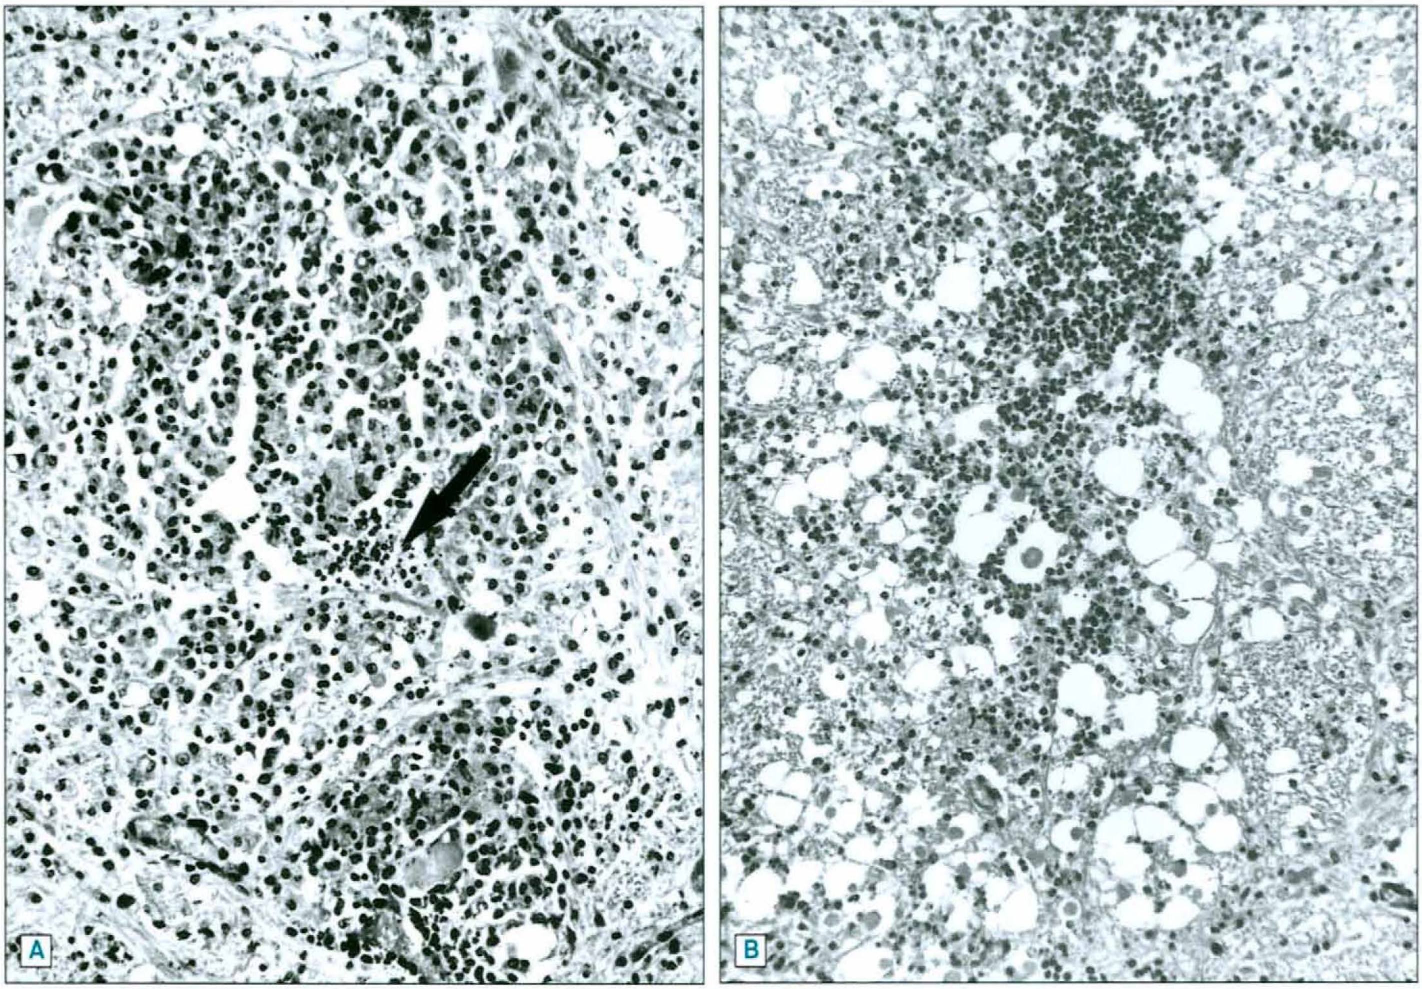

Figure 3.112 Listeriosis. A. Microglial reaction with small focus of **suppuration** (arrow) in a sheep. **B. Suppurative encephalitis** in an ox.

expand much, but suppurative foci may streak through the white matter. Apparently, the organism is not highly toxigenic because the parenchyma surrounding the glial nodules and focal abscesses may be little changed. Commonly however, the white matter is edematous and rarefied. Such areas may be large and lightly, but diffusely, infiltrated by neutrophils and hypertrophied microglia. Focal softening occurs and may coalesce. They are related to vessels that are occluded by inflammatory and thrombotic changes.

Acute vasculitis with exudation of fibrin occurs in the white matter in relation to suppurative foci. The vasculitis is secondary to drainage in the Virchow–Robin spaces from the primary parenchymal foci. It is in this manner that the meningeal infiltrates develop. Perivascular cuffing is heavy. The cuffs are composed mainly of lymphocytes and histiocytes with a few admixed neutrophils and eosinophils; granulocytes predominate in some cases.

Confirmation of the *diagnosis* is by culture, which is usually difficult and needs special procedures. Demonstrating gram-positive intramonocytic or intraneutrophilic bacilli in tissues in association with the aforementioned lesions is pathognomonic for listerial encephalitis.

Histophilus somni infections (histophilosis, or H. somni disease complex)

Histophilus somni (formerly *Haemophilus somnus*) is the only species of the genus *Histophilus*, family Pasteurellaceae, and encompasses bacteria isolated from cattle and previously described as *Haemophilus somnus*, as well as ovine isolates formerly referred to as *Histophilus ovis* and *Haemophilus agni*. *H. somni* is a fastidious gram-negative coccobacillus, and a facultative anaerobic organism that is considered normal flora of the male and female bovine genital tract and to lesser extent the bovine nasal cavity. Calves are infected by carrier cows in the first months of life, and they in turn disseminate the infection in feedlots. The mechanism, site, and circumstance by which the bacteria invade the bloodstream are not known, but it is possible that organisms in genital discharges or aerosolized urine invade via the respiratory tract. Infection, especially the respiratory form, is usually preceded by stress factors such as transportation.

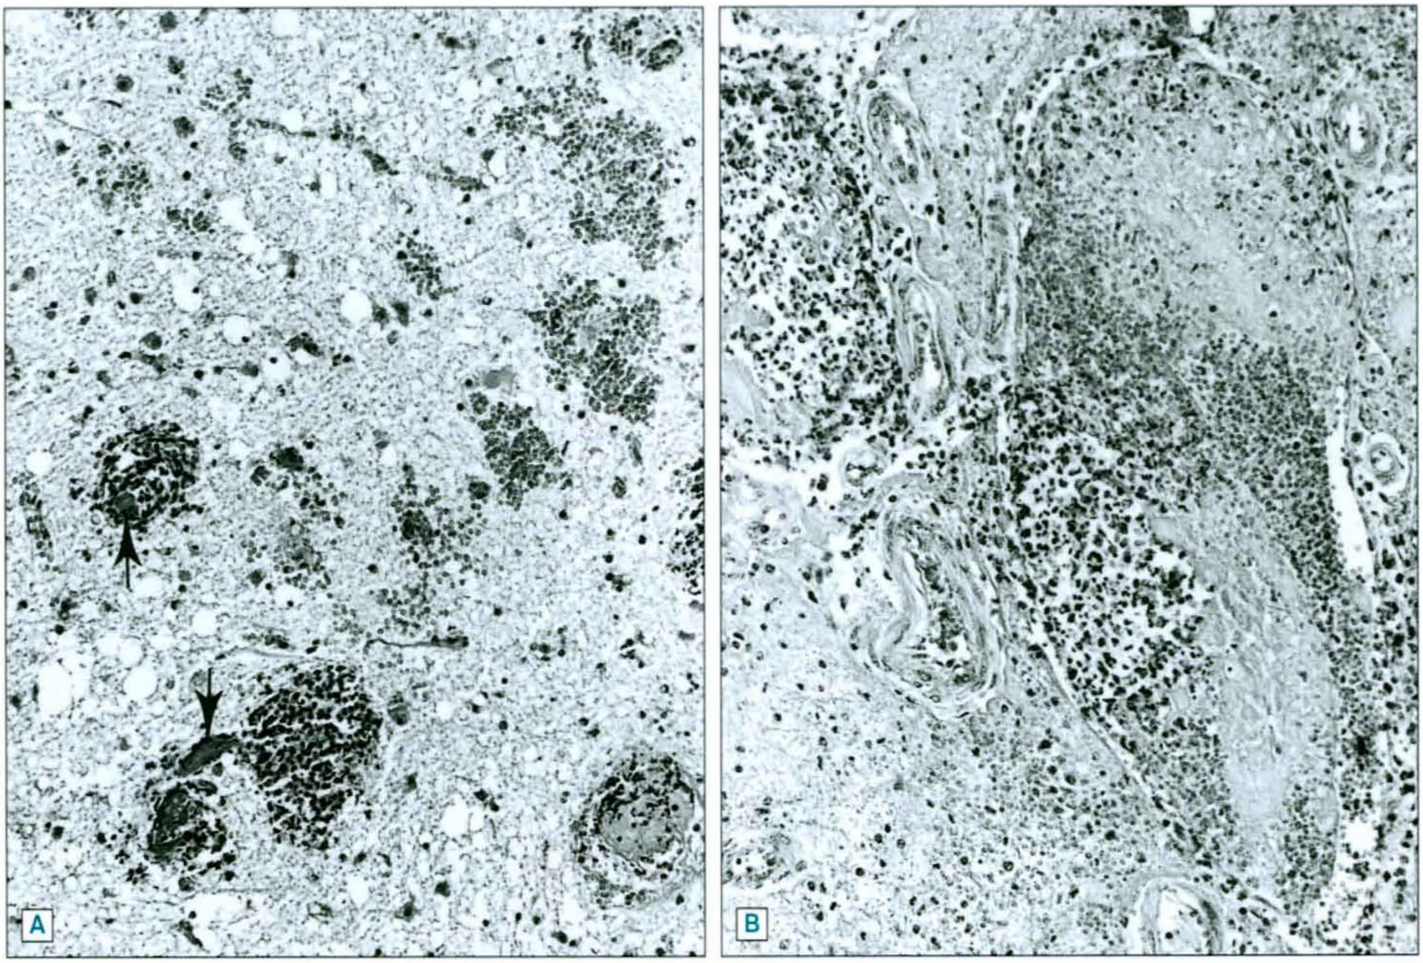

Figure 3.113 ***Histophilus somni*** infection in an ox. **A.** Thrombosis, hemorrhage, and bacterial colonies (arrows) in cerebral white matter. **B.** Thrombosis of meningeal vessels.

These bacteria have virulent and avirulent strains. Important *virulence factors* include lipo-oligosaccharide (LOS), immunoglobulin Fc binding proteins, inhibition of oxygen radicals, and intracellular survival. The mechanism of vasculitis in *H. somni* infection is complex but it can be partially explained by the effect of LSO on endothelial cells. LSO triggers apoptosis of bovine endothelial cells in vitro by caspase-3 activation. This effect is associated with the production of reactive oxygen and nitrogen intermediates. Cerebral blood vessels are particularly vulnerable to damage by the organism, but vasculitis can develop in most organs.

Histophilus somni causes a *septicemia* that may result in acute death or it may localize in one or several organs causing subacute or chronic, fatal or nonfatal disease. The septicemic phase of the disease is brief, and accompanied by fever and stiffness with few other signs. In some cases, the infection is controlled at this stage without localization, but often it leads to cerebral vasculitis with acute thrombosis, hemorrhage, and necrosis (Fig. 3.113A, B).

Histophilus somni can infect several bovine organ systems and cause infectious thrombotic meningoencephalitis (ITME), otitis externa, pneumonia, laryngitis/tracheitis, myocarditis, abortion, metritis/infertility, arthritis, mastitis, orchitis, and conjunctivitis. *Vasculitis with secondary thrombosis is the hallmark of the infection.* Bacterial embolism does not occur but may be simulated microscopically by intravascular proliferation of bacteria at sites of thrombosis. Thus, the former name "thromboembolic meningoencephalitis" is inaccurate. Histophilosis is an important disease of young cattle, but acute and chronic infections involving other organs are also economically significant.

Septicemia caused by *H. somni* develops in cattle of various ages maintained under various management systems, but in North America the disease is more prevalent in feedlots. It is most common in early winter, shortly after susceptible animals are moved there from pastures. Infection occurs in a large proportion of animals, but disease occurs in a minority. *H. somni* induces conditions in sheep identical to the bovine disease, i.e., septicemia, ITME, abortion, etc.

Cerebral localization produces a variety of neurologic signs, and without treatment affected animals become comatose and die within 1–2 days. The cerebral lesions are distinctive, and are visible in a large majority of untreated cases. The cerebrospinal fluid is cloudy and may contain pus and fibrin. *Scattered throughout the brain and spinal cord are multiple foci of hemorrhage and necrosis* (Fig. 3.114A, B). These foci may be 1–30 mm in diameter, and range from the bright red of recent hemorrhage to dark red-brown in older lesions. They have near-random distribution throughout the brain, but there may be some predilection for the thalamus and junction of the gray and white matter of the cerebral cortex. Meningitis is usually visible grossly and is most easily identified over the hemorrhagic foci. In animals that

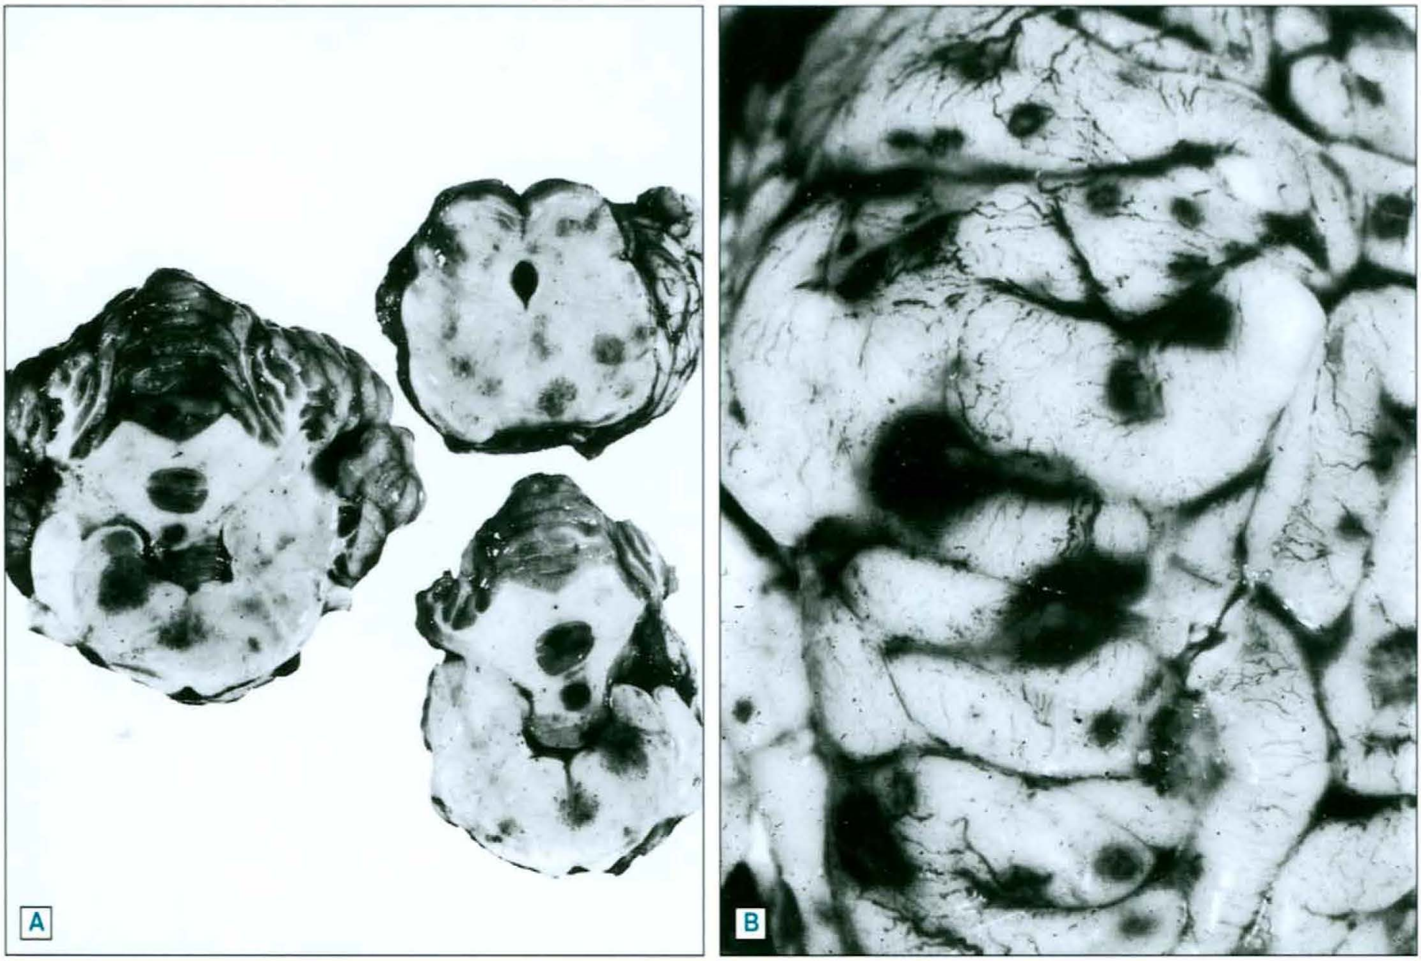

Figure 3.114 ***Histophilus somni*** infection in an ox. Multiple areas of hemorrhage and necrosis in brain stem (**A**) and cerebral cortex (**B**).

survive for a day or more, diffuse purulent leptomeningitis involves the basilar portions of the brain, and in these animals the older parenchymal lesions may have begun to soften.

The *histologic lesions* are similar in all organs but are usually most severe in the brain and consist of *intense vasculitis with thrombosis* and extension of the inflammation into the surrounding parenchyma, with or without infarction (Fig. 3.113A, B). Small venules (thrombophlebitis) are primarily affected, with thrombi often containing colonies of bacteria. The inflammatory response is neutrophilic, and cerebral lesions are quickly converted to abscesses.

Although cerebral vascular localization is a common and most dramatic result of the septicemia, *petechiation and evidence of inflammation are often visible throughout the body*, even in animals that die from fulminating disease. Foci of inflammation are easiest to identify in the renal medulla, skeletal muscle, lung, and laryngeal mucosa, but may also be visible in myocardium, intestine, and urinary bladder. Subacute to chronic disease develops commonly in some organs, especially joints, lungs, and heart, and is an important manifestation of *H. somni* infections.

In the acute disease, there is excess fluid in many *joints*, particularly the atlanto-occipital, where the capsule is distended by fluid that contains fibrin and sometimes blood. The synovial membranes and connective tissues around the affected joints are edematous and petechiated. The organism is sensitive to antimicrobials, and the course of the disease is often modified by therapy. The joints of animals that have survived several days contain thick mats of fibrin and pus, and the periarticular tissues are browned by old hemorrhage. Erosion of articular cartilages is rare.

Histophilus somni has been isolated from cattle with a variety of types of *pneumonia*, and its role in the bovine respiratory complex is discussed in the chapter on respiratory diseases. Pneumonia is an uncommon feature of the acute encephalitic form of the disease, but the lung can be involved as part of widespread vasculitis. *Ulcers of the larynx* occur in other diseases of feedlot animals, but, like atlanto-occipital arthritis, they are a regular enough feature of *H. somni* infection to serve as a valuable clue to the diagnosis and prompt a search for lesions in the brain. Similarly, *retinal hemorrhages* are grossly visible in a percentage of animals, and are of diagnostic assistance clinically and when gross brain lesions are absent.

A major manifestation of *H. somni* infection in some parts of North America, especially in western Canada, is *myocardial localization* following asymptomatic septicemia. Infarction, myocarditis, or abscess formation may result, and can lead to cardiac failure with or without mural and valvular endocarditis. In many animals, myocardial abscesses are found only when the myocardium of animals with chronic pneumonia or pleuritis is incised. Abscesses are most common in the left ventricular free wall, particularly in the papillary muscles.

Histophilus somni causes sporadic disease involving many other organs, including the ear, mammary gland, and those of the male and female genital tracts. It can also colonize the pregnant uterus and produce fetal disease and abortion (see The female genital system). The reported cases have not involved animals with cerebral localization, and may result from asymptomatic septicemia or transcervical invasion.

Viral infections of the nervous system

Viral infections of the central nervous system are common, usually as part of systemic infections rather than examples of a specialized affinity for nervous tissue. Several viruses are neurotropic, however only a few are neurovirulent. A neurovirulent virus is a virus that multiplies in neural tissue and is able to induce lesions.

The **routes of invasion** of the nervous system available to viruses are *via nerves*, including the olfactory tracts, and *hematogenous*. Centripetal spread in axons does not depend on viral replication in axons, but passage is provided by the mechanisms of fast axoplasmic transport. Invasion by the olfactory route is theoretically simpler since olfactory receptors extend into and beyond the olfactory epithelium, and a cuff of arachnoid extends through the cribriform plate to the olfactory submucosa. This arrangement would allow viruses to spread along nerves without first penetrating to the submucosa or, having penetrated to the submucosa, to reach the CSF directly. This may be the route taken by *Bovine herpesvirus 1, Porcine teschovirus*, and Pseudorabies virus in young pigs. The olfactory route could be used following intranasal exposure or following hematogenous seeding of the olfactory epithelium or mucosa.

For most viruses, spread to the CNS is *hematogenous* after multiplication in some other tissue and the development of viremia of sufficient magnitude and duration. Viruses are susceptible to removal from blood by histiocytes, but viremia can be sustained if the viruses are small, associated with cells of blood, or replicated in endothelium or lymphatic tissues. Some viruses, such as *Canine distemper virus*, infect vascular endothelial cells whereas others infect surrounding glia suggesting transport across endothelium in pinocytotic vesicles. Invasion across the choroid plexus is not impeded by the fenestrated endothelial cells there but would require active infection of the epithelium and ependyma. There are areas of selective permeability to indicator dyes in the brain, such as the tuber cinereum and area postrema, but there is no evidence that these are selectively used by viruses.

The means by which viruses *spread in nervous tissue* are not known. Rapid dissemination can occur in the CSF, but some viruses, such as *Rabies virus*, extend rapidly through the parenchyma. The rate of spread of *Rabies virus*, assuming cell-to-cell growth and transmission, is probably more rapid than its generation time would permit, and permeation of the limited extracellular spaces of the brain by large viruses seems unlikely.

Separation of the specialized cells of the CNS into neurons, oligodendrocytes, astrocytes, and ependymocytes understates the diversity of cell populations in the brain and cord. Different cell populations may show different susceptibilities to infection by different viruses. Thus, Pseudorabies virus is nonselective in the destruction of cells in the rostral cortex of piglets, *Feline panleukopenia virus* selects rapidly proliferating cells of ependyma and cerebellar cortex, and *Porcine teschovirus 1* appears to affect particularly the spinal motor neurons.

Degeneration of neurons, reactivity of the glia, and perivascular reactions are the general hallmarks of viral infection of the CNS, and imply a sequence of viral cytopathogenicity and reaction to cellular degeneration. However, viruses that produce manifestations deviating from this rather simple system are many. *Classical swine fever virus* and *Bluetongue virus* at a suitably early fetal stage of development may produce **malformations** characterized by degeneration of tissue without reaction; later when the animal is immunologically competent, these viruses may produce ordinary encephalomyelitis. *Feline panleukopenia virus* causes cerebellar hypoplasia in the neonate but is without effect at a later stage of development.

Some viruses may produce *persistent tolerated infection* without clinical signs or lesions. At the other end of the spectrum is *Rabies virus*, which can cause death with minimal cytopathic effect and reaction, or no morphological change at all. Some virus infections are characterized by long latency and slow attrition, visna/maedi of sheep being the standard example expressed as either degeneration or chronic inflammation. *Transformation of nervous system cells by viruses* can be demonstrated in vitro, and a variety of tumors of the nervous system can be produced by viruses in experimental animals, but they have, as yet, no natural counterpart. The contribution of an immunological response to both the progress and morphology of encephalomyelitis is very difficult to determine.

General pathology of viral inflammation of the nervous system

Viral infections of the CNS typically induce **nonsuppurative inflammation**, a term that includes quite a variety of quantitative and qualitative changes. The changes are not specific for viral infections, being produced in some bacterial infections such as salmonellosis in swine, in the rickettsial infection, "salmon poisoning," of dogs, and probably in other rickettsioses. Nor are the lesions qualitatively the same in all viral infections, a fact that is of considerable usefulness in differential diagnosis. The differences are due in part to inherent characters of the agents, routes of invasion, patterns of localization, success of viral replication and release, duration and degree of cellular injury, and host defense reactions. As well as the differences, there are also the very considerable similarities that allow them all to be included with the "nonsuppurative encephalomyelitides."

The distribution of lesions in different viral infections is a reflection of the varied affinities of the viruses, and is useful in differential diagnosis but only generally applicable. The distributions of lesions or of inclusion bodies are only very rough guides to the distribution and activity of the virus.

Perivascular cuffing, or accumulation of cells in the adventitia of vessels and in the perivascular Virchow–Robin space, is almost constant in encephalitis, and, when present, is usually the most striking microscopic change. The accumulated cells are usually leukocytes, but in some diseases there may be very few hematogenous elements recognizable, the cuffs being composed instead of histiocytic cells that appear to have proliferated in situ from adventitial elements. These latter frequently fragment to resemble degenerate neutrophils if the postmortem interval is prolonged. Injury to the vessel wall proper is not constant, but when it occurs it may affect the arteries as a hyalinizing or fibrinoid change. This is characteristic of malignant catarrhal fever, for example, and occurs also in equine encephalitis. The endothelium may be selectively injured in classical swine fever and infectious canine hepatitis. The lesions associated with *Equid herpesvirus* infection may be limited to quite subtle endothelial swelling and proliferation in small blood vessels. When, in inflammation, the perivascular cuffs are large enough to disorganize the wall of the vessel and compress it, the endothelium frequently shows signs of swelling and proliferation, and there may also be altered adhesiveness so that leukocytes and red cells tend to stick to it. Thrombosis is incidental and very seldom observed, but compression of the vessels probably accounts for the ischemic parenchymal softenings that occur.

Infiltrating cells are predominantly lymphocytes, and they accumulate in the perivascular spaces (see Fig. 3.19). The earliest cells in the perivascular spaces may be neutrophils; in acute lesions, some of these can be found wandering in parenchyma or grouped in dense clusters. They soon disappear but may be found later for a short time in areas that soften. Lymphocytes remain in the cuffs and are admixed after a week or so with an increasing number of plasma cells and macrophages. A few eosinophils may also be found in pigs. Perivascular cuffing is not specific for viral infections. It is also a reaction to degeneration of neural tissue.

Glial reactions occur if the parenchyma is injured, even though the injury may not be appreciable, but the reaction may be absent in those infections that selectively involve the vessel walls. In inflamed areas, the oligodendroglia degenerate. Astrocytes degenerate or react depending on how strictly and severely they are injured – the stimuli for astrocytic reaction were discussed earlier in this chapter. *The gliosis that is so frequently a feature of nonsuppurative encephalomyelitis is almost solely microglial. The gliosis may be diffuse or focal but is commonly both* (see Fig. 3.17). Diffuse gliosis may be more apparent than real if due more to hypertrophy than to proliferation of these glia. Focal gliosis may occur anywhere in the parenchyma and may be related to small vessels and injury to microvasculature. When there are more than a dozen or so cells in such foci, some of the cells are likely to be lymphocytes, and occasionally there are a few plasma cells. The microglia in the center of a focus are frequently degenerate. There are two specifically named forms of microgliosis: "*neuronophagic nodules*" are foci of microglia about degenerating neurons (see Fig. 3.2D); "*glial shrubbery*" is an accumulation of these cells in the molecular layer of the cerebellum in relation to degenerating Purkinje cells (Fig. 3.115).

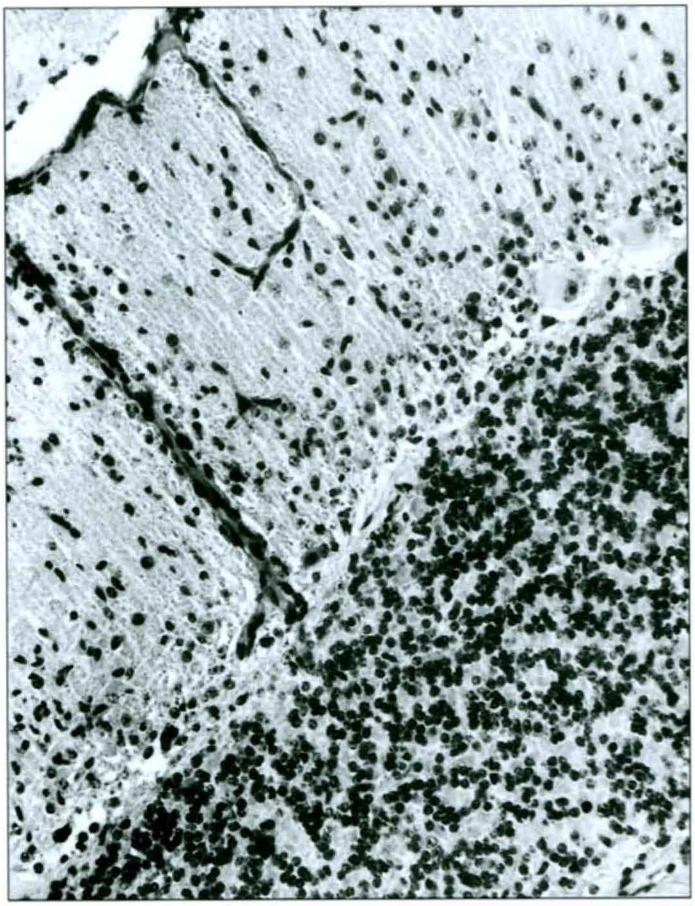

Figure 3.115 Encephalitis in **louping-ill** in a sheep. Destruction of Purkinje cells and gliosis in molecular layer of cerebellum ("glial shrubbery").

Neuronal changes must be the principal determinants of the outcome of the infection. The distribution of neuronal degeneration is to some slight extent specific, but the extensiveness is nonspecific and varies considerably. The morphological features of the degenerate cells are nonspecific. As a rule, the more severe degrees of neuronal degeneration are caused by viruses that are highly neurotropic, such as *Rabies virus*, but the severity of neuronal degeneration is not a dependable "lead" in differential diagnosis. The fact that *Rabies virus* can be lethal without morphological change in the CNS raises the possibility that other viruses may cause severe encephalopathy without inflammatory change. *The usual form of neuronal degeneration is central chromatolysis*, which may extend to completion with the cell then swollen, pale, and devoid of a nucleus. This is typical of the axonal reaction to injury, but the axons are intact. Many neurons appear as if coagulated, being shrunken, rounded, and isolated, and staining darkly with eosin. The nucleus is pyknotic or has disappeared. The coagulated neuron stimulates the formation of the neuronophagic nodule, but not all necrotic neurons elicit the reaction. Usually, intact neurons can be found adjacent to degenerate ones.

Lesions in white matter occur consistently even though many viruses are supposed to be specifically tropic for gray matter. Cuffing reactions are to be expected even if degeneration is limited to adjacent gray matter. *Microgliosis* is focal rather than diffuse and the nodules are small. Some degree of *disintegration of myelin* is inevitable, but conspicuous demyelination is a feature only of canine distemper, lentivirus leukoencephalitis of goats, and visna. Demyelination associated with viral diseases may be due to direct infection of melanin-forming cells, i.e., oligodendroglia, as in infection with *Canine distemper virus*, or may be a bystander lesion due to injury from inflammatory cytokines associated with viral infection.

Meningitis is seldom severe except in local distributions, and these tend to overlie parenchymal lesions. Some agents, of which typical examples are those of sporadic bovine encephalomyelitis (see Fig. 3.60) and malignant catarrhal fever, have a selective affinity for meningeal structures in the CNS. Others, such as *Canine distemper virus*, share the affinities so that leptomeningitis is part of the primary response. In the more purely neurotropic infections, such as rabies, the meningitis, or more precisely the meningeal infiltration, is due probably to drainage of products of reaction via the Virchow–Robin spaces from the brain or cord. The reacting cells in the meninges are of the same type as those in the brain, and they float freely in the arachnoid spaces.

No virus is known to be tropic for peripheral nerves in the sense of selectively producing direct lesions in them. Degenerative changes occur fairly early in the end plates and terminal parts of axons when the central cell body is destroyed. Foci of microglia and lymphocytes occur in the nerve roots quite commonly. Inflammation of the paravertebral ganglia, and especially the trigeminal (Gasserian) ganglia, is characteristic of rabies and of Teschen disease and related infections in pigs, but the frequency and distribution of this lesion in other viral encephalomyelitides and in other ganglia is unknown.

Inclusion bodies may form in neurons, neuroglia, or microglia and other mesenchymal cells. Inclusion bodies in the nervous system are usually acidophilic. They may be found only in neurons as in rabies, in glia, or in both. They may be cytoplasmic, nuclear, or both. Intranuclear inclusions, which must be distinguished from altered nucleoli, have considerable specificity; somewhat less reliance can be placed on intracytoplasmic inclusions. Cytoplasmic viral inclusions must be distinguished from normal inclusions.

Lyssavirus infections

Rabies is caused by *Rabies virus* (RABV), which belongs to the genus *Lyssavirus* of the family Rhabdoviridae. The RABV glycoprotein (RVG), which is a trimeric and surface-exposed viral coat protein, is responsible for RABV neurotropism by binding to several neural tissue receptors including the neuronal cell adhesion molecule (NCAM), and the p75 neurotrophin receptor (p75NTR). Evolutionary studies based on genes encoding the surface glycoprotein *suggest that RABV evolved first in bats*, possibly in vampire bats much more widely distributed than at present, and only later became adapted to terrestrial carnivores. There is a single major antigenic type with minor variations that allow epidemiological surveillance. *Seven genotypes* are defined by phylogenetic analysis. Type 1 is the classical *Rabies virus* of animals and vampire bats, and of all other bat lyssaviruses in North America. Type 2 (*Lagos bat virus*), type 3 (*Mokola virus*), type 4 (*Duvenhage virus*) are African genotypes. Types 5 (EBLV-1) and 6 (EBLV-2) are *European bat lyssavirus* 1 and 2, and type 7 (Ballina virus) is the *Australian bat lyssavirus*. The seven genotypes may further be allocated into *two major phylogroups* based on pathogenicity for mice and cross-neutralization. Phylogroup 1 includes genotypes 1, 4–7, and phylogroup 2 includes genotypes 2 and 3. Excepting *Mokola virus*, bats may be the preferential vector species for genotypes 2–7.

Rabies virus has two biotypes: "fixed" virus and "street" virus. *Fixed RABV*, which is the basis of vaccine strains, is a laboratory biotype stabilized in its properties by serial intracerebral passage. It is highly neurotropic, is not secreted in saliva, and does not produce Negri bodies. *Street RABV* is the feral biotype that circulates in enzootics and epizootics. In addition to neurotropism, it is tropic for salivary glands, in which it reaches high concentration, and possibly in other mucus-secreting epithelia, and produces Negri bodies.

The establishment of infection ordinarily depends on inoculation of the virus into a wound, such usually being inflicted by the bite of a rabid animal. Contamination of a fresh wound by infected saliva or tissues is much less dangerous. The virus replicates in myocytes around a bite wound for a short period of time, and then buds from the plasma membrane. Viral particles invade the local neuromuscular junction through conjugation of the RVG with the nicotinic acetylcholine receptor, and then invade neurotendinous spindles and ascend to the CNS and paravertebral ganglia via axoplasmic flow. Viral replication in the CNS is followed by centrifugal spread to major exit portals, such as the adrenal gland, nasal mucosa, and salivary glands; the virus is secreted with the saliva for a few days prior to the appearance of clinical signs. The incubation period is variable from weeks to months.

Although there are species differences in susceptibility, rabies is one disease to which *all mammals are susceptible*. The disease can be regarded as one of carnivores because it is almost always transmitted naturally only by bites, and man, herbivores, etc. are dead-end hosts. There are exceptions to the rule that RABV is bite-transmitted: *oral infection* can occur in diverse species and the application of modified RABV in "baits" utilizes this potential; *aerosol infection* can occur, as in dense congregations of colonial bats in bat caves, probably as droplet infection from salivary secretions; and a variety of aberrant circumstances may provide transfer opportunities for infectious virus, as has been reported for *corneal transplants*.

Reservoir hosts vary from time to time and from region to region. The principal reservoir vectors are: foxes and skunks in the USA and Canada, with the raccoon of importance on the Atlantic seaboard; foxes and dogs in northern Canada; foxes moving from east to west in Europe; wolves in eastern Europe and Iran; jackals in India and Northern Africa; the mongoose and genet cat in South Africa; and the mongoose in the Caribbean. *Sylvatic vectors* are responsible for most transmissions to man and domestic animals in countries where dog populations are controlled. Oral vaccination of wild carnivores, by using vaccine-laden baits, and routine vaccination of dogs have led to almost complete elimination of canine-transmitted rabies in developed countries. Rarely, vaccination of severely stressed animals with vaccines containing modified-live virus may induce post-vaccinal rabies. In tropical areas where domestic and feral dogs are not controlled, these animals are the principal hazards for man and livestock.

Bats present a special epidemiologic problem. Fructivorous and insectivorous bats as well as vampires are capable of transmitting RABV. Vampire bats inhabit South and Central America extending into northern Mexico and are, historically, responsible for a high incidence of rabies in mammals, especially cattle but including humans. When clinically affected, vampire bats manifest the disease as the furious form and show unnatural daylight activity.

The **clinical course** of rabies is usually acute, from 1–2 days, but can be as long as 10 days. It is seldom that a clinical diagnosis of rabies can be made with confidence. The terms "*furious rabies*" and "*dumb rabies*" place emphasis on particular features within a spectrum of behavioral changes and are inappropriate for noncarnivorous animals. *Aberrant behavioral patterns* can be recognized in affected animals during epizootics. The period of salivary excretion of virus before the onset of neurological signs is expected to be not more than a few days, vampire bats possibly excepted, and the duration of clinical disease to be a few days only. Once expressed clinically as neurologic disease, *rabies is almost invariably fatal*; recovery with or without neurologic deficit is quite rare but has been observed in several species following experimental exposure. Progressive infection and clinical disease do not inevitably follow exposure; up to 25% of feral populations may have specific antibodies as evidence that the infection provoked an immune response without progression to neurologic disease.

Specific gross lesions are not present at necropsy, but self-inflicted wounds and foreign bodies in the stomach of a carnivore should raise suspicion. The **histologic lesions** of rabies, when present, are *typical of nonsuppurative encephalomyelitis, with ganglioneuritis and parotid adenitis*. Inflammatory changes are usually present, but they may be very mild or absent. To some extent at least, the severity of lesions reflects the duration of the clinical disease. In the CNS, inflammatory and degenerative changes are most severe from the pons to the hypothalamus and in the cervical spinal cord, with relative sparing of the medulla. This relative sparing of the medulla appears to apply to all domestic species. The most severe lesions of the disease are generally found in dogs whereas other species, especially ruminants, which are highly susceptible, may show little more than an occasional vessel with a few cuffing lymphocytes and a few very small glial nodules (*Babès' nodules* in this disease), and this in spite of having numerous Negri bodies. These reactive phenomena probably reflect largely the degree of neuronal degeneration, and this may be remarkably slight in herbivores and remarkably severe in dogs.

The reaction is typically one of *perivascular cuffing and focal gliosis*. The cuffs are 1 to several cells thick and composed solely of lymphocytes (Fig. 3.116A); ring hemorrhages confined largely to the perivascular space are common about cuffed vessels. Hemorrhages are occasionally severe enough to be visible grossly in the spinal cord of horses and cattle (Fig. 3.116B). The Babès' nodules are composed of microglia, and they occur in both white and gray matter. The nodules vary greatly in size, some containing only six or seven cells and

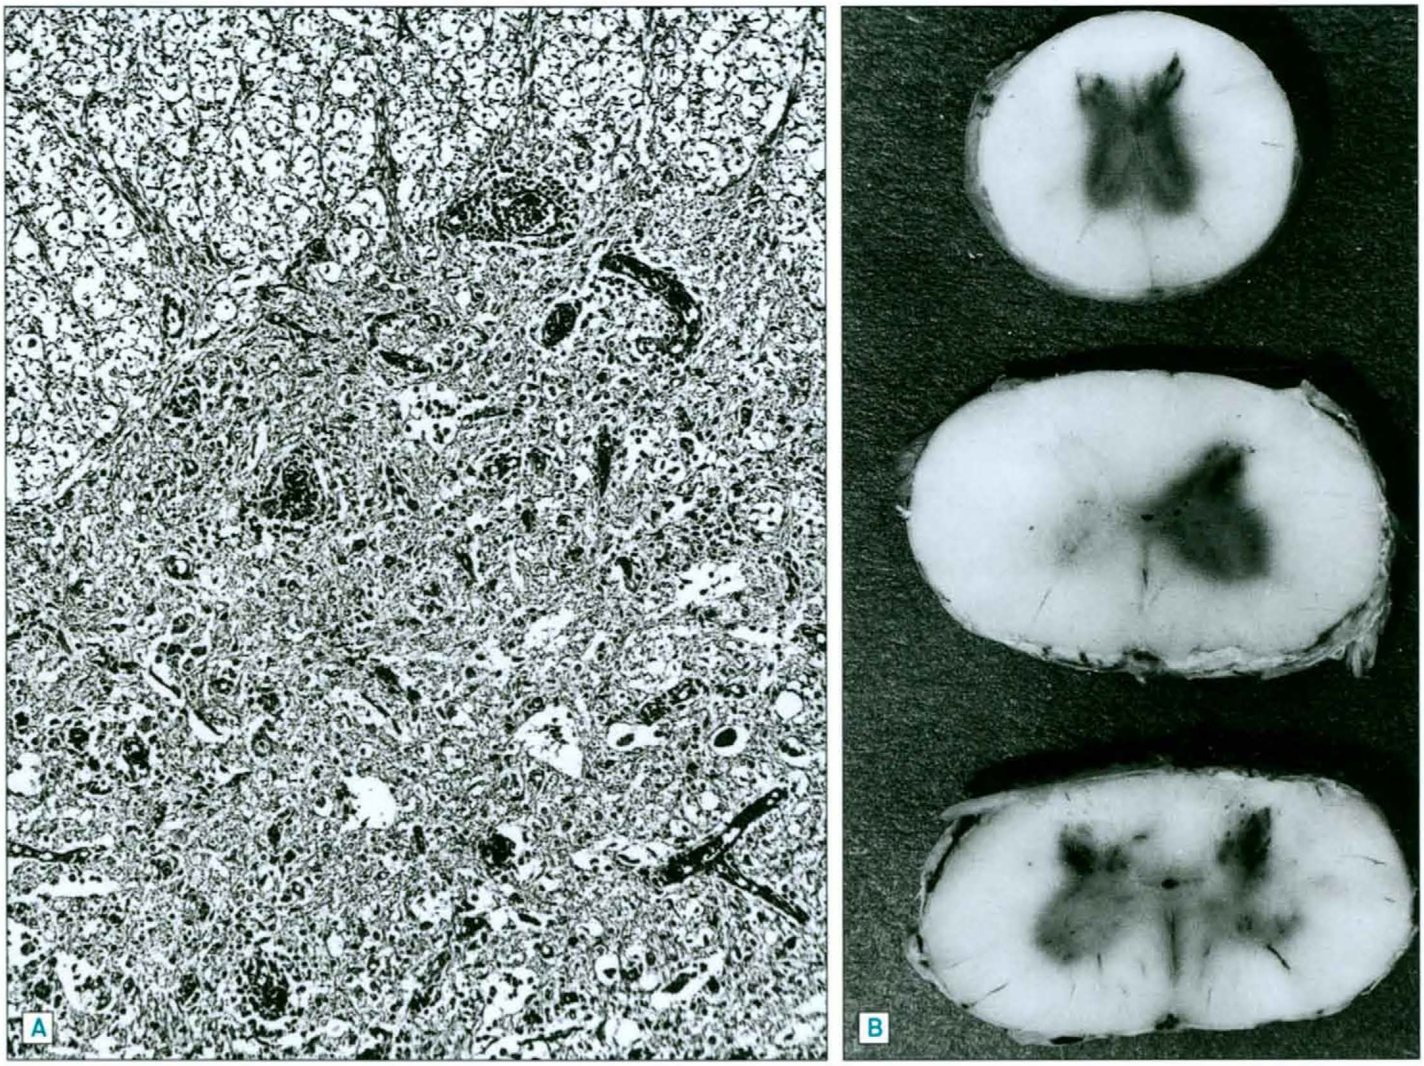

Figure 3.116 Rabies. A. Perivascular cuffs and focal gliosis in a horse. **B.** Hemorrhage in gray matter of spinal cord.

some containing 100 or more. Diffuse as well as focal gliosis occurs in areas of gray matter such as the pons and in the spinal cord, both horns of the latter being involved.

Neuronal degeneration in carnivores may be very extensive and quite out of proportion to the observed reactive changes, but may be very slight in pigs and herbivores. Neuronal and/or gray matter neuropilar vacuolation (*rabies-induced spongiform encephalopathy*) is reported to occur in experimental and natural rabies. The specificity of the neuronal changes and of the whole pathologic picture depends on the *inclusion bodies of Negri*. These are always *intracytoplasmic* and are present most commonly in the hippocampus of carnivores and in the Purkinje cells of herbivores. Fixed RABV does not produce Negri bodies, and street RABV fails to do so in up to 30% of cases. Neurons of any distribution may contain inclusion bodies, but they tend to be scarce where the inflammatory reaction is severe. Indeed Negri bodies may be found only in neurons that are otherwise histologically normal; they are not present in degenerate neurons. They have also been found, but rarely, in ganglion cells of the adrenal medulla, salivary glands, and retina. While the number of Negri bodies has little relation to the length of the incubation period, there is a relation to the duration of the clinical disease. They may not be found if the animal is killed instead of being allowed to die. They are produced consistently in white mice, the usual test animal.

Negri bodies are round or oval structures usually ~2–8 μm in diameter (Fig. 3.117A). They are plastic, their shape being molded to their environment. Those in the dendrites, seldom observed except in Purkinje cells, are oval and those in the cell body are usually rounded. There may be one or more per cell, and affected cells are otherwise only little changed. The inclusions are surrounded by a clear thin halo. Nonspecific homogeneous inclusions may be found in the pyramidal cells of the hippocampus in cats, skunks, and dogs. There may be several such inclusions per cell but each is minute, not measuring more than 1.5 μm. In old sheep and cattle, larger neurons, especially of the medulla and cord, may contain nonspecific inclusions. These have a dust-like distribution, are usually numerous, and are brightly acidophilic, angulated, and ~1.0 μm in size. Nonspecific inclusions that are indistinguishable from Negri bodies by light microscopy occur in the lateral geniculate neurons in cats. *Fluorescent antibody techniques are required for positive identification* and are essential in the rare chronic cases which may not yield virus on mouse inoculation.

If there is no *ganglioneuritis* in the paravertebral ganglia, then the possibility of the animal having rabies is very remote. If there is ganglioneuritis, it may be part of rabies or something else. Pigs, for example, get ganglioneuritis in the Teschen group of infections. Inflammatory changes in the trigeminal (Gasserian) ganglion in rabies may be present without inflammatory or neuronal changes being clearly evident in the brain. The ganglionic changes are of the same character as those in the brain, namely acute degeneration of ganglion cells, proliferation of capsule cells, and microglial nodules (Fig. 3.117B).

The natural transmission of RABV depends on virus being present in the saliva and, therefore, in the salivary glands. Fixed virus

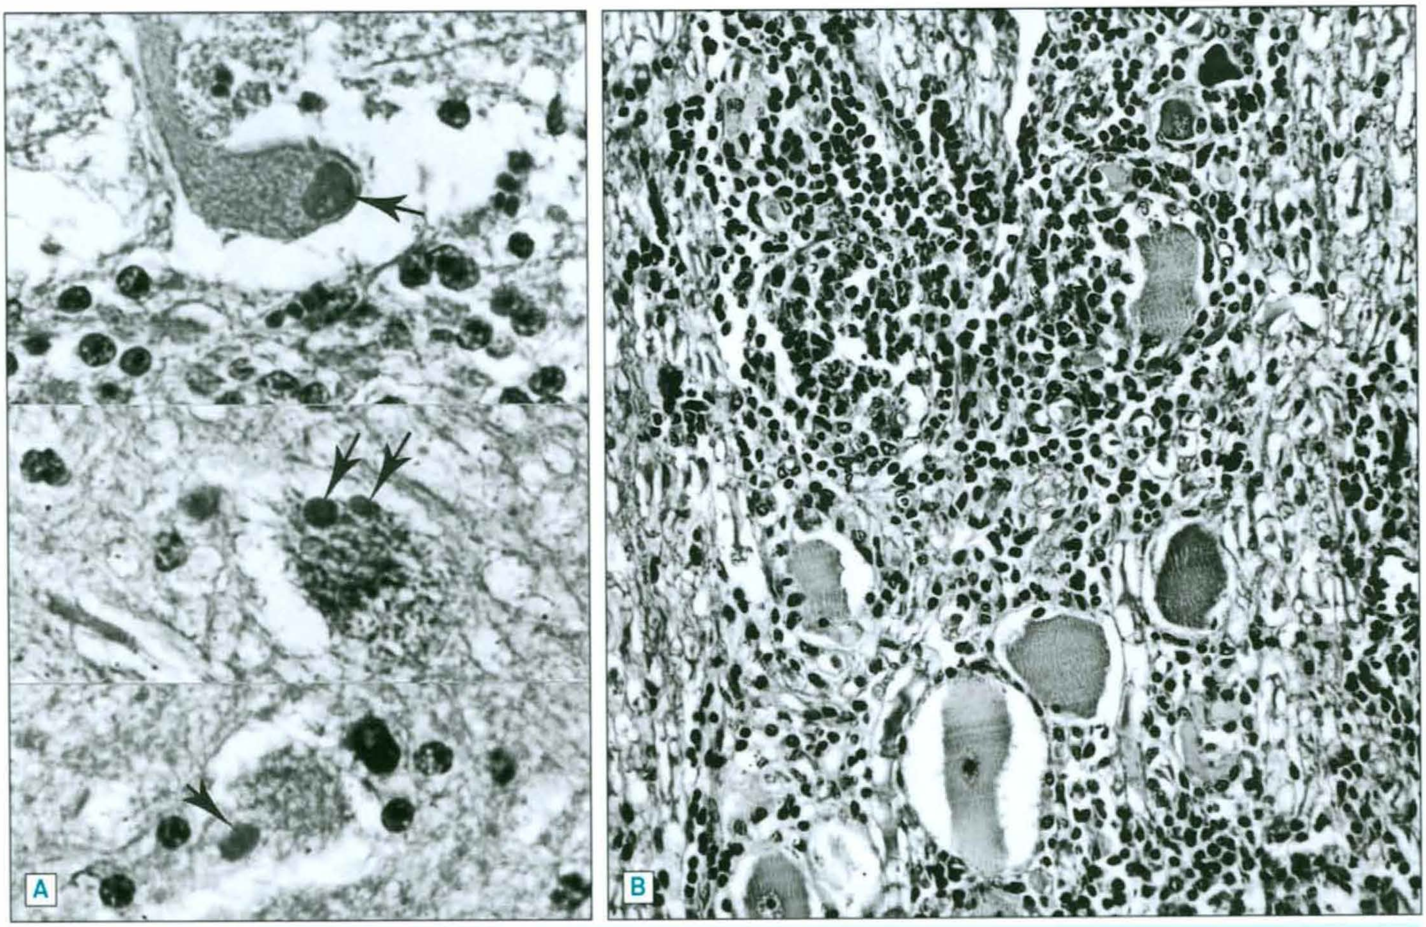

Figure 3.117 Rabies. A. Composite picture showing Negri bodies (arrows) in neuronal cytoplasm. **B.** Severe nonsuppurative inflammation of trigeminal ganglion.

has no affinity for the salivary glands, and none is present in some cases of infection with the street virus. Degenerative changes are reported in the epithelium of the mandibular salivary gland, but not in the parotid, in dogs.

The **diagnosis** of rabies is made by utilizing fluorescent antibody labeling on fresh or fixed tissue, or by virus isolation in cell culture.

Pseudorabies

Pseudorabies is also known as Aujeszky's disease, mad itch, infectious bulbar paralysis, and porcine herpesvirus infection. The causative agent, ***Suid herpesvirus 1*** (SuHV-1; Pseudorabies virus, PRV), belongs to the genus *Varicellovirus*, subfamily Alphaherpesvirinae, family Herpesviridae, but is unusual for a member of that group in its relative lack of host specificity and by being spread laterally as well as vertically in swine. A number of strains have been identified which exhibit a wide range of virulence. Pseudorabies virus is capable, as are other members of the family Herpesviridae, of establishing latent infection. Trigeminal ganglion, olfactory bulb, and tonsil are the most consistent sites of latency of PRV. In these organs, viral DNA can be detected in the absence of infectious virus. The pig is the only natural host, but the common domestic species are naturally susceptible; there are very few reports in horses and goats. Progressive infections do not occur in humans. The disease is reported worldwide, except for Canada and Australia. Natural infections occur in rats and mice and various species of wildlife and on fur farms. Of the laboratory animals, the rabbit is the most susceptible and is preferred for identification of the virus because of the fairly consistent development of intense local pruritus following subcutaneous inoculation. Guinea pigs are less susceptible and may resist subcutaneous inoculation but succumb to intracerebral and, occasionally, to intraperitoneal inoculation.

The virus is maintained in enzootic areas in wild and domestic swine, for which it is highly contagious but usually asymptomatic, and probably in brown rats. *Transmission* can occur by ingestion, but the usual method of spread between pigs is thought to be by contact of infective secretions with nasal mucosa or abraded skin. Animals are susceptible to intranasal inoculation and, regardless of the route of infection, the *virus can be found in nasal secretions*. The virus may also be present in saliva and urine. It is also present in blood, but this is of no significance for epidemiology or transmission. The infection will occur in pigs by contact very readily and probably by direct nose-to-nose transmission, but it does not appear to be contagious between individuals of other species and they probably acquire their infection by contact with swine or, possibly, rats. Pigs may harbor virus for many months in tonsils and nasopharyngeal secretions after exposure, but in other domestic species the virus is fairly strictly neurotropic, and therefore is not excreted unless given experimentally in large doses. Ingestion of *infected pig meat* is the usual source of infection for dogs and cats. Cattle and sheep may become infected by direct contact with carrier swine or by aerosol exposure, but there is strong circumstantial evidence implicating contaminated feed.

The *pathogenesis* of the infection following local inoculation is well established for the rabbit and is probably comparable in other species. The virus causes a local reaction at the site of inoculation if percutaneous and then spreads centripetally along the related nerve to the spinal cord; it then spreads outwards again along other peripheral nerves as other segments of cord are progressively invaded by spread within the CNS. Because of the progressive advance of infection along the cord, death may occur before demonstrable amounts of virus reach the brain and before lesions have time to develop there. Intracerebral inoculation produces encephalitis, and virus spreads to the cord and centrifugally along peripheral nerves to an extent that depends on survival time. Because the virus also circulates in the blood, there is some possibility but no evidence that it invades the brain directly, the evidence instead suggesting that it localizes in viscera and invades the nervous system along autonomic nerves. Following nasal or intraocular exposure, the virus spreads along the related nerves. The route of invasion following ingestion is by retrograde transneuronal infection. Transplacental infections occur in pigs causing abortion in about 50% of sows pregnant in the first month, and the delivery of macerated, mummified, and normal fetuses when infection occurs at later stages of gestation. The virus is reported to be present in the semen of carrier boars.

The *signs and course* of pseudorabies in pigs are very variable. Most cases are of mild febrile illness without pruritus or nervous signs, and with recovery expected in a week or so. Sows may subsequently produce mummified litters. Age is a very important factor governing the severity of the disease in swine; the mortality rate in nursing pigs and young weaners may be very high. Very young sucklings do not show specific nervous signs but rapidly become prostrate and die in 12–24 hours. In slightly older piglets, incoordination progresses rapidly to paralysis with muscular twitchings, tremors, and convulsions. Some pigs showing severe signs of encephalitis recover. Experimental peripheral inoculation will produce asymptomatic meningitis and encephalitis in swine, the inflammatory lesions being severe. The disease in older pigs is often characterized by fever, rhinitis, and coughing. There may be generalized pruritus in natural cases but it is not severe, being expressed usually by rubbing of the nose or head. Fetal resorption, mummification, stillbirths, and abortions are frequently reported.

The characteristic clinical sign of pseudorabies in animals other than pigs is *intense cutaneous irritation* developing at the point of inoculation or at the terminal distribution of a nerve trunk which passes the point of inoculation. This does not occur until the virus reaches the related segment of cord. Dogs may become frenzied, and besides the intense pruritus (mad itch) there may be jaw paralysis and drooling reminiscent of rabies. The clinical course in these species, which always ends in death, is frequently acute (a few hours) and never longer than 1 week. Pseudorabies may occur in sporadic, although significant, outbreaks in sheep and cattle. The mortality rate is very high. Death may occur without signs of illness or within 1–2 days of the onset of clinical signs. There is fever, and the itching may be on any part of the body but is most frequently about the head or hindlimbs. Other neurological signs are variable but constantly present.

There are *no specific gross lesions* of pseudorabies. At the site of cutaneous infection, there is acute serofibrinous inflammation, ballooning degeneration, and epithelial necrosis with rare intranuclear inclusions. Self-trauma due to intense itching may exacerbate these lesions. The intense pruritus at the site of inoculation is likely due to stimulation of regional sensory nerves by viral spread and multiplication. Gross changes are seen mostly in young pigs. There may be necrosis of tonsils and sometimes of the trachea and esophagus. Rhinitis with patchy epithelial necrosis is common. The lungs may be edematous. Tiny foci (1–2 mm) of hemorrhagic necrosis typical of alpha-herpesviral infection may be seen in liver, spleen, lung, intestines, adrenals, and placenta.

The **histologic lesions** reflect the neurotropic and epitheliotropic nature of the virus. Lesions are similar in all susceptible species, however, epitheliotropic lesions are more commonly seen in young, aborted, or stillbirth piglets and rarely seen in ruminants or carnivores, where the brain lesions are more common. In brain, the gray matter especially is affected, but death may occur before there are clear indications of neuronal degeneration or inflammatory reaction in the brain. With naturally acquired infections, the inflammatory changes are *nonsuppurative*. In addition, focal gliosis and lesions typical of neuronal degeneration (neuronophagia and satellitosis) are usually present (Fig. 3.118A, B). There is severe ganglioneuritis in paravertebral ganglia. The specificity of the reaction in the brain depends on the development of *acidophilic intranuclear inclusion bodies in neurons and astroglia* (Fig. 3.118C). These inclusion bodies occur in all species, including pigs; fixation in a mercurial fixative is helpful for their demonstration. Inclusions in swine are *solid and amphophilic*, but in other species the inclusions are granular and often small and multiple in an affected nucleus. By any route of infection, piglets tend to develop panencephalitis with most severe lesions in the cerebral cortex, brain stem, spinal ganglia, and basal ganglia of the brain (Fig. 3.118B); in other domestic species, the distribution of lesions in the CNS is local to, and determined by, the route of exposure. Lymphoplasmacytic inflammation with neuronal degeneration of the gastric myenteric plexi is also described.

Epitheliotropic lesions include the presence of tiny areas of coagulative or lytic necrosis in the liver, tonsils, lung, spleen, placenta, and adrenals with the presence of the characteristic intranuclear inclusions. Pulmonary lesions may be mild or severe. Edema and mild cellular infiltration may be diffuse and there may be focal or confluent necrotizing, hemorrhagic pneumonia (Fig. 3.118D). Hemorrhage and necrosis is present in lymph nodes, and foci of necrosis may be found in tonsils, liver, spleen, and adrenal. Necrotizing vasculitis is described in natural infections in sheep and experimentally in piglets. In aborted or stillborn piglets, which are suitable for examination, there is usually no evidence of encephalitis, but foci of necrosis may be found in liver and other parenchymatous tissues together with focal bronchiolar necrosis and interstitial pneumonia.

Rapid **diagnosis** can be achieved by fluorescent antibody tests on frozen sections of tissue, e.g., tonsils, liver, or brain. Isolation in eggs or tissue culture is also available.

Porcine hemagglutinating encephalomyelitis virus

Porcine hemagglutinating encephalomyelitis virus (HEV), a member of genus *Coronavirus*, family Coronaviridae, can be isolated from the respiratory tract of normal pigs, and is present worldwide. Other porcine coronaviruses include *Transmissible gastroenteritis virus*, *Porcine epidemic diarrhea virus*, and *Porcine respiratory coronavirus*. HEV is a group 2 species coronavirus antigenically related to *Bovine coronavirus*, *Human coronavirus OC43*, and *Murine hepatitis virus*. The pig is the only natural host for HEV. Although there is serological evidence of wide distribution in many swine-raising areas, clinical disease is rare because most piglets receive protective levels of colostral antibodies to HEV. Disease occurs in piglets 1–3 weeks of age and follows a clinical course of about 3 days to 3 weeks. The mortality rate is very high and survivors are usually unthrifty.

Following exposure, replication of virus occurs in the epithelium of nose, tonsil, lung, and small intestine, with spread to the CNS along peripheral nerves rather than hematogenously; viremia is not important in the pathogenesis. Viral antigen is detectable in alimentary ganglia during the incubation period of the disease. It is first demonstrable in the brain in trigeminal and vagal sensory nuclei, with later rostral spread in brain stem. Viral replication occurs in the myenteric plexus of the stomach, and involvement of the autonomic system probably can explain the predominant clinical signs of vomition and constipation.

Two *clinical syndromes* are recognized. Neurologic signs occur in 4–7-day-old piglets in some outbreaks and consist of stilted gait, hyperesthesia, progressive paresis, and convulsions in some cases. Clinical signs in 4–14-day-old piglets are dominated by anorexia and vomiting, and this syndrome is called "*vomiting and wasting disease*."

Lesions in the CNS may be found in some affected piglets that do not show clinical signs of nervous disease. The frequency with which inflammatory change is found is quite variable. Lesions when present are those of *nonsuppurative encephalomyelitis* affecting particularly the gray matter of medulla and brain stem. In such cases

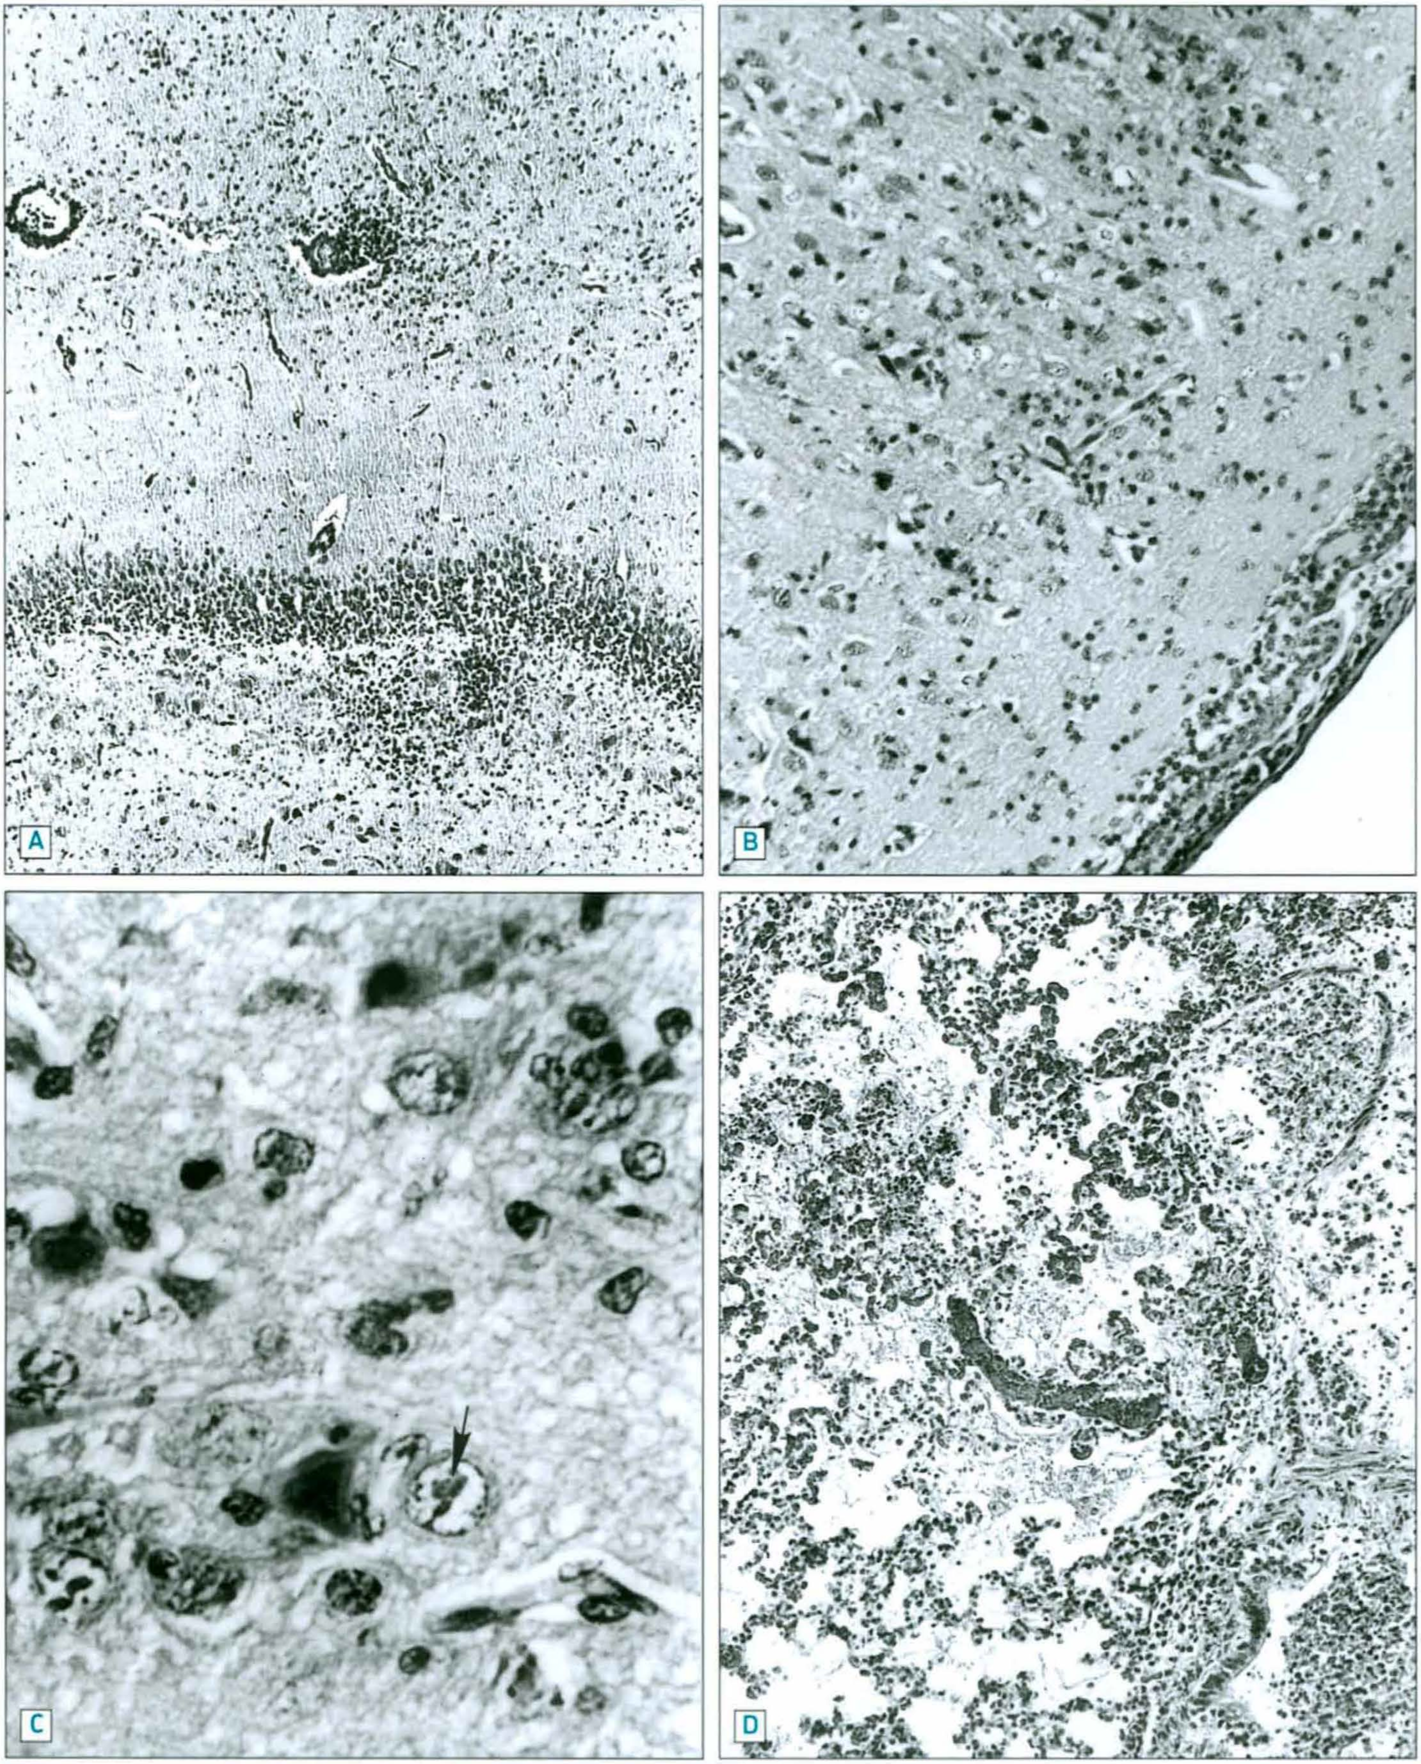

Figure 3.118 Pseudorabies in a pig. **A.** Perivascular cuffing, focal and diffuse gliosis in dentate gyrus. **B.** Meningitis and necrosis of cells in cerebrum. **C.** Neuronal necrosis and irregular inclusion bodies in nuclei (arrow). **D.** Necrotizing bronchopneumonia.

there is inflammation of the trigeminal, paravertebral, and autonomic ganglia. The gastric myenteric plexi are occasionally infiltrated with a few lymphocytes and plasma cells.

Diagnosis of HEV is problematic. Serology on acute and convalescent sera may help in detecting acute infection. Isolation of HEV can be attempted from brain stem of acutely ill piglets. Differential diagnoses of nervous conditions with high mortality in piglets include pseudorabies, classical swine fever, polioencephalomyelitis (Teschen disease), bacterial meningitis, streptococcal septicemia, and hypoglycemia.

Enterovirus/teschovirus polioencephalomyelitis of pigs

Encephalomyelitis of pigs caused by porcine enteroviruses occurs in many countries and is distinguishable only by a study of the agents. Porcine enteroviruses are ubiquitous but are limited in their pathogenicity to swine. ***Porcine enterovirus*** *A* (PEV-A, formerly PEV serotype 8) and *Porcine enterovirus B* (formerly serotypes 9, 10) are in the genus *Enterovirus*, family Picornaviridae. Porcine enteroviruses serotypes 1–7 and 11–13 have been reclassified as ***Porcine teschovirus*** *1–7, 11–13*, genus *Teschovirus*, family Picornaviridae. Further reclassifications of picornaviruses can be expected. Infection by one enterovirus/teschovirus serotype does not confer protection against infection by another.

Infection is most commonly acquired by pigs after weaning due to waning maternal immunity and mixing of pigs from different sources. Infection follows the fecal–oral route and indirectly through contaminated fomites. Initial replication occurs in the tonsils and the intestinal epithelium, especially of ileum and colon; the enteric phase is not clinically significant or accompanied by tissue change. The enteric phase is followed by viremia and then invasion of the CNS. Viremia by some serotypes may lead to localization in the pregnant uterus and death of fetuses.

Infection with virulent virus may produce nervous signs as soon as 6 days after exposure. The virus is present in large amounts in tonsils and cervical lymph nodes by 24 hours, and in the mesenteric nodes and feces by 48 hours. The disease has two clinical forms: the highly fatal and severe form (**Teschen disease**) and a less virulent milder form (**Talfan disease**, poliomyelitis suum, benign enzootic paresis, Ontario encephalomyelitis, and polioencephalomyelitis.). Teschen disease, first recognized in 1929 in Teschen, Czech Republic, is caused by highly virulent ***Porcine teschovirus 1*** and is limited mostly to Europe, but sporadic epizootics occur in Africa. Talfan disease, caused by infection with less virulent strains of the virus, is more common than Teschen disease and occurs worldwide. Teschen disease is of high morbidity and high mortality affecting all age groups and expressed clinically as convulsions, opisthotonos, nystagmus and coma. Death commonly occurs in 3–4 days. Survivors may have residual paralysis. Talfan disease is characterized by lower morbidity and mortality, and the clinical signs are expressed as paresis and ataxia that seldom progresses to complete paralysis. The infection is asymptomatic in the absence of neurological signs, and up to 95% of exposed pigs develop latent or inapparent infections.

The *pathological changes* in these syndromes are the same although minor differences in severity and distribution of the lesions are reported. There are no gross changes. The histological changes are those of *nonsuppurative polioencephalomyelitis* extending throughout the cerebrospinal axis from the olfactory bulbs to the lumbar cord. Any series of cases of each of the syndromes provides a continuous spectrum of severity and distribution of the lesions. Lymphocytic meningitis is mild in the cerebral meninges and usually overlies areas of parenchymal injury in the cerebrum. In weaners and older animals in which the course is more prolonged than in very young pigs, intense lymphocytic meningitis develops over the cerebellum, usually in conjunction with inflammatory lesions in the underlying molecular layer (Fig. 3.119). Cerebellar meningitis is very slight if the course of the disease is 4–5 days or less, so that, although emphasized in reports of Teschen disease, it is not a feature in very young animals in which the course is short. The most severe lesions occur in the brain stem from the hypothalamus through the medulla and

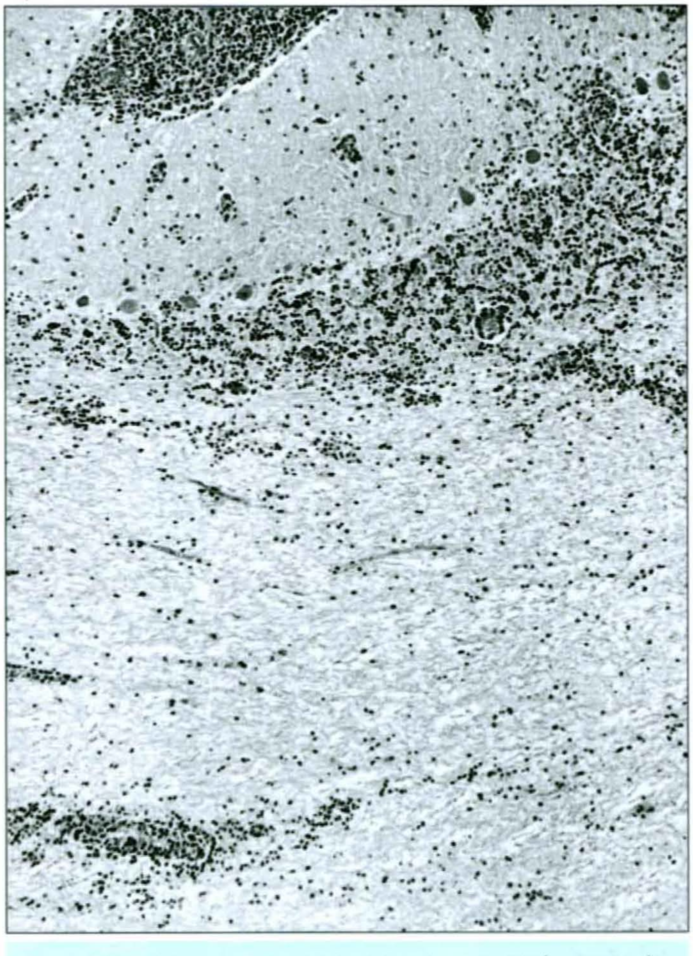

Figure 3.119 Nonsuppurative meningitis and encephalitis (cerebellum) in **enteroviral encephalomyelitis** in a pig.

decrease in intensity and diffuseness down the spinal cord. There is relative sparing of the cerebral and cerebellar cortices, but the deep substance of the cerebellum is consistently and often severely involved. Lesions in the spinal cord in each syndrome are largely confined to the gray matter, particularly the ventral horns, but may selectively involve the dorsal horns in very young pigs. Cord lesions are those of nonsuppurative myelitis and the motor neurons, particularly in gray matter of the ventral horns, experience different stages of neuronal degenerative and necrotic changes (neuronal swelling, chromatolysis, satellitosis, and finally neuronophagia). Lesions are consistently present in the dorsal root ganglia, and especially the trigeminal ganglia (Fig. 3.120).

Diagnosis can be achieved by virus isolation or immunohistochemistry.

Flaviviral encephalitides

The genus *Flavivirus* of the family Flaviviridae contains several important viruses that cause encephalitis in domestic and wild animals. Some of these viruses are emerging as very important not only for animal health but also for public health as they are highly zoonotic. The viruses of veterinary importance in this genus belong either to the *tick-borne virus group* or the *mosquito-borne virus group*. Viruses of both groups are maintained in a cycle involving ticks or mosquitoes respectively as invertebrate vectors, and wild vertebrate hosts as reservoirs. In most cases, infections of humans and/or domestic animals are incidental, and are not important for viral transmission or maintenance in the environment.

Diseases caused by tick-borne flaviviruses

Important veterinary viruses in this group include *Louping ill virus* and *Tick-borne encephalitis virus*; these two viruses are very closely related, and may have originated from a common ancestor. The group also includes several other viruses – *Langat virus, Kyasanur Forest disease virus, Omsk hemorrhagic fever virus*, and *Powassan virus* (POWV) – that are primarily of importance in humans. POWV causes severe encephalitis in humans in the USA, Canada, and Siberia, but induces encephalitis in animals only under experimental conditions.

Louping ill (ovine encephalomyelitis)

Louping ill is a tick-borne viral encephalomyelitis of sheep caused by *Louping ill virus* (LIV), which has been enzootic in England, Scotland, and Northern Ireland for more than a century and has been reported in Norway. The disease is named after the leaping (or louping) demonstrated by the diseased sheep. A similar disease has been reported in Spain, Greece, and Turkey affecting sheep or goats but because the etiologic viruses are different by nucleotide sequencing from LIV, each was considered a subtype of LIV but assigned different names: *Spanish sheep encephalomyelitis virus, Greek goat encephalomyelitis virus*, and *Turkish sheep encephalomyelitis virus*. Cattle, horses, goats, and deer pastured with affected sheep sometimes contract the disease, and nonfatal human infections are known. The virus causes fatal encephalomyelitis in red grouse (*Lagopus scoticus*). Outbreaks in piglets have followed the feeding of raw meat from lambs, and a case has been described in a dog.

The tick responsible for transmission in Great Britain is *Ixodes ricinus*, the castor-bean tick. Other species of *Ixodes*, and perhaps other arthropods, are potential vectors. *Ixodes ricinus* is parasitic on a variety of mammals in addition to sheep and on birds, however, the most significant wildlife host is the red grouse. Larval and nymphal ticks acquire the virus when feeding on infected sheep, and transmit the infection to new hosts in the succeeding nymphal and adult phases. Because of its natural mode of transmission, louping ill is most prevalent in early summer and early autumn when the ticks are active. After infection, the virus propagates in regional lymph nodes, proceeds to viremia, and then enters the CNS via the hematogenous route. Alternatively, the virus may localize indirectly from the blood in nasal structures and enter the brain via the olfactory nerves. Under experimental conditions, a number of factors may facilitate entry of virus into the brain, and facilitation is apparently given in natural cases by concurrent tick-borne fever, a rickettsiosis also transmitted by *I. ricinus*, and known to impair humoral and cellular defense mechanisms.

Although tick transmission is the usual mode of infection, the disease can be contracted in humans, monkeys, and mice by inhalation of infective droplets, but this route is not thought to be important naturally. Rabbits and guinea pigs are not susceptible even by intracerebral inoculation.

Louping ill is a systemic infection and, while it remains so, the disease is mildly febrile but otherwise of no consequence. When it invades the CNS and produces signs of encephalitis, the mortality rate is very high. The morbidity in endemic areas is quite low, and the disease is largely confined to either naïve lambs or to older lambs and yearlings whose colostral immunity is not reinforced by natural exposure. The viremic phase of louping ill is clinically silent or a febrile phase with dullness. Recovery may occur in a couple of days and leave solid immunity. If neurologic signs are to develop, they do so at about day 5 and are characterized by incoordination, tremors, cerebellar ataxia, and terminal paralysis.

There are no gross lesions. The disease is an *acute polioencephalomyelitis*. There is mild leptomeningitis corresponding to areas of inflammation of the parenchyma. Inflammation of the cerebellar leptomeninges may be quite severe when the cerebellar cortex is acutely affected (Fig. 3.115). The inflammatory lesions are more obvious than in most viral encephalitides, but are of the usual type, although unusually large numbers of neutrophils may be present in very severe cases, and largely restricted to gray matter, although cuffing and focal gliosis occur in the white matter. Neuronal degeneration may be severe and neuronophagia prominent. Some degree of selective vulnerability of the Purkinje and Golgi cells of the cerebellum is generally accepted and, although it can be demonstrated in many cases, its detection probably depends to a large extent on the duration of active infection. The spinal lesion is poliomyelitis affecting particularly the ventral horns (see Fig. 3.17). Inclusion bodies have not been observed in sheep but acidophilic, intracytoplasmic inclusions in neurons of the brain stem and cord are reported in experimentally affected monkeys and mice. Immunohistochemistry is available, and viral antigen can be identified easily, especially in the Purkinje cells of the cerebellum and their dendritic processes.

Encephalitis caused by *Tick-borne encephalitis virus*

Tick-borne encephalitis virus (TBEV) is a serious human threat that causes thousands of cases of encephalitis every year in endemic areas in Europe and Asia. Several wild and domestic animals are susceptible to infection but the infection is frequently subclinical, however TBEV is pathogenic for dogs and is able to cause fatal meningoencephalitis. The virus is transmitted to humans and animals mainly by *Ixodes ricinus* or *Ixodes persulcatus*. Humans can also become infected through consumption of milk from infected ruminants. Most infected dogs seroconvert without developing TBE, but the peracute disease in dogs has a high fatality rate. Affected dogs are usually euthanized due to associated severe convulsions, tremors, and ataxia. The histologic lesions are those of severe necrotizing lymphoplasmacytic and histiocytic meningoencephalomyelitis with severe glial nodule formation affecting mostly the basal ganglia, thalamus, mesencephalon, neuroparenchyma surrounding the fourth ventricle, and the medulla oblongata.

Diseases caused by mosquito-borne viruses

The important veterinary viruses in this group include *West Nile virus* and *Japanese encephalitis virus*. Also included in the mosquito-borne, Japanese encephalitis virus group, are *Murray Valley encephalitis virus* and *St. Louis encephalitis virus*.

West Nile virus encephalomyelitis

West Nile virus (WNV) was first discovered in 1937 in the West Nile district of Uganda. In 1999 it was introduced into New York City where it caused a massive outbreak in animals and humans. During the period of 1999 to 2004, the virus spread rapidly to most of the USA and southern parts of Canada. It has been suggested that the virus was imported from the Middle East, due to genetic similarity between strains isolated in the Middle East and New York. The virus is now distributed throughout Africa, central and southern Asia, Australia (where it is called *Kunjin virus*), the USA, Canada, Mexico, and the Caribbean. The virus is divided genetically into two lineages – lineage 1 WNV is present in North America and some other parts of the world, lineage 2 is restricted to enzootic areas in Africa. Lineage 2 WNV strains are either nonpathogenic or occasionally cause mild human and equine disease. Some clades in lineage 1 (e.g., clade 1a) are highly virulent and are believed to be responsible for the recent outbreaks in North America. The virus has a wide host range, but is maintained in the environment mainly by a bird–mosquito–bird cycle. Wild birds, especially corvids, i.e., crows, are the main amplifying hosts. Wild birds usually develop prolonged viremia and the virus is distributed in almost every organ. In contrast, the viral antigen in infected horses, which is by far the most susceptible species of domestic animal, is sparse and limited to the CNS. Infection between birds or between birds and mammals or reptiles is mainly via mosquitoes. Mosquitoes of the *Culex* spp. are the main maintenance vectors. The virus is also found in other vectors such as ticks, but the biological importance of these vectors is yet to be determined. Rare methods of virus transmission include direct contact with infected materials and ingestion. Transplacental WNV transmission is only reported in human.

The *pathogenesis* of the encephalitis induced by WNV is not completely understood, however after the virus is injected by an infected mosquito, it probably propagates in regional endothelial cells and fibroblasts, viremia develops, and the virus reaches the brain hematogenously.

Equids, especially horses, are very susceptible to the infection. In naive areas, the first signs of WNV are the marked increase in cases of equine encephalitis and increased numbers of wild bird, especially corvid, mortalities. WN fever is a seasonal disease, related to the time of the year of mosquito activity, i.e., summer and fall. When naive horses are infected by the virus, mortality can reach up to 50% of affected horses, and clinical signs range from weakness and anorexia to severe acute ataxia or recumbency. However, the mortality rate decreases dramatically in the following seasons. Gross lesions are usually absent, but a few cases may have acute areas of hemorrhage or malacia affecting the thoracic and/or lumbar spinal cord. *Histologic lesions* are present mainly in the brain stem and thoracolumbar spinal cord, and to a lesser extent in cerebral cortex and cervical cord. The cerebellum is usually spared. *Lesions are those of nonsuppurative encephalomyelitis, gliosis, and glial nodule formation with occasional neuronal degeneration and necrosis* (Fig. 3.121A, B). Lesions are more pronounced in the gray matter. The glial nodules usually contain a few neutrophils amid the glial cells. Areas of hemorrhage and malacia are present in severe cases, especially in brain stem and the ventral horn of the thoracic and lumbar spinal cord. Axonal swelling and spheroid formation is frequent. The severity of lesions is greatly variable between outbreaks, and frequently the severity of clinical signs is not correlated with the severity of lesions. In most cases, the lesions are mild and confined to thin cuffs of a few blood vessels in the brain stem. Extraneural lesions, e.g., hepatitis, myocarditis, etc., which occur in avian WNV infection, do not occur in equine WNV infection.

The information about clinical signs and lesions in non-equine domestic species other than birds is very limited. Ruminants, canids, felids, and swine are far less susceptible to the disease than are horses or birds. These species are susceptible to the infection and develop very short viremia with subclinical disease; histologic lesions are very similar to those described in horses.

Diagnosis of WNV infection can be achieved by detection of WNV antigen in the brain using PCR or immunohistochemistry. WNV antigen in many cases can be very sparse, which makes the interpretation of IHC difficult. Positive IHC staining in most cases is limited to sparse axonal immunostaining.

Japanese encephalitis

Japanese encephalitis virus (JEV) is found through much of eastern, southern, and southeastern Asia, Papua New Guinea, and the Torres Strait of Northern Australia, where the disease is endemic with dramatic annual epidemics. In humans, there is a high ratio of subclinical to overt infections, with a case fatality rate of 10–15% and a high incidence of residual neurologic deficits in survivors. Transplacental infection followed by abortion occurs in humans and this is also the most serious expression of the disease in *pigs, the domestic species most importantly infected.*

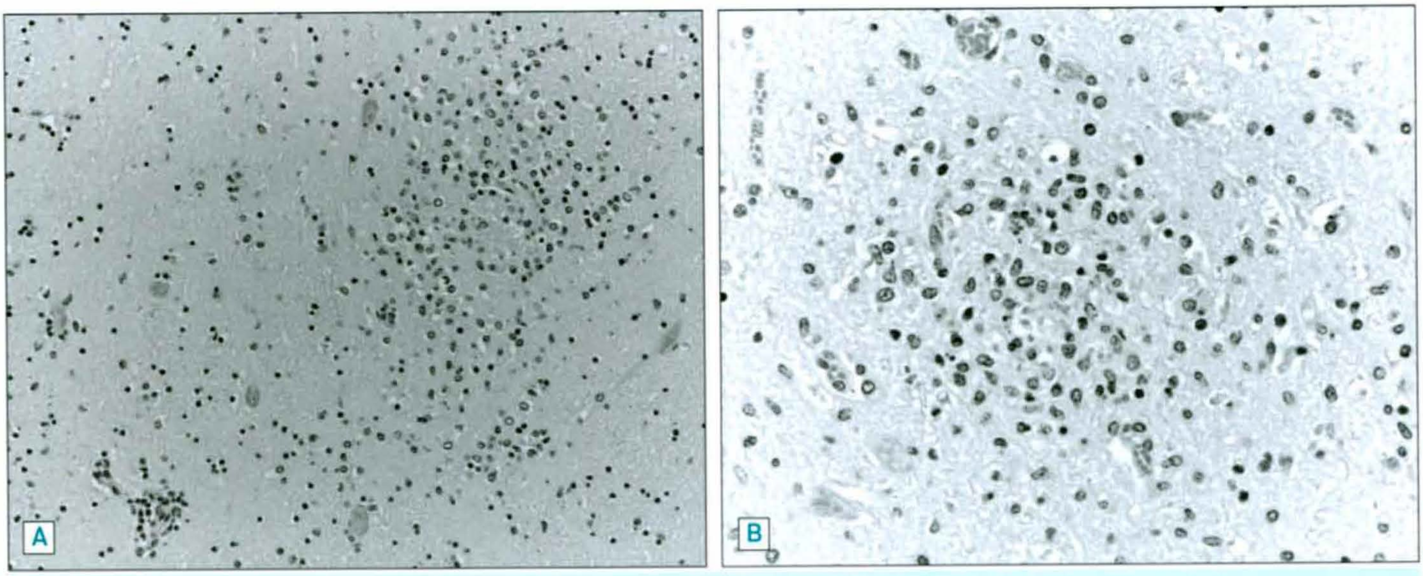

Figure 3.121 Brain stem of a horse with **West Nile viral encephalomyelitis. A.** Perivascular cuffs composed of lymphocytes and plasma cells are usually thin. **B.** Multifocal glial nodules are common and usually contain only a few neutrophils. (Courtesy of MJ Hazlett.)

The virus is maintained through mosquito–bird or mosquito–pig cycles. The virus is transmitted mainly by the mosquito, *Culex tritaeniorhynchus*, but other species of this genus and of the genera *Aedes* and *Armigeres* may be important as the virus is known to be vertically transmitted through some of them. *Ardeid water birds (e.g., herons and egrets) are the main maintenance reservoirs.* Many species of animals and birds are susceptible to mosquito-borne infection and develop antibody responses in timing with suitable climatic and habitat cycles. The pig is a very important domestic animal in many of the endemic areas and it is the most important amplifier host for the virus, developing sustained viremia of sufficient titer to infect feeding mosquitoes and indeed is probably the preferred host for *C. tritaeniohynchus*. Infection of humans and horses is incidental and both species are considered to be dead-end hosts.

Most horses, pigs, and cattle in endemic areas possess neutralizing antibodies against the virus. Intranasal and intracerebral inoculation can produce fatal encephalitis in calves, but natural cases of encephalitis in this species are quite rare. Among animals infected naturally with the virus, *only horses and donkeys develop clinical encephalitis*. There are no clinical signs of encephalitis in pigs, but pregnant susceptible sows may produce *stillborn piglets*. Infected stillborn and neonatal pigs may show hydrocephalus, cerebellar hypoplasia, and hypomyelinogenesis and anasarca; histological changes are restricted to the nervous system and may include *nonsuppurative encephalitis*. The lesions in these neonatal and stillborn piglets probably reflect the timing of infection in relation to the development of immune competence. Diffuse nonsuppurative encephalitis occurs in the brain and cord of piglets up to 6 months of age, but in the cerebellum it affects rather selectively the molecular and Purkinje layers. The histological pattern of Japanese encephalitis in pigs appears similar to that of Teschen and related diseases. In boars, the virus induces orchitis.

Severe epidemics of encephalitis have occurred in horses in Japan. The incubation period in horses ranges from 4–14 days, and case fatality is 5–15%. Lesions are confined to the CNS, are more prevalent in the cerebral hemispheres, and include extensive perivascular lymphoplasmacytic cuffing, gliosis, and areas of malacia with hemorrhage. The lesions in quality and distribution are the same as those produced by the *Eastern and Western equine encephalitis viruses*. Inclusion bodies are not reported in the Japanese disease. *Diagnosis* is best achieved by detection of viral RNA using PCR.

Alphaviruses – equine encephalitides

Several members of the genus *Alphavirus*, family Togaviridae, cause either overt or subclinical encephalitis in horses or other animals. They all require an arthropod vector (frequently mosquitoes) for transmission.

Eastern, Western, and Venezuelan encephalitis in horses

Western equine encephalitis virus (WEEV), Eastern equine encephalitis virus (EEEV), and Venezuelan equine encephalitis virus (VEEV) are all members of the genus Alphavirus, family Togaviridae. Horses were originally regarded as the primary hosts of the EEVs, but horses are actually accidental and unfortunate hosts; birds for the American viruses (eastern and western type) or rodents for the Venezuelan virus are the most common vertebrate reservoir hosts, and mosquitoes are the principal vectors. Horses and humans, in both of which species the disease is of very considerable importance, are now known to be, in terms of transmission and often literally as well, dead-end hosts in which the titer of virus in blood is ordinarily too low to be a source of infection for mosquitoes.

Not all birds are capable of acting as reservoir hosts. Red-winged blackbirds, cardinals, sparrows, cedar waxwings, and the captive Chinese pheasant are highly susceptible to infection and nearly always die. Many other species, including adult domestic fowl and turkeys, are not sickened by the infection although fatalities can be produced in the young of these species.

EEEV is endemic along the North American Atlantic course, in the Caribbean, Central America, and along the northeastern coast of South America. The virus cycles between water birds and the mosquito, *Culiseta melanura*, which feeds on birds and does not feed on large mammals. Horses are likely to get infected by other mosquitoes, *Aedes sollicitans* and *A. vexans*, which feed on both horses and birds.

WEEV is present mostly in the valleys of western North American states, where the cycle is between wild birds, especially passerines, and the mosquito, *Culex tarsalis*. This mosquito feeds readily on animals, and human and animal cases occur regularly.

VEEV has two major different strain groups, the enzootic strains that are avirulent and cycle between *Culex* spp. mosquito and small rodents in the Caribbean areas, and the epizootic strains that are virulent to human and horse, found mainly in Venezuela, Colombia, and Peru, and circulate between several mosquito species and horses, which produce high titered viremia sufficient to infect the vector mosquitoes. Outbreaks of EEE and WEE occur in seasonal patterns related to the time of the year when mosquitoes are active. VEE outbreaks usually occur in a cyclical pattern approximately every 10 years.

Once infected, mosquitoes are known to remain so for life, and there is evidence that the virus is capable of multiplying in the insects. Arthropods other than mosquitoes may also be of some, but lesser, importance. The virus has been found in chicken mites (*Dermanyssus gallinae*), chicken lice (*Menopon pallidum, Eomenocanthus stramineus*), and assassin bugs (*Triatoma sanguisuga*). The spotted-fever tick, *Dermacentor andersoni*, is capable of transmitting the infection stage to stage and hereditarily. Transmission by aerosolization is reported only in humans; laboratory workers are at high risk of infection by aerosols.

Although humans and horses are the principal mammalian victims, other species are susceptible. Pigs readily develop asymptomatic infections but a few outbreaks have been reported in this species with histology typical of EEE. Pigs are not of significance for natural propagation of the virus because they do not develop significant viremia. Calves are susceptible to intracerebral inoculation but recover in 2 weeks. Guinea pigs and white mice are highly susceptible, rabbits are less so, and sheep, dogs, and cats are refractory.

The three viruses are similar in their pathogenesis. After the mosquito bite, the virus replicates in the regional blood vessels and lymph nodes, viremia develops, followed by secondary replication in lymph nodes and muscles. A second viremia then develops and is followed by brain invasion via the blood. In the CNS, the virus replicates in neurons, glial cells, and blood vessels. The virus causes neuronal necrosis, likely via stimulation of apoptosis.

Young horses are more susceptible than the old. Initially, there is viremia with fever and depression, usually unnoticed. The animal may then recover or the virus may invade the CNS, by which time the fever has subsided. The neurologic signs are characterized by derangements of consciousness and terminal paralysis. There may be early restlessness with compulsive walking, often in circles. There is central blindness. The animal becomes somnolent and assumes unnatural postures. At this stage, the course may remain static and the animal lives as a "dummy," or paralysis may develop, often first affecting cranial nerves but later general and flaccid. *The signs are largely cortical and the cortex is the principal site of the lesions.* The course, if fatal, is usually 2–4 days.

There are no gross changes. The microscopic changes are limited almost exclusively to *gray matter* (see Fig. 3.2D). When the course is short, 1 day or less, the reaction is largely on the part of neutrophils. These infiltrate the gray matter diffusely and may be found in foci suggestive of malacia (Fig. 3.122). There is early microglial reaction to produce rod cells. Endothelial cells, especially of veins are swollen, and hyaline or granular thrombi are common in these vessels. There are narrow cuffs of lymphocytes and neutrophils with perivenous hemorrhage and edema. After a couple of days, the neutrophils disappear, the cuffs are composed of lymphocytes, and there are both focal and diffuse microglial proliferations as in the standard nonsuppurative reactions. Neuronal degeneration and neuronophagia are common findings. Intranuclear inclusions similar to those in Borna disease may be present, but may be very difficult to identify.

The most severe lesions are in the cerebral cortex, especially the frontal, rhinencephalic, and occipital areas, with lesions of lesser intensity in the pyriform lobes. Severe lesions are also present in thalamus and hypothalamus. From the thalamus caudally, the intensity of inflammation diminishes but reveals no selectivity for particular nuclear masses. The cerebellum is less severely injured than other portions, although inflammatory changes may be found in the deep nuclei and spottily in the cortex. Mild changes occur in both dorsal and ventral horns of the cord, but their distribution is irregular. The trigeminal ganglia are not affected. The encephalomyelitis in the Venezuelan type may be purely nonsuppurative. Extraneural lesions are common in humans and birds but are rare in susceptible domestic mammals. Small intestinal lesions in a horse with EEE include multifocal myonecrosis and lymphomonocytic infiltration in the muscular layer and focal mild perivascular lymphocytic infiltration in the submucosa. Myocarditis is not uncommon in pigs suffering from EEE. Horses infected with VEEV can occasionally have some nonspecific extraneural lesions such as myeloid depletion in bone marrow and lympholysis in spleen and lymph nodes.

Other *Alphavirus* encephalitides

Highlands J virus of America's east coast, ***Getah virus*** of southeast Asia, and ***Semliki forest virus*** of the Americas are all equine pathogens that are able to induce at least a febrile disease. All of these viruses are maintained in the environment by a mosquito–bird–mosquito cycle. Several mammals and birds seroconvert to these viruses, however overt disease is rare. *Highlands J virus* was reported as the cause of encephalitis in two horses. *Getah virus* does not induce encephalitis but clinical signs and lesions with some similarities to equine viral arteritis.

Borna disease

Borna disease, named after the village of Borna in Germany, is caused by *Borna disease virus* (BDV), which is the only member of the genus *Bornavirus*, family Bornaviridae. The virus exists worldwide in many vertebrates but most commonly infects horses, sheep, cattle, cats, dogs, and ostriches. The traditional endemic area is central Europe, but antibodies to the virus are found in horses outside Europe, including the USA and Japan. The mortality rate may be high (>80% in horses, 5–40% in sheep); surviving horses may be asymptomatic carriers, or may suffer relapses of disease. The virus has a controversial link to several human neuropsychiatric illnesses. In experimental hosts (tree shrews, rats), infection with BDV not only produces pathoanatomic changes, i.e., nonsuppurative encephalitis, but also behavioral changes and learning deficits.

The virus replicates in the nucleolus of the host cell without cytopathic effect, persistently infects cells, and induces brain lesions by *immune-mediated mechanisms*. In Lewis rats, acute (4–8 weeks post-infection) BDV infection is followed by massive infiltrates in the brain of CD4+ Th1, CD8+ T, and NK cells with a predominance of Th1 cytokines that favors cell-mediated immunity. In the chronic stage (beyond 15 weeks of infection), the aforementioned cellular infiltrates significantly decrease and the predominant cytokines are of Th2 type, favoring the shift to a humoral immune response; the resultant antibodies are not protective and have no significant effect on the disease. Due to this unique feature, infection of neonatal or immunocompromised animals does not lead to disease or to encephalitis.

The epidemiology of Borna disease, including reservoir, methods of transmission, and infection, remains obscure. Inflammation of the olfactory bulbs at the early stages of natural infection in humans suggests an intranasal route of infection followed by transaxonal migration to the olfactory bulb. Vertical transmission in horses and rats with life-long persistent infection is also suggested.

Clinically, the disease occurs sporadically or in clusters, however severe outbreaks are described in different species. *Equids and sheep are the most susceptible animals*, but natural disease is reported in many domestic species including but not limited to cattle, alpacas, cats, dogs, and ostriches. Most infections in horses remain subclinical and BDV-specific antibodies are frequently found in clinically healthy horses. The incubation period is not less than 4 weeks and introduces a clinical syndrome that is purely neurologic but of varied course, death occurring in 1–3 weeks. The mortality rate in diseased horses is 90–100%. Recurrent episodes at time of stress occur in surviving animals. Clinical signs include pharyngeal paralysis, hyperesthesia, standing in awkward positions, circling, muscular tremors, and spasms; blindness is common. Drowsiness and flaccid paresis develop terminally.

There are no gross lesions. The distribution of lesions in Borna disease differs from that in other equine encephalomyelitides and parallels closely the distribution of viral antigen, as displayed by immunohistochemistry, and the distribution of infectivity, as determined by titration in cell cultures. Virus and lesions are present mostly in the gray matter of olfactory bulbs (early stage), hippocampus (Fig 3.123), limbic system, basal ganglia, and brain stem. The dorsal cerebrum and the cerebellum are relatively spared. Lesions may be present in optic nerves and retina. Histologic lesions are those of *nonsuppurative encephalomyelitis* with predilection for the aforementioned areas. Perivascular cuffs can be dramatically thick (>7 cell layer) and usually there are neuropilar clusters of lymphocytes and plasma cells. Other lesions include neuronophagia and focal gliosis. The presence of inclusion bodies (Joest–Degen bodies) is fairly pathognomonic; these are mainly in nuclei, especially in the hippocampus, and are very occasionally cytoplasmic. They stain well and red with Giemsa, and have a clear halo. Commercial PCR and immunohistochemistry kits are available for diagnosis.

Borna disease virus has been proposed as the cause of a chronic, slowly progressive neurologic disease affecting *cats* of all ages, sexes, and breeds. The disease is known clinically as *staggering disease,* and clinical signs include ataxia, paraparesis, and tetraparesis. Behavioral change is not a constant finding. Lesions are more prevalent in the gray matter of brain stem and in dorsal and ventral horns of the thoracic and/or cervical spinal cord segments. Lesions include mild to moderate lymphoplasmacytic cuffing with neuronophagia and neuronal degeneration and astrogliosis. Severe Wallerian degeneration is usually present in ventral and lateral columns of the cervical and thoracic spinal cord.

Lentiviral encephalomyelitis of sheep and goats

Caprine arthritis encephalitis virus (CAEV) of goats and *Visna/maedi virus* (VISNA) of sheep, in the genus *Lentivirus* of the family Retroviridae, are small-ruminant lentiviruses (SRLV). CAEV is the causative agent of caprine arthritis-encephalitis of goats and VISNA is the causative agent of the visna/maedi disease complex of sheep; at least some strains of the SRLV are transmissible between sheep and goats. In both natural hosts, *four clinical and pathological syndromes are recognized*, namely **mastitis, arthritis, interstitial pneumonia** (maedi and ovine progressive pneumonia) and **encephalomyelitis** (visna of sheep). Within endemic situations, any one or combination of the four syndromes may be present and when in combination one syndrome usually predominates.

Once infected, the virus is never eliminated and, while present, it is active even though there may be no clinical sign of neurologic deficit. Typically for this type of virus infection, the virus is highly cell-associated and replicates only slowly, infection persists for the life of the animal, the incubation period before seroconversion may be several months and before clinical disease may be months or years, the clinical disease is progressive, and the lesions are dominated by active mononuclear inflammatory cells. The pathogenesis and epidemiology of the various conditions are described in detail in Vol. 2, Respiratory system. Described below are the gross and histologic lesions and clinical signs found in the encephalomyelitis form of these diseases.

The encephalomyelitis form in sheep is called **visna** (Icelandic for wasting). As a natural disease, visna occurs in sheep of both sexes but clinical signs are seldom, if ever, observed in animals less than 2 years of age. Disease onset is insidious. The earliest sign may be barely perceptible caudal ataxia and fine trembling of the lips. The first sign to be noticed may be extensor paralysis of the hindlimbs. Once paralytic signs are evident, a fatal outcome appears certain. There is no fever and no sign of cerebral dysfunction, and death is due to starvation or secondary infection. The incidence of visna is relatively low. The course of the infection can be followed fairly well by routine examination of the CSF for lymphocytosis.

Normal sheep are expected to have $\leqslant 0.005 \times 10^9$ cells/L ($\leqslant 5/\mathrm{mm}^3$) of CSF; in visna, cell numbers, chiefly lymphocytes, can be markedly elevated. After intracerebral inoculation, there is a latent period of up to 8 weeks, after which the CSF cell count begins to increase. The cell count may remain high for several months without other signs of disease. Thereafter, the animal may recover, as indicated by a drop in the CSF cell count, or the cell count may remain high, paralysis develops, and death follows.

The disease in the brain is chronic and demyelinating. There are no gross neural changes in this disease, and the histologic change is one of *patchy demyelinating encephalomyelitis*. The distribution of lesions, involving principally the white matter, is unlike the distribution produced by other neurotropic viruses. There is a mild to severe mononuclear type of cerebrospinal meningitis. The parenchymal lesion may be well-established by 1–2 months, and these early lesions are intensely inflammatory with perivascular cuffing and gliosis. They reveal clearly that the process begins in, and immediately beneath, the ependyma diffusely throughout the cerebrospinal axis. In this early stage, the myelinated fibers in the inflammatory foci remain remarkably intact; the gray matter of the cord is irregularly but often intensely affected by a nonsuppurative reaction even 2–3 months after inoculation. In the paralytic and terminal stages of the disease, the periventricular destruction of white matter in the cerebrum and cerebellum is extensive, and in some sections of the brain, especially in the cerebellum, almost every bit of white matter is destroyed leaving the gray matter free.

Destruction of myelinated fibers in the spinal cord is patchy and not due to progressive spread of the pericentral inflammation. The demyelinated plaques are characteristically peripheral and triangular in shape with a base on the pia mater. Although dorsal and lateral tracts are most frequently involved, there is no selectivity for particular fiber tracts and no symmetry. The degenerating foci are almost malacic in their severity, and the plaques contain numerous reactive microglia and astroglia. Spinal nerve roots share in the degenerative process. Germinal centers may form in the choroid plexus. In areas of intense inflammation, liquefactive foci of necrosis occur in the white matter and the loss of myelin is expected to be of Wallerian type. In the spinal cord, evidence of remyelination can be found indicating that oligodendrocytes are not target cells and that demyelination may be primary.

Caprine arthritis-encephalitis (CAE) appears to be widely distributed, but the expression of the infection is highly variable, and many infected goats show little or no clinical disease. Clinical disease of the nervous system affects kids 2–4 months of age and is frequently fatal. Animals that develop the early nervous disease or have early inapparent infections tend to develop synovitis and periarthritis in adulthood (see Bones and joints).

The clinical signs of CAE are referable to motor spinal dysfunction without signs of cerebral disease. Onset is indicated by hindlimb lameness and ataxia with paresis that progresses over several weeks to paralysis. The inflammatory lesions in the CNS may remain active for several years in goats that survive (see Fig. 3.124A, B). In the early clinical phase of the disease, changes are widely distributed in the white matter of the brain and cord, particularly in the subependyma and beneath the pia in the cord. The distribution and character of the lesions in the nervous tissue in the goat are, in general, similar to those in visna of sheep. There is, however, less tendency for the periventricular lesions to progress to gross cavitation of cerebral white matter. Instead, there is a tendency for the inflammatory and myelinoclastic areas to increase in number and severity caudally from the mesencephalon. As in visna, the spinal cord changes are discontinuous and, where present, involve the myelin in subpial plaques or in one or

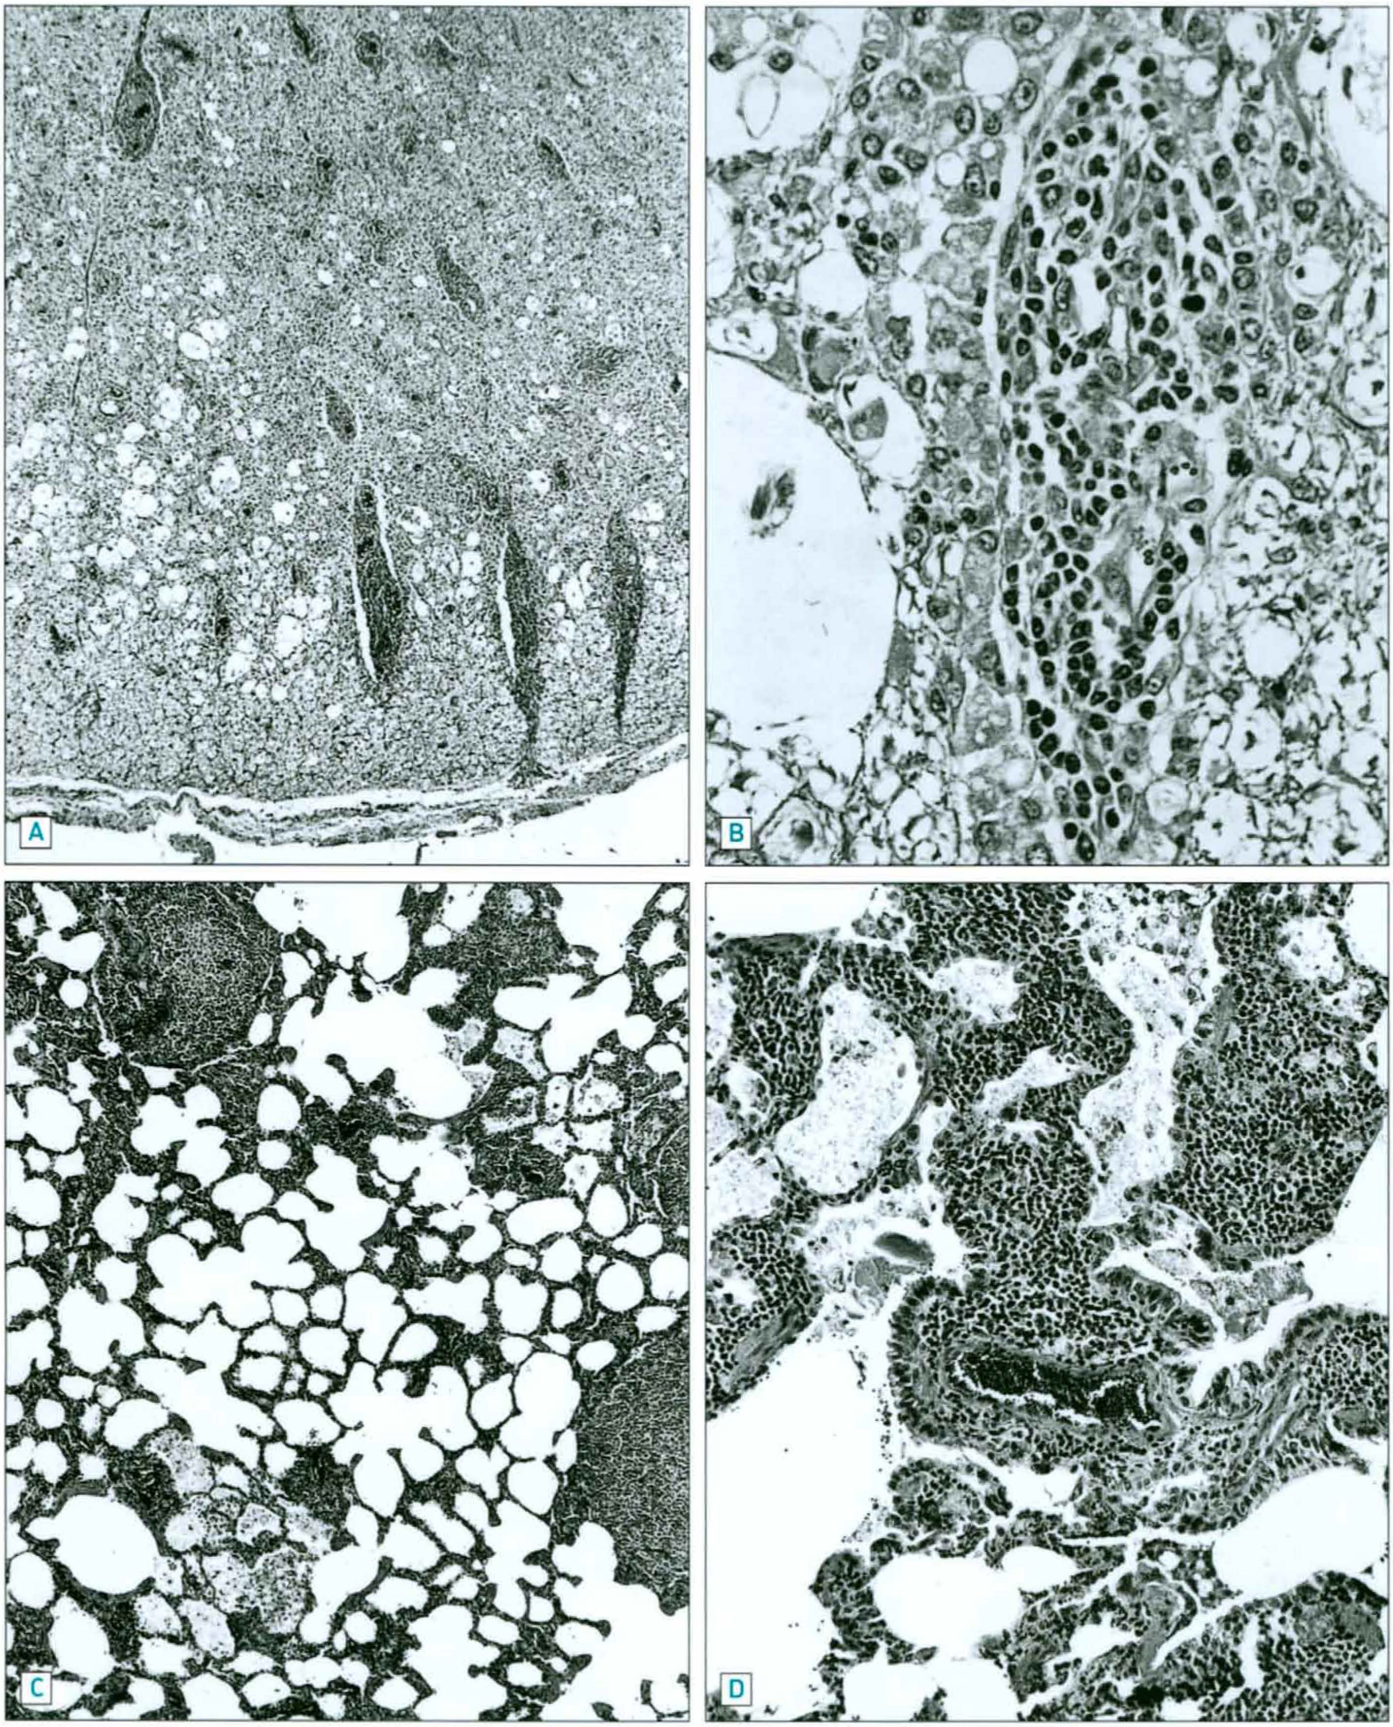

Figure 3.124 Caprine arthritis-encephalitis. A. Leukomyelitis. **B.** Detail of perivascular reaction. more quadrants of the cord. The extent of perivascular infiltration by mononuclear cells (see Fig. 3.124B) is also greater in kids than in sheep. In addition to the encephalomyelitis, mastitis, and arthritis seen in CAE, interstitial pneumonia occurs in some natural and experimental cases (Fig. 3.124C, D).

Paramyxoviral encephalomyelitis of pigs

Porcine rubulavirus encephalomyelitis (blue eye disease)

Blue eye disease is caused by *Porcine rubulavirus* (La-Piedad-Michoacan-Mexico virus) of the genus *Rubulavirus*, family Paramyxoviridae. The disease is characterized by encephalomyelitis, reproductive failure, and corneal opacity. Outbreaks have been recorded in Mexico since 1980, but appear to be self-limiting in commercial pigs. In pregnant sows, the infection may be subclinical or responsible for *fetal death, mummification, and stillbirths,* and for the occasional appearance of corneal opacity in the sow. Piglets up to 2 weeks of age are most susceptible with up to 50% morbidity and very high mortality. The clinical signs are of encephalomyelitis leading to death within 2–4 days, although subclinical infections are also frequent and may be manifested only by corneal opacity.

The lesion is a typical *nonsuppurative encephalomyelitis* affecting mainly gray matter of the thalamus, midbrain, and cortex. Inclusion bodies have not been demonstrated. Anterior uveitis is mild, the inflammatory cells congregating in the iridocorneal angle and the corneoscleral junction. The corneal opacity is due to edema, which will resolve if the animal survives.

In mature male pigs, experimental exposure will result in epididymitis in almost all exposed and in a lesser number with orchitis and testicular atrophy. Interstitial pneumonia is part of the description.

Nipah virus encephalitis

Nipah encephalitis, an emerging disease characterized by severe and rapidly progressive encephalitis, is caused by *Nipah virus* (NiV) of the genus *Henipavirus*, a novel genus in the family Paramyxoviridae. This genus also contains *Hendra virus*. Both are newly emerging viruses that can cause fatal encephalitis and pneumonia in humans and several animal species. The first severe outbreak of NiV encephalitis in humans occurred in 1998 near Ipoh, Malaysia, primarily among pig farmers and their families; the outbreak was preceded by an outbreak of encephalitis and pneumonia affecting pigs on many local farms. *Fruit bats* of the *Pteropid* species were later confirmed to be the natural reservoir host of NiV. Bats shed virus in their urine and saliva, which contaminates fruit that falls into pig pens and is eaten by pigs; bats in these trees also urinate directly on pigs. Initial human infection occurred in pig farmers by direct contact or aerosolization from infected pens. Pig-to-pig or pig-to-domestic-animal infections occur by direct contact with infected pig or mechanically by contact with contaminated utensils or feed. Direct transmission from bats-to-human or from human-to-human is controversial.

Pigs are the animals most susceptible to infection, but natural infection is reported in horses, cats, goats, and dogs; these species were infected by direct contact with infected pigs. Morbidity rates in pigs are ~10%, with case mortality rates of <15%. The incubation period is estimated to be 1–2 weeks. The virus targets two systems, the CNS and the respiratory system. Clinical signs are those of acute dyspnea (labored and harsh respiration, open-mouth breathing, severe cough) and acute nervous signs (trembling, seizures, or tetanus-like spasms). Abortion may occur to pregnant sows.

The lung is diffusely edematous with patchy acute hemorrhage. Meningeal blood vessels are severely congested. The histologic hallmark is *necrotizing vasculitis affecting arterioles, venules, and capillaries* with the presence of binucleated or multinucleated syncytial cells attached to the endothelium of affected blood vessels. Blood vessels undergo fibrinoid degeneration and leukocytoclastic vasculitis. Affected blood vessels are present most commonly in lung, brain, renal glomeruli, and lymphoid organs. Other pulmonary lesions include moderate lymphoplasmacytic bronchointerstitial pneumonia with mild necrotizing bronchiolitis and mild-to-moderate filling of alveoli with neutrophils, even in the absence of significant secondary bacterial infection. Severe lymphocytic and neutrophilic meningitis with mild lymphoplasmacytic encephalitis and occasional gliosis are consistent findings. Due to vasculitis, large areas of hemorrhage and infarction are common in affected organs. Occasionally, *eosinophilic intracytoplasmic and intranuclear inclusions* are present in neurons and syncytial endothelial cells. Syncytial cells can also be found attached within lymphatic vessels and to pulmonary alveolar septa.

Other porcine paramyxoviral encephalitides

An outbreak of respiratory disease (necrotizing bronchointerstitial pneumonia) and encephalitis was recorded in a large pig farm affecting all ages. The etiologic agent was a previously unknown, as yet unclassified, paramyxovirus different than the other known porcine paramyxoviruses. CNS signs were characterized by recurring episodes of distress, head pressing, tremors, and hindlimb ataxia. No gross lesions were observed in brain. CNS lesions were lymphocytic perivasculitis and diffuse gliosis.

Akabane viral encephalitis

Akabane disease is caused by *Akabane virus* (AKAV) of the *Simbu virus group,* in the genus *Bunyavirus,* family Bunyaviridae. Iriki virus, a strain of AKAV, causes similar disease. The group also contains *Aino virus,* which causes congenital disease identical to that caused by AKAV. As mentioned earlier in this chapter, AKAV is a common cause of congenital CNS defects in infected bovine fetuses, however the virus has also been associated with nonsuppurative meningoencephalomyelitis in adult cows and young calves. Histologic lesions are more prominent in brain stem, pons, medulla oblongata, and the spinal cord ventral horn. Lesions are those of lymphohistiocytic cuffing with multifocal gliosis, neuronal necrosis, and occasional neuronophagia with microglial cells.

Bovine herpesviral encephalitis

Bovine necrotizing meningoencephalitis caused by *Bovine herpesvirus 5*

Bovine herpesvirus 5 (BoHV-5), the cause of bovine necrotizing meningoencephalitis, is antigenically related to *Bovine herpesvirus 1* (BoHV-1), the cause of infectious bovine rhinotracheitis. Both viruses are neurotropic, undergo latency in the trigeminal ganglia, and can be reactivated by natural or experimental stress; however, BoHV-1 rarely causes encephalitis. Both of these herpesviruses are in family Herpesviridae, subfamily Alphaherpesvirinae, genus *Varicellovirus.* Outbreaks of severe BoHV-5 necrotizing meningoencephalitis have occurred most frequently in South America, but the disease has been observed in other countries including the USA. Infection is by direct contact or aerosolization. Following intranasal inoculation, BoHV-5 reaches and invades the brain through the olfactory pathway. BoHV-5 envelope glycoproteins E (gE), gI, and Us9 convey viral neurovirulence and neuroinvasiveness by affecting anterograde viral spread via the olfactory pathway.

BoHV-5 encephalitis occurs as a sporadic disease or sometimes as outbreaks in calves and yearlings. The morbidity in herds may be as high as 50%, but is usually much lower; few recognizably sick animals survive. The incubation period is 1–2 weeks, followed by anorexia, apathy, circling, jaw chomping, and finally paddling and recumbency. These clinical signs may be associated with mild to severe rhinitis.

Gross lesions are usually absent, however in the severe form of the disease, bilaterally symmetrical areas of malacia, hemorrhage, and necrosis are described in the gray matter of the rostral cerebrum (Fig. 3.125). The hallmark histologic lesion is *severe cytonecrotizing nonsuppurative meningoencephalitis with marked gliosis* (Fig. 3.126A, B). Lesions are more commonly present in the gray matter of the rostral cerebrum, including olfactory bulb, and to a lesser extent in the cerebellum and diencephalon. Perivascular cuffs can be markedly thick (more than six layers of lymphocytes, plasma cells, and fewer histiocytes). Necrotic neurons are usually swollen, have lost their angularity, are basophilic, and have pyknotic nuclei. Typical *intranuclear alpha-herpesviral inclusions* are occasionally present in degenerate neurons and astrocytes (Fig. 3.126B). Trigeminal ganglioneuritis, neuronophagia, and satellitosis are commonly present. Necrotic or malacic areas can take the laminar cortical necrosis pattern of bovine polioencephalomalacia, however, the latter syndrome is not associated with the severe perivascular cuffing present in BoHV-5 encephalitis. Vasculitis affecting the cerebral microvasculature is only described in rabbits experimentally infected with the virus. The histologic lesions are fairly pathognomonic, however, confirmation of the diagnosis by PCR is recommended.

Bovine meningoencephalomyelitis caused by *Bovine herpesvirus 1*

Nonsuppurative encephalomyelitis due to *Bovine herpesvirus 1* (BoHV-1) is reported worldwide. BoHV-1 causes multiple and diverse conditions in cattle such as abortion, infectious bovine rhinotracheitis, infectious bovine vulvovaginitis, and balanoposthitis. Some BoHV-1 serotypes are neurovirulent and are able to induce encephalitis. Marked upper respiratory disease typically precedes or occurs concurrently with the encephalitis. The pathogenesis and clinical signs are similar to those described for BoHV-5. Histological lesions are those of *nonsuppurative encephalomyelitis with occasional intranuclear herpetic inclusions.* The massive neuronal necrosis and gliosis described in BoHV-5 are not usually seen in association with BoHV-1. BoHV-1 encephalitis is more prevalent in calves; however sporadic cases can affect adult cattle particularly in the Near and Middle East.

Malignant catarrhal fever

Malignant catarrhal fever (MCF) is a fatal multisystemic lymphoproliferative and inflammatory disease affecting many ruminant species. The details of MCF, including the lesions associated with its encephalomyelitic form, are described in Vol. 2, Alimentary system.

Nonsuppurative meningoencephalitis is reported in "malignant catarrhal fever" in *swine* in Europe resulting from infection with *Ovine herpesvirus 2*. *Caprine herpesvirus 2*, a gamma-herpesvirus, does not cause overt disease in goats, but causes fatal goat-associated MCF in certain species of deer.

Bovine paramyxoviral meningoencephalomyelitis

Sporadic cases of nonsuppurative meningoencephalomyelitis due to paramyxovirus are rarely reported. The causative virus is restricted to the European continent and is still not classified within the Paramyxoviridae but is distinct from the other bovine paramyxoviruses such as *Bovine parainfluenza virus 3*. The disease should be differentiated from the sporadic bovine encephalitis caused by *Chlamydophila* spp.

Porcine circovirus type 2 encephalopathies

Porcine circovirus type 2 (PCV2), the cause of porcine postweaning multisystemic wasting syndrome, produces nonsuppurative or granulomatous encephalitis with gliosis under experimental conditions, either alone or in association with porcine parvovirus. The PCV2 antigen has been identified in brain in these cases demonstrating neurotropism of the virus under experimental conditions. The role of PCV2 in encephalitis associated with natural infection is controversial. PCV2 antigen has been detected in brains of pigs with naturally occurring encephalitis but always in association with other pathogens that can cause encephalitis alone and under natural conditions (e.g., PRRSV or *Streptococcus suis*). Also, the PCV2 antigen was demonstrated in neonatal pigs in association with naturally occurring congenital tremor type A2 (see Porcine hypomyelinogenesis); however, the exact role of PCV2 in this condition is yet to be determined.

Porcine encephalitis associated with PRRSV infection

Porcine reproductive and respiratory syndrome virus (PRRSV) is neurovirulent especially in young pigs and can cause encephalitis under natural conditions, often in association with other PRRSV syndromes (e.g., interstitial pneumonia) (see Vol. 2, Respiratory system).

California encephalitis virus meningoencephalomyelitis

Several serotypes of species *California encephalitis virus* of genus *Orthobunyavirus*, family Bunyaviridae, usually cause only asymptomatic infections, but are capable of causing encephalitis. These include La Crosse virus (LACV), Snowshoe hare virus, and Jamestown Canyon virus.

La Crosse virus is maintained in the environment and transmitted between susceptible hosts by *Aedes triseriatus* mosquitoes. Chipmunks (*Tamias striatus*) and squirrels (*Sciurus carolinensis*) are the principal amplifying vertebrate hosts. Other wild mammals such as foxes (*Vulpes fulva* and *Urocyon cinereoargenteus*) and woodchucks (*Marmota monax*) may also contribute to virus maintenance. The virus causes encephalitis and secondary neurologic deficits in humans, particularly school-aged children. A few cases have been reported in dogs in Florida and Georgia, USA. The most predominant clinical signs in these dogs were seizures and head tilt. Gross lesions were usually unremarkable, but areas of malacia may be present in cortex. Histologic lesions are predominantly in the cerebral cortex and characterized by *histiocytic and lymphoplasmacytic meningoencephalitis* with fairly thick cuffs and multifocal necrotizing panencephalitis. The necrotic areas in the acute stage are histiocyte and neutrophil rich. The lesions of this disease are similar to those seen in idiopathic granulomatous meningoencephalomyelitis (GME) described below.

Antibodies to **Snowshoe hare virus** have been found in a wide range of wild and domestic mammals, but overt disease is very rare. Encephalitis in association with SSHV was reported in two horses from Canada, but the diagnosis was made based on detection of seroconversion; one horse recovered and the pathologic changes found in the second case were not described.

Canine herpesviral encephalitis

Canid herpesvirus 1 can cause an acute, highly fatal disease of neonates. Puppies after the age of 3 weeks are resistant to infection. The incidence is low, and the disease is only diagnosed at autopsy. Hypothermia predisposes to disease in neonates, in which the infection would otherwise be asymptomatic. Infection at birth is followed by cell-associated viremia and viral replication in vascular endothelium. This tropism is reflected in large hemorrhages at postmortem most apparent in renal surface, adrenal and serosa of gastrointestinal tract. Focal necroses occur in parenchymatous organs and inclusion bodies may be demonstrated in these foci. *Nonsuppurative meningoencephalitis* is most severe in cerebellum and brain stem. It may be accompanied by necrosis especially in the cerebellar cortex. Vascular endothelial hypertrophy and hyperplasia is accompanied by mononuclear infiltrates. There may be inflammatory changes in the retina, peripheral nerves, and ganglia.

Equine herpesviral myeloencephalopathy

Equid herpesvirus 1 (EHV-1) and *Equid herpesvirus 4* (EHV-4) are two antigenically related but distinct viruses in the genus *Varicellovirus*, subfamily Alphaherpesvirinae, family Herpesviridae. Both viruses are widespread in horses, have significant economic impact on the equine industry, and are responsible for several clinical conditions including respiratory disease, pulmonary vasculotropic disease, enteric disease, and abortion. *Equine myeloencephalopathy is an important neurological disease* characterized clinically by ataxia, paresis, and paralysis, and caused mainly by EHV-1 and incidentally by EHV-4. Almost all recent outbreaks have been associated with EHV-1 infection. Other members of equine alpha-herpesviruses that are pathogenic but do not cause neurologic disease include *Equid herpesvirus 3* (Equine coital exanthema virus) and *Equid herpesvirus 8*

(Asinine herpesvirus 8), which induces interstitial pneumonia in donkeys. *Equid herpesvirus 9* (Gazelle herpesvirus) causes severe encephalitis experimentally in several species of domestic animals; the natural outbreak of fulminant encephalitis has been reported in a herd of Thomson's gazelles that were in close association with zebra. The natural reservoir for EHV-9 is unknown, but zebras or other equidae have been suspected.

Most horses show serologic evidence of exposure to EHV-1 and EHV-4 but are asymptomatic, and vaccination does not necessarily confer protection from neurologic manifestations. Both viruses contain at least 13 glycoproteins, which are important virulence factors for attachment, entry to the host cell, and cell-to-cell dissemination. The natural spread of EHV-1 is through direct horse-to-horse contact, by inhalation of nasal aerosols from infected horses, or through direct contact with an infected aborted fetus or placenta. EHV-1 replicates first in upper respiratory tract epithelium and local lymph nodes, and then induces T-cell and monocyte-associated viremia that ends with invasion of endothelial cells of the CNS and pregnant uterus. This leukocyte-associated viremia protects the virus from humoral immunity. *The virus is endotheliotropic, epitheliotropic, and neurotropic, but not neurovirulent.* The replication of virus in endothelial cells of the CNS leads to initiation of the inflammatory cascade that ends in *thrombo-occlusive necrotizing vasculitis.* The resultant myeloencephalopathy is due to destruction of CNS tissue secondary to vasculitis. The vasculitis is either due to direct viral cytotoxic effect or due to an immune-mediated (Arthus-type reaction) mechanism. A similar mechanism is responsible for EHV-1-induced abortion and pulmonary vasculotropic disease. There are no genetic or antigenic differences between the EHV strains isolated from neurogenic cases versus abortigenic or respiratory cases.

EHV-1 and EHV-4 have life-long latency in T cells and in neural tissue such as trigeminal ganglia. Latent virus can be reactivated experimentally after very high doses of corticosteroids and naturally after stress (such as castration). In contrast to the extensive studies on EHV-1, the pathogenesis of EHV-4 infection is poorly documented.

The disease occurs sporadically, but in several recent outbreaks, most affected horses either died or were euthanized. The disease is common in late winter and spring, which is also the time of greatest prevalence of EHV-1 abortion outbreaks. The incubation period is 6–10 days and usually occurs in association with abortion and/or respiratory disease but can occur without preceding signs. All ages are susceptible, but *pregnant mares and mares nursing foals are over-represented.*

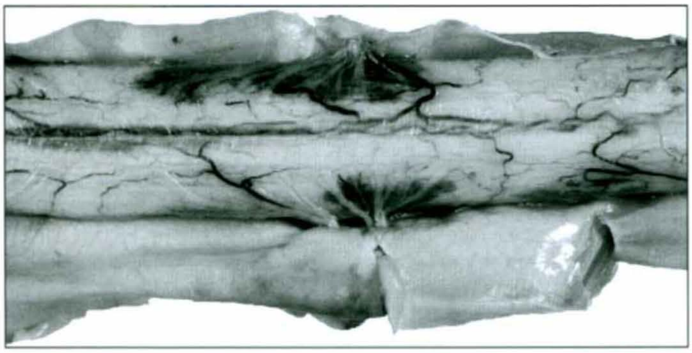

Figure 3.127 Acute spinal cord hemorrhage in a horse with **equine herpesviral myeloencephalopathy**. (Courtesy of RF Slocombe.)

Clinical signs start with fever and mild rhinitis. Neurologic signs are variable and depend on the part of the CNS affected by vasculitis, however common clinical signs include variable degrees of symmetrical ataxia and paresis that are more severe in pelvic limbs. Fecal and urinary incontinence are common, and clinical signs may end in hemi- or paraplegia. Gross and histologic lesions are sequelae to vasculitis. Gross lesions are not always present, but small (0.2–0.5 cm) random multifocal areas of hemorrhage may be present throughout the meninges, brain, and spinal cord (Fig. 3.127). In severe cases, multifocal necrohemorrhagic or malacic areas (up to 1.5 cm in diameter) can be present, especially in the white matter of spinal cord or the white or gray matter of the brain. *The characteristic histologic lesions are nonsuppurative necrotizing vasculitis and thrombosis,* with greater prevalence in the meningeal and parenchymal blood vessels of the brain stem and spinal cord. Perivascular edema, hemorrhage, focal areas of malacia, and infarction are present adjacent to the affected blood vessels. Occasionally, axonal swelling and mild nonsuppurative trigeminal ganglionitis are present. Extraneural lesions include uveal vasculitis and optic neuritis, especially in foals, and testicular and epididymal vasculitis in stallions.

Canine distemper and related conditions

Canine distemper is discussed in detail in Vol. 2, Respiratory system. Three neurologic conditions are discussed here: multifocal distemper encephalomyelitis in mature dogs, postvaccinal distemper, and old-dog encephalitis.

Multifocal distemper encephalomyelitis in mature dogs

This rare chronic progressive disease occurs when *Canine distemper virus* infects dogs at 4–8 years of age. This disease is not preceded by the classic form of canine distemper, and signs of systemic illness are often absent or transient. Clinical signs have a slow progressive course and include weakness of the pelvic limbs, generalized incoordination, but no seizures or personality changes, and occasionally head tremors. Lesions are restricted to the CNS and are most prevalent in the cerebellum and white matter of the spinal cord. The cerebral cortex is frequently spared. This distribution differentiates this condition from an extremely rare condition, old dog encephalitis, wherein the cerebral cortex is constantly affected. The lesions are those of *multifocal necrotizing nonsuppurative encephalitis* with rare canine distemper intranuclear intra-astrocytic inclusion bodies, and demyelination in the internal capsule and corona radiata.

Post-vaccinal canine distemper encephalitis

This condition occurs in young dogs 1–3 weeks after vaccination with attenuated *Canine distemper virus* vaccines and is characterized by an acute to subacute clinical course (1–5 days). The acute course is characterized by clinical signs reminiscent of the furious form of rabies including aggressive behavior and attempts to attack. It is not completely clear why some dogs develop this condition post-vaccination. Immune stimulation by other canine viruses (e.g., *Canine parvovirus*) at the time of vaccination was suggested. The lesions are not well documented, however, lesions are always restricted to the CNS and are reminiscent of the natural disease, but distinguished by the relative sparing of the white matter.

"Old dog" encephalitis

"Old dog" encephalitis (ODE) is rather rare. Most cases occur in dogs past middle age but it has been observed in dogs as young as 1 year of age. The disease is of insidious onset and is characterized by circling, swaying, and weaving. Compulsive walking with pushing against fixed objects is typical, but there is neither paralysis nor convulsions. The disease progresses over 3–4 months to coma or termination.

ODE is caused by *Canine distemper virus* (CDV), apparently as a consequence of long-term subclinical, persistent infection: CDV appears to persist in a replication-defective state. ODE does not appear to be simply a progression of the encephalomyelitis of canine distemper. Virus can be isolated from affected animals only by explantation of affected brain and then only with difficulty, and the disease is not transmissible by direct inoculation. Inclusion bodies are readily found in some cases, and their structure is identical with paramyxovirus nucleocapsids of CDV in nervous tissue. Antigen that responds to fluorescent antibody prepared against CDV is abundant in cells of the gray matter, and serum antibody titers can be very high.

Lesions are confined to the brain, which appears slightly reduced in size. The ventricles are moderately dilated. Lesions are diffusely distributed throughout the cerebral cortex, thalamus, and midbrain. The reaction is nonsuppurative, qualitatively always the same but varying in degree. The most obvious change is cuffing, and the cuffs are remarkable for their large size and the purity of the lymphocytic populations in them. Plasma cells are present in small numbers. The infiltrating cells are confined to the Virchow–Robin space and seldom spread into the parenchyma. The large cuffs occur in both gray and white matter but are most common at the junction of these two zones. Focal gliosis does not occur in this disease, but there is some proliferation of astrocytes about vessels and neurons. There is uniform and rather diffuse atrophic sclerosis of the cerebral white matter, which gives an impression of gliosis, but astrogliosis is not prominent. There is some demyelination, producing typical punched-out areas in the white matter, and distorted myelin sheaths in the heavily myelinated tracts are quite extensive when specially stained. Lymphocytes may be found in the choroid plexuses where they are inserted into the brain, and about vessels where they enter the parenchyma.

Nerve cells, especially in Ammon's horn and the pons, reveal chromatolysis with only a few remnants of Nissl substance in the periphery of the cytoplasm. The chromatolytic cytoplasm is slightly acidophilic. The neuronal nuclei in the forebrain are remarkably swollen in most of the altered nerve cells. In occasional nuclei, there is pink inclusion-like material. Neuronophagia does not occur. The astrocytic nuclei are remarkably swollen, have an irregular outline, and may contain traces of pink deposit in the nucleoplasm. In a proportion of cases, possibly those of longest duration, prominent *intranuclear and cytoplasmic eosinophilic inclusion bodies* may be found easily.

Parasitic infections

Protozoal infections

The cerebral complications of infections by protozoa such as *Babesia, Theileria, Trypanosoma,* and *Toxoplasma* are discussed elsewhere in these volumes. *Acanthamoeba*, a free-living ameba, can produce granulomatous meningoencephalitis in dogs as part of an opportunistic generalized infection (Fig. 3.128).

From time to time and in individual cases, pathologists observe *sporozoan parasites* in neural tissues of fetuses, neonates, and adults and lesions presumed to be the consequence of their presence. There are, however, difficulties in specific identification of the parasites and in attribution of pathogenicity. The syndromes considered here are reasonably defined but are subject to revision as the parasites are identified and their lifecycles clarified.

Encephalitozoonosis

Encephalitozoon (Nosema) cuniculi is a microsporidian parasite capable of establishing infection in a wide variety of mammalian species and birds. It is rarely a zoonotic infection. Endemic infection is

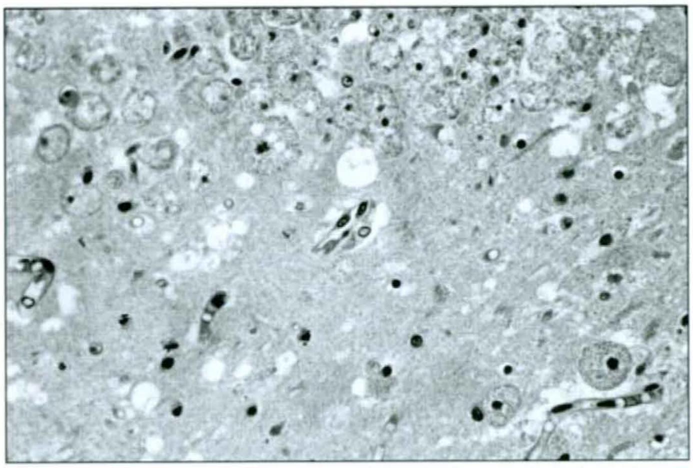

Figure 3.128 Amebic encephalitis in a dog; large numbers of amebae are present in this field, with only minimal reaction. (Courtesy of RF Slocombe.)

common in colonies of laboratory rodents in which the clinical consequences are mild but the pathologic changes may confuse other studies. Amongst domestic species, the disease is of interest in carnivores, especially farmed foxes in which serious mortalities occur, and occasionally in dogs and mink. The incidence of subclinical infection is not known, but a serological survey of an unselected population of asymptomatic stray dogs identified 10–15% to be seropositive.

The organism is an *obligate intracellular parasite* with a direct life cycle. It develops in parasitophorous vacuoles in cells of many tissues, especially endothelial cells, but is most easily found in brain and kidney in acute active infections. In chronic infections, the organisms can be sparse or impossible to find in microscopic sections, although it seems that animals once infected remain permanently so and excrete the organism mainly in urine.

Clinical disease occurs in dog and fox pups; the organism is shed in urine and feces of affected animals. In both hosts, transplacental infections appear to be important, but oral transmission, as by ingestion of infected rabbit carcasses, may occur. Experimental infection of mature dogs does not lead to clinical disease.

Tissue changes in encephalitozoonosis are most prominent in brain and kidney, but the organism selectively parasitizes vascular endothelium, and the *segmental vasculitis* that results is responsible for lesions in many tissues. Gross lesions may be limited to the kidneys as severe, nonsuppurative interstitial nephritis (Fig. 3.129A). Organisms are abundant in sections of kidney early in the disease but they are difficult to find at later stages. They are especially numerous in the epithelium and lumen of tubules, in glomerular capillaries and in the interstitium, and are present in small vessels and in the media and adventitia of intrarenal arteries. Fibrinoid necrosis affects some glomeruli and the arterial lesions resemble those of periarteritis nodosa. Focal hepatic necrosis and nonsuppurative portal infiltrations are associated with organisms in hepatocytes and Kupffer cells and with nodular vasculitis in the triads. Focal myocardial necrosis and inflammation are frequently associated with vasculitis.

The lesions in the nervous system are those of *widespread nonsuppurative meningoencephalomyelitis*. The severity of lesions varies unpredictably in different parts of the nervous system reflecting the random localization of the organism and the irregular distribution of inflammatory vascular change. Focal gliosis and microscopic granulomas surround small vessels (Fig. 3.129B). About larger vessels showing segmental fibrinoid change, mononuclear cells form cuffs involving the adventitia and perivascular space and eventually assume an epithelioid cell appearance. There is astrocytosis in the surrounding parenchyma. The vascular lesions in the meninges in the acute disease resemble those of polyarteritis nodosa and become dominated by sclerotic changes in the chronic disease in which perivascular cuffing and granulomatous reactions persist.

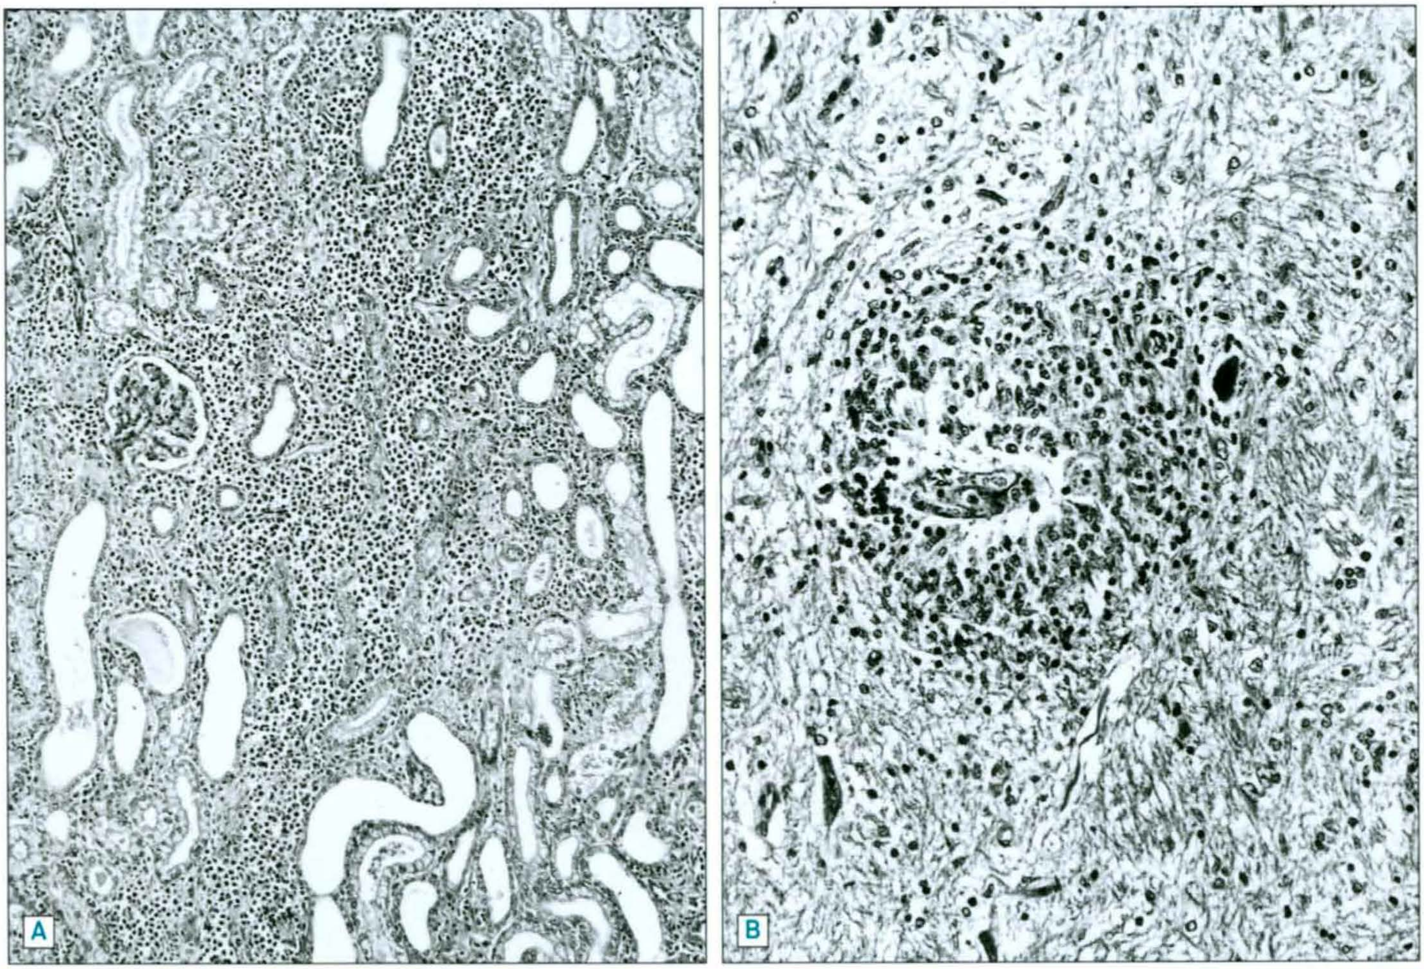

Figure 3.129 Encephalitozoonosis in a dog. **A.** Severe diffuse nonsuppurative interstitial **nephritis.** **B.** Focal granulomatous **encephalitis.**

Puppies which survive the early clinical disease may remain stunted and develop progressive renal disease. It is possible that encephalitozoonosis, as for any sporadic disease, is underdiagnosed especially in chronic infections in which the organism is difficult to demonstrate. Immunohistochemical methods help to identify sparse organisms and to distinguish them from similar parasites, particularly *Toxoplasma* and *Neospora*.

Equine protozoal myeloencephalitis

Equine protozoal myeloencephalitis (EPM) is caused mainly by ***Sarcocystis neurona***, an apicomplexan protozoan parasite, however identical disease is reported in association with ***N. caninum*** and ***N. hughesi***. Opossums (*Didelphis* spp.) are the definitive host for *S. neurona,* and they are infected by eating intermediate host tissues that contain infective tissue cysts. *S. neurona*-induced EPM is restricted to the Americas in the geographical range of the opossum. Natural intermediate hosts (e.g., armadillos, sea otters, raccoons, skunks, cats) are infected by ingestion of food or water contaminated by sporocysts shed in opossum feces. Horses are assumed to be dead-end hosts, but may also act as intermediate hosts.

Exposure to *S. neurona* is widespread among horses, but the prevalence of the classic progressive disease is much lower. A seropositive horse is positive for exposure but not necessarily for the presence of the disease. However, the presence of seropositivity and the clinical signs of weakness and acute ataxia usually indicate active disease. Infection with *S. neurona* has no age predilection. Most EPM cases due to *S. neurona* infection appear in the summer and fall. Affected horses are presented with ataxia, limb weakness, lameness, and rarely seizures.

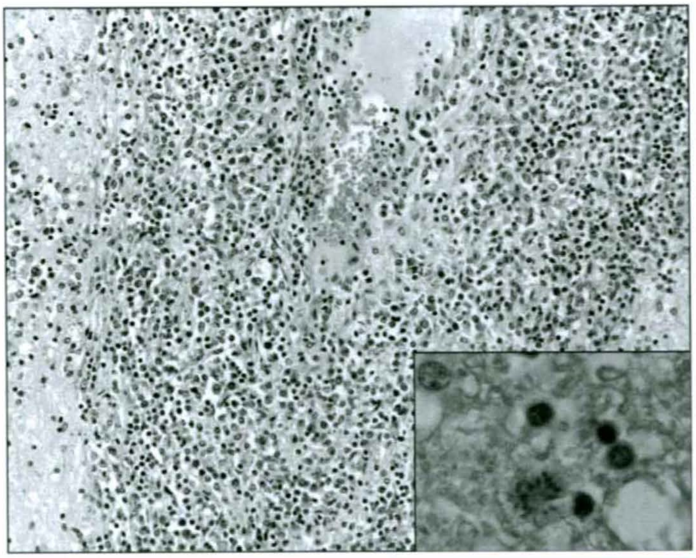

Figure 3.130 Massive mixed inflammatory encephalitis with variable numbers of eosinophils with rare intralesional ***Sarcocystis neurona*** schizonts (inset) in a horse with equine protozoal myeloencephalitis.

Gross lesions are present only in severe cases, and range from multifocal acute hemorrhage to the presence of discrete multifocal gray to dark yellow areas primarily in cross-sections of fixed brain stem, obex, pons, and cervical and thoracic cord. The histologic lesions are usually moderate to severe and characterized by multifocal areas of necrosis, malacia with aggregation of gitter cells, gliosis, and infiltration of large numbers of lymphocytes, histiocytes, plasma cells, and fewer eosinophils and neutrophils with severe involvement of the meninges (Fig. 3.130). The blood vessels in these areas have swollen activated endothelium with thick perivascular cuffs of mononuclear cells and occasional eosinophils. Also and particularly in cord sections, there is axonal swelling or loss besides the appearance of spheroids and some digestion chambers. In chronic cases, the inflammation can be predominantly histiocytic with occasional eosinophils and multinucleated giant cells.

Finding *S. neurona* merozoites or schizonts can be a challenge and serial sections must be examined in most cases. *S. neurona* schizonts are almost always present near areas of inflammation and necrosis, schizonts are oval or irregularly round, have very thin walls ($<0.5\,\mu m$), are up to $20\,\mu m$ in diameter, and contain a few basophilic ovoid merozoites $5\,\mu m \times 1.5\,\mu m$. The stage infective to the definitive host, i.e., sporocysts, can be found in tongue and other skeletal muscles. The *S. neurona* sporocyst is round ($50–100\,\mu m$) or elongate ($500\,\mu m$ long and $40\,\mu m$ wide), and contains a number of bradyzoites.

EPM-like disease can occur in other *S. neurona* intermediate hosts, including the cat, and this disease should be considered in the differential diagnosis of inflammatory encephalomyelitis in this species. Both *N. hughesi* and *N. caninum* can cause identical EPM lesions in horses. The complete life cycle and methods of transmission for *N. hughesi* have not been determined. *Neospora hughesi* tachyzoites are crescent-shaped, approximately $5 \times 2\,\mu m$. Definitive diagnosis of EPM in a live horse is challenging. Detection of *S. neurona* or *N. hughesi* antibodies in serum and cerebrospinal fluid by an immunoblot test is available. Positive results indicate exposure, but do not necessarily indicate that the horse has EPM. The postmortem diagnosis depends on finding characteristic lesions, especially in the presence of the characteristic protozoal stages. Immunohistochemistry kits for *S. neurona* and *N. caninum* are available commercially.

Neosporosis

Neospora caninum is an apicomplexan coccidian parasite that is a major pathogen of cattle, in which it causes abortion, and for dogs. Other species, such as goats, sheep, deer, and horses, can be infected occasionally. Dogs are the primary definitive host, and they are also considered as an intermediate host. Other canids, e.g., coyotes (*Canis latrans*), may also be important definitive hosts. *N. caninum* has three infectious stages: tachyzoites, tissue cysts, and oocysts. Tachyzoites and tissue cysts are found both in intermediate hosts and the definitive host. However, oocysts are only present in the definitive host. Tachyzoites have been found in neurons, reticuloendothelial cells, hepatocytes, muscle cells including myocardium, and bovine placenta. Tissue cysts have been found in the CNS, muscles, and retina. The exact modes of transmission are not well understood. Dogs become infected by ingesting tissues contaminated with tissue cysts, and then shed oocysts in their feces. Cattle and other intermediate hosts become infected by ingesting sporulated oocyst-contaminated food, water, or soil. However, the principal route for infection in cattle is transplacental (vertical) transmission.

N. caninum does not cause significant clinical disease in adult **cattle**, however it causes abortion in both dairy and beef cows particularly at mid-term, although cows can abort at any time from 3 months to term. Infected fetuses may die in utero, be mummified, stillborn, or born alive with or without clinical signs. Extraneural lesions in bovine fetuses include *lymphocytic, plasmacytic and, to a lesser extent, histiocytic, hepatitis, pancarditis or myocarditis, myositis, and placentitis*. Cotyledonary necrosis may be associated with the placentitis. Intralesional *Neospora caninum* tachyzoites are occasionally present in the aforementioned organs. Tachyzoites appear in groups, either intracellular in neurons, endothelium or epithelial cells, or extracellular. Tachyzoites are spindle-shaped, 4–7 × 2 μm. Tissue cysts are primarily present in the CNS and rarely in skeletal muscles. Cyst diameter is up to 107 μm, with wall thickness of 1–4 μm, and containing numerous bradyzoites 8 × 2 μm.

The most frequent and almost pathognomonic CNS lesion in *bovine fetuses* is the presence of *multifocal discrete foci of necrosis* (~100–300 μm diameter), particularly in the brain and to a lesser extent in the cord (Fig. 3.131A, B). The necrotic areas are fairly well circumscribed, have necrotic centers and are surrounded by a rim of glial cells and macrophages. In advanced lesions, the necrotic area may be completely replaced by macrophages and a few glial cells, which make the lesions appear as discrete granulomas. The recognition of *N. caninum* tachyzoites and tissue cysts in aborted fetal brain or other fetal tissue is usually difficult on H&E stain, and immunohistochemistry must be performed to confirm the diagnosis of neosporosis. Other CNS lesions include mild nonsuppurative meningoencephalomyelitis. Fetal anomalies are not common in association with *Neospora* abortion.

Infection in **dogs** is transmitted either horizontally or vertically (transplacental). Dogs of any age can be affected and the infection can be generalized affecting any organs, including the skin, or can be localized. Infection in adult dogs is usually subclinical. Infection in young congenitally infected dogs is severe and characterized pathologically by encephalomyelitis and myositis/polyradiculoneuritis and clinically by hindlimb paresis that is followed by paralysis. CNS lesions are those of *necrotizing granulomatous, lymphoplasmacytic, and occasionally eosinophilic meningoencephalomyelitis* with diffuse gliosis, occasional axonal swelling, digestion chamber formation, and intralesional *N. caninum* tachyzoites and cysts (Fig. 3.132). These lesions are widely distributed in the brain and cord, however in the cortex the gray matter is affected predominantly. Lesions associated with the neuritis/polyradiculoneuritis is frequently severe, mostly affecting pelvic limbs, and characterized by severe lymphohistiocytic and occasional eosinophilic inflammation with associated secondary degenerative and necrotizing changes either in muscles or nerves with intralesional tachyzoites and rare cysts.

Experimental infection of pregnant **ewes** and **does** produces a disease that is identical pathologically to that observed in cattle, however natural disease is rare.

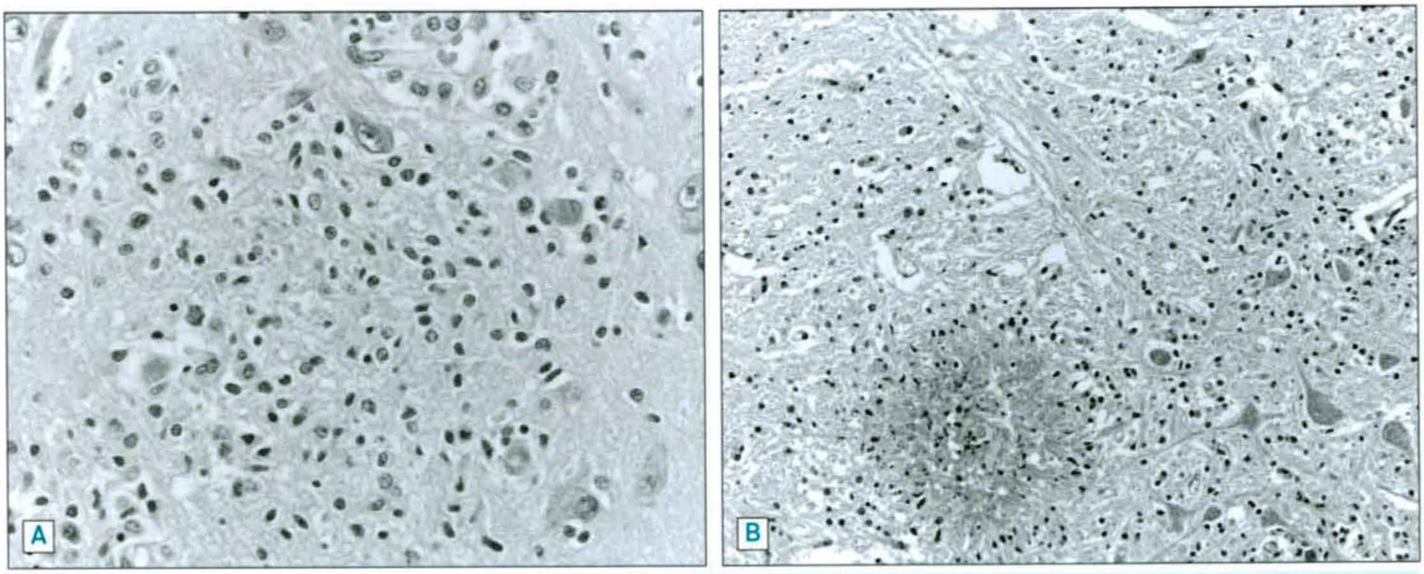

Figure 3.131 Lesions of neosporosis in fetal bovine brains may consist only of focal gliosis (**A**) or may occur as multifocal areas of neuropilar necrosis (**B**) encircled by glial cells and rarely giant cells. *Neospora caninum* cysts are rarely seen.

The epidemiology and methods of transmission of *N. caninum* and other *Neospora* in **horses**, e.g., *N. hughesi*, are not completely understood. Transplacental infection is suggested but not completely confirmed. *N. caninum* has been isolated from a few aborted fetuses. *N. caninum* and *N. hughesi* are rare causes of equine protozoal myeloencephalitis (see above).

Toxoplasmosis

Toxoplasmosis is one of the most common protozoal diseases affecting humans and animals and is caused by ***Toxoplasma gondii***. Diseases caused by *T. gondii* are very similar in clinical presentation and pathology to those caused by *N. caninum*. Felids are the only definitive host and they also can act as an intermediate host. Other intermediate hosts include humans and other mammals. *T. gondii* has three infectious stages: tachyzoites, tissue cysts, and oocysts. Tachyzoites and tissue cysts are found in both intermediate and definitive hosts, however, oocysts are only present in the definitive host. Tachyzoites and tissue cysts are present more commonly in neural tissue and muscles, but can be present in virtually any tissue. Felids become infected by ingestion of tissues contaminated with tissue cysts, and shed oocysts in their feces. Human and other intermediate hosts including felids can become infected by ingesting sporulated oocyst-contaminated food, water, or soil. Transplacental transmission is important in cats, goats, and sheep. The extraneural pathology of toxoplasmosis is discussed elsewhere in these volumes. The nervous system lesions, including polyradiculoneuritis, are identical to those described above for neosporosis, however *the tissue cyst has a thinner wall ($<0.5\,\mu m$), is 5–70 μm in size, and contains several bradyzoites 0.7–1.5 μm. Tachyzoites are 2–6 μm in size.* The encephalitic form of toxoplasmosis is most likely to occur in immunosuppressed dog and cats or kittens. Toxoplasmosis in pigs is generalized and can cause devastating disease with lesions including nonsuppurative encephalomyelitis with intralesional *T. gondii* stages.

Sarcocystis canis encephalitis

A rare and generalized disease affecting dogs mostly in North America is caused by *S. canis* and characterized histologically by multisystemic vasculitis, hepatitis, and necrotizing lymphohistiocytic encephalitis in association with the presence of intralesional *S. canis* schizonts and merozoites (schizonts are 5–25 × 4–20 μm and contain 6–40 merozoites of 5–7 $\mu m \times 1\,\mu m$).

Helminth and arthropod infestations

Nothing is known of what motivates and directs the migration of larval parasites. Those that migrate somatically are apt to go astray, and this appears especially likely when they wander in an alien host. Aberrant pathways include the nervous system with such frequency as to suggest that nematodes have a special propensity for wandering in the CNS. Whether this is indeed the case remains to be proven, but parasitic migrations in nervous tissue are more likely to be symptomatic than aberrant migrations in other tissues, and there is an impressive list of parasites that have been found in brain or cord. Many of these infestations and the parasites in question are discussed elsewhere in these volumes.

Cestodes

Adult cestodes live almost exclusively in the small intestines of the final host, however certain larval stages can infest the brain of the intermediate host. ***Coenurus cerebralis***, the larval stage of ***Taenia***

multiceps, which infests the small intestines of dogs and wild carnivores, is fairly common in the brains of sheep in Europe, less common in other herbivores, and rather rare in horses and humans. About 40% of pigs harboring ***Cysticercus cellulosae*** (the larval stage of the human tapeworm ***Taenia solium***) have cysts in the meninges and brain as well as in the muscle, and the same species has been identified in the brains of dogs. Possibly ***Cysticercus bovis*** (the larval stage of human tapeworm ***Taenia saginata***) and other cysticerci will invade nervous tissue with comparable frequency. Apparently, hydatids are seldom found in brain.

Nematodes

The term **cerebrospinal nematodiasis** is applied to nervous diseases resulting from aberrant nematode larval migrations. The few nematodes that produce the syndrome with any frequency are discussed below.

Parastrongylus *(Angiostrongylus)* ***cantonensis*** is a metastrongylid lungworm whose only known definitive host is the rat. It is widely distributed in the warm Pacific regions, but its distribution is much more limited than that of the gastropod intermediate hosts and the rat. The parasite resides in the pulmonary arteries of rats, eggs lodge as emboli in alveolar capillaries and the larvae, which hatch in about 6 days, and follow the tracheal–intestinal route to the exterior. First-stage larvae actively penetrate terrestrial and aquatic slugs and snails, which act as intermediate hosts. Transport hosts for third-stage larvae include frogs, crabs, and prawns. In addition to the rat, dogs, humans, and occasionally other species are infected by eating intermediate or transport hosts and, possibly, directly by ingestion of infective larvae that have emerged from intermediate hosts. Ingested larvae enter and are dispersed by the circulation to many tissues, but predominantly to brain, kidney, and muscle. Molting larvae in the brain produce a mild to severe inflammatory reaction before re-entering the venous circulation for return to the pulmonary arteries. Aberrant infections are important in humans and dogs, and are reported in horses and macropods. The human disease, eosinophilic meningoencephalitis, is usually mild and without sequelae, but infection in dogs can be accompanied by ascending paralysis. Larvae that enter the brain in dogs are probably inhibited in their development and destroyed there (Fig. 3.133). The lesions are granulomatous, randomly distributed in the cord and brain and are most frequent and severe in the cord (Fig. 3.134). Rarely, degenerate parasites are present in the granulomas, but apparently viable worms in the tissue are not accompanied by an inflammatory reaction. Eosinophils infiltrate the granulomas but are more numerous in affected meninges.

Parelaphostrongylus *(Pneumostrongylus)* ***tenuis*** is a metastrongylid parasite of white-tailed deer, *Odocoileus virginianus*, in North America. The intermediate hosts are terrestrial slugs and snails. Ingested larvae reach the spinal cord of the deer in ~10 days. They develop for up to 1 month in the dorsal horns of the cord at all levels and then migrate into the meningeal spaces. Some penetrate the dural veins and sinuses and mature. Eggs or larvae are carried in venous blood to the lungs. The larvae do very little to the cord in white-tailed deer, but the reaction is more severe in other species, including red deer, elk, moose, and sheep (Fig. 3.135). ***Elaphostrongylus panticola*** and ***E. rangifera*** of deer in northern Europe and Russia have a life cycle similar to that of *P. tenuis*, but infections are usually subclinical.

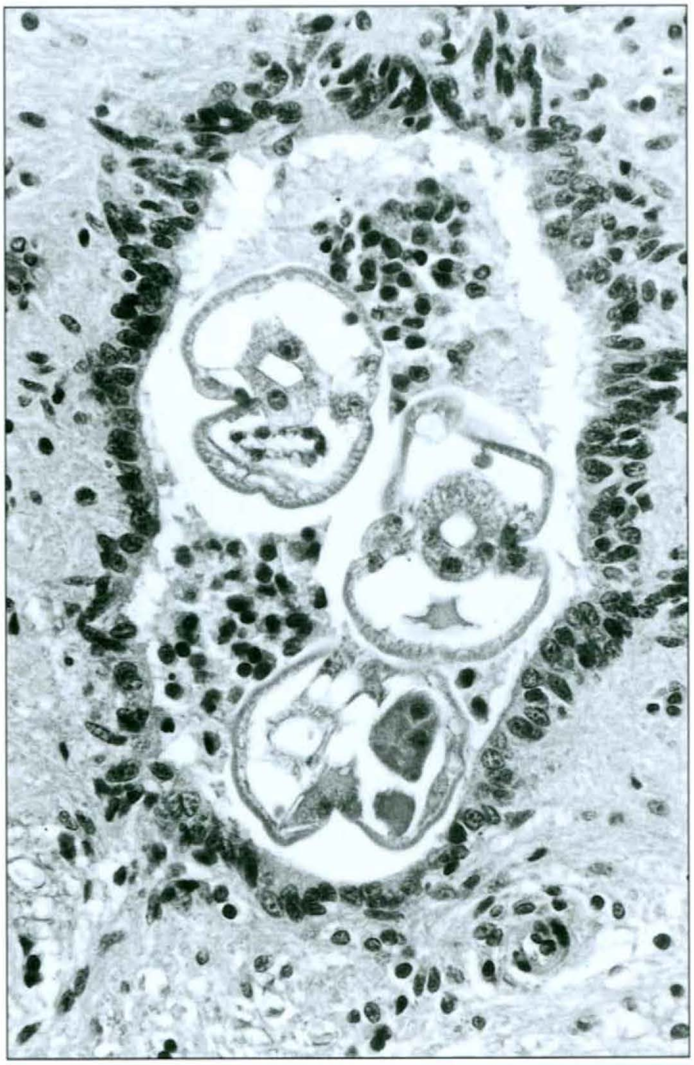

Figure 3.133 Larvae of ***Parastrongylus*** sp. in central canal of spinal cord in a dog.

When larvae of ***Elaeophora schneideri*** – a filarial parasite discussed in the Cardiovascular system – develop in the leptomeningeal arteries of various cervids, sheep and goats, they can cause ischemic necrosis of brain tissue.

Setaria digitata is normally found as an adult in the peritoneal cavity of cattle and buffalo in Asia (see also Peritoneum). Microfilariae can be carried to aberrant hosts such as horses, camels, sheep, and goats by mosquitoes, and larvae wandering in the brain and spinal cord are responsible for the neurological disease known as *kumri* (lumbar paralysis) in Asia. The migrating larvae apparently cause little or no damage in the natural host. The location of the lesions is variable, as are the clinical signs produced. Characteristically, the neurological signs are ataxia, weakness, or paralysis. The severity of the signs varies from slight weakness to quadriplegia, depending on the number and location of the wandering parasites; however, affected animals may remain bright and alert. The CNS lesions produced are fundamentally traumatic, and lead to microcavitation, as described below.

Halicephalobus gingivalis *(Micronema deletrix)* is a free-living nematode that is accidentally, but rarely, a parasite; this nematode is characterized by a rhabditiform esophagus. Massive intracranial invasion is reported in horses. The syndrome is acute and of short

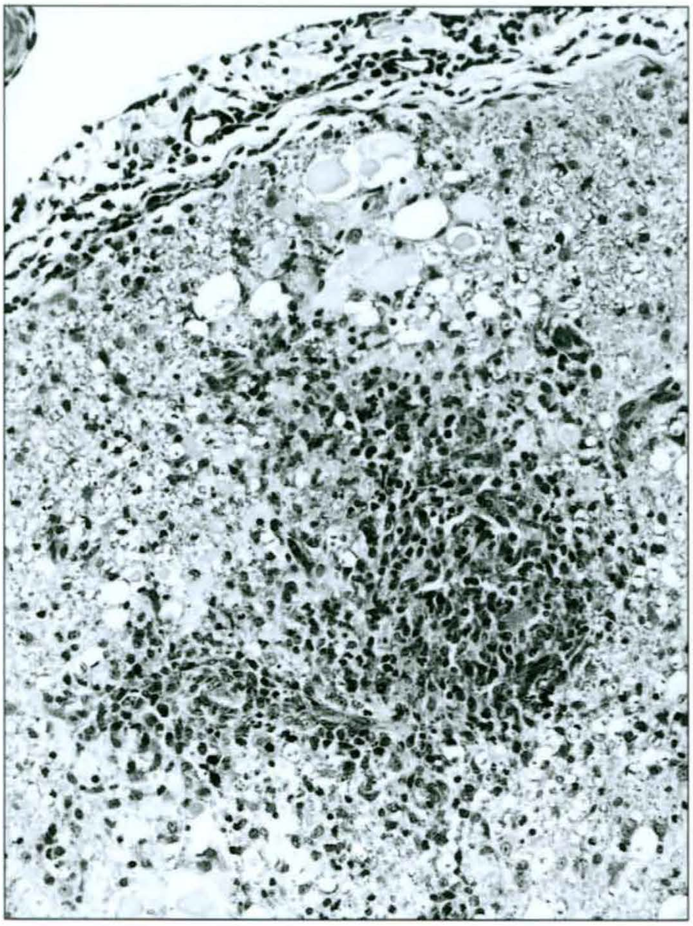

Figure 3.134 Granuloma formation, Wallerian degeneration, and spinal meningitis due to ***Parastrongylus*** infestation in a dog.

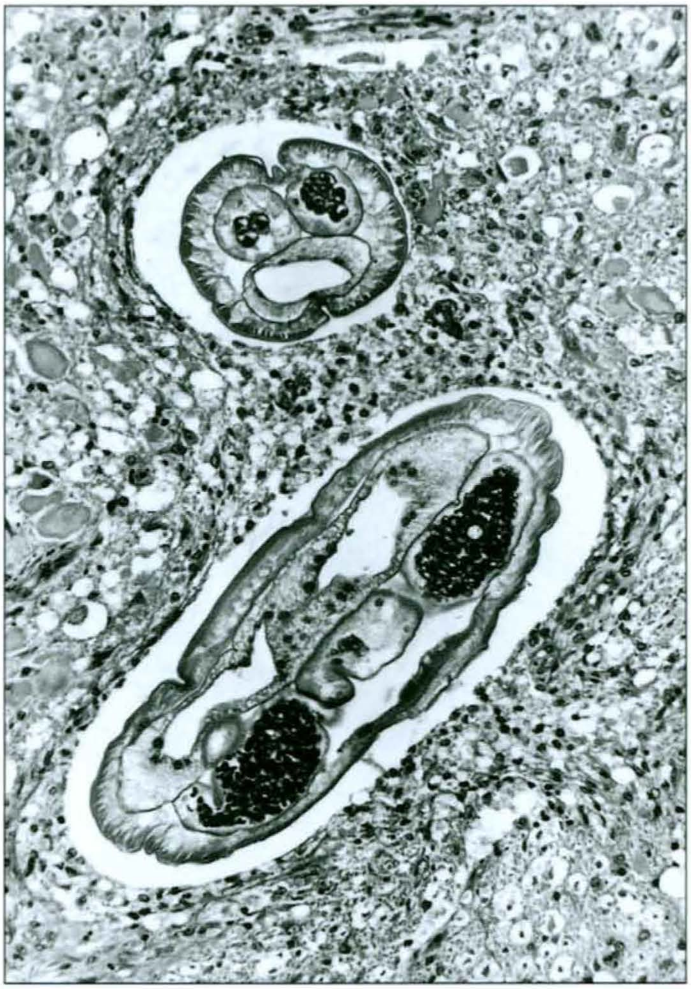

Figure 3.135 ***Parelaphostrongylus*** in spinal cord of a sheep.

duration. There are focal arachnoid hemorrhages and patchy meningeal thickenings. Only parthenogenetic female worms and larvae are found among the specimens in the brain, most easily in perivascular spaces (Fig. 3.136). Depending on the area of the CNS affected, lesions are granulomatous and eosinophilic meningoencephalitis, myelitis, polyradiculitis, or even cauda equine neuritis-like lesions. Parasitic granulomas in the kidney and gingiva may accompany the cerebral invasion. Little is known about the life cycle and method of transmission of this nematode. Oral ingestion or wound contamination then hematogenous distribution is suggested. Also, transmission from infected dam to her foal through milk is described in one case.

Gurltia paralysans, found in the spinal veins of cats, is reported to be responsible for a high incidence of paralysis in this host, and ***Angiostrongylus vasorum*** has caused hemorrhagic malacia in the brains of dogs. Aberrant hosts can develop severe cerebrospinal nematodiasis when they incidentally ingest the eggs of ***Baylisascaris procyonis*** (raccoon ascarid) or *Baylisascaris columnaris* (skunk ascarid).

Larval worms may also migrate aberrantly in the CNS of their natural hosts. ***Stephanurus dentatus*** quite frequently invades the spinal canal and may even encyst in the meninges in pigs. ***Strongylus* spp**. occasionally invade the brains of horses; Figure 3.137 shows the type of lesions that occur, and, although not identified in this case, the larvae were probably of *S. vulgaris* because these were identified in thrombi in the aortic bulb and carotid artery. **Ascarids** have a propensity for wandering in the brain of alien hosts and occasionally do so in their natural hosts.

Trematodes

Trematodes apparently have little tendency to invade nervous tissue. ***Troglotrema acutum*** may invade the brain from its normal habitat in the paranasal sinuses. The eggs of the lung flukes, ***Paragonimus* spp**., have been observed in the brains of dogs, possibly arriving there as emboli.

Arthropods

The only larval arthropods of interest are ***Hypoderma bovis***, which normally migrates through the spinal canal, and ***Oestrus ovis***, which may invade the brain from the nasal sinuses.

Cuterebra spp. (larva of a rodent or rabbit bot) in an abnormal host, i.e., cat and to a lesser extent dog, can undergo aberrant migration and has been reported in many organs including the eyes and CNS. Adult *Cuterebra* are nonparasitic and are seldom observed. Lesions in the brain are characteristic and indicative of vascular compromise and direct toxicity by toxin released from the larvae. These lesions include superficial laminar cerebrocortical necrosis, cerebral

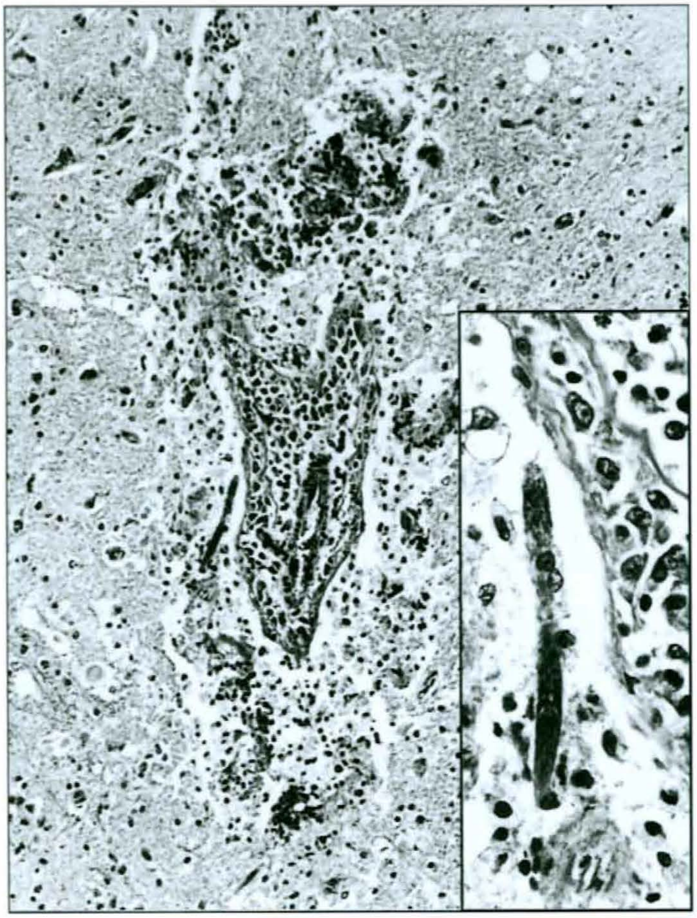

Figure 3.136 Perivascular inflammation in the brain of a horse caused by ***Halicephalobus gingivalis*** (*Micronema deletrix*). Inset: parasite with cellular reaction.

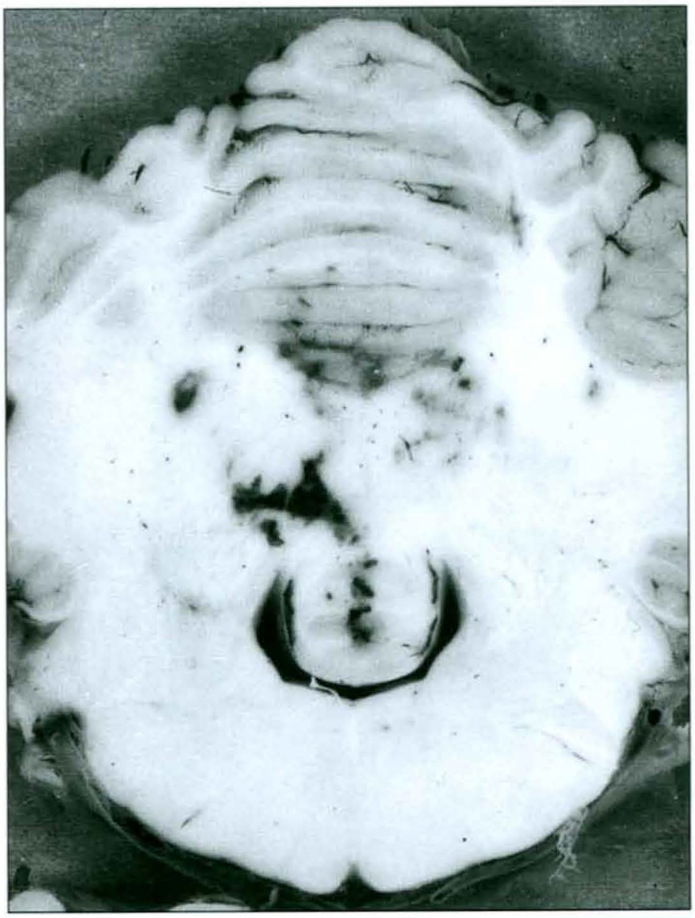

Figure 3.137 Hemorrhagic tracks in cerebellar white matter probably produced by ***Strongylus vulgaris*** in a horse.

(particularly at the olfactory bulbs and peduncles) and subependymal malacia and infarction, and finally larval migratory track lesions that are characterized by focal necrosis, hemorrhage, and infiltration of eosinophils, lymphocytes, plasma cells, and fewer neutrophils. Most of the track lesions are present in caudate nucleus or thalamus. Cuterebral larval migrans in the feline brain is thought to be the cause of *feline ischemic encephalopathy*.

The few parasites specifically mentioned are the most important in terms of neuropathology. Occasionally helminth larvae are discovered accidentally but rarely identified in sections of brain or cord, and it is somewhat more common to find lesions typical of those produced by migratory parasites without being able to locate the parasite. Some parasites, such as *Elaphostrongylus*, usually remain in the CNS whereas others, such as ascarids and strongyles, can be expected to keep moving. Finding the parasite is, therefore, largely a matter of luck, even when it is sought very early after the onset of clinical signs.

The lesions produced in nervous tissue by migratory larvae are mainly *malacic* and, although random, are fairly distinctive in their pattern. *Coenurus cerebralis* produces, in the invasion phase, purulent meningoencephalitis and later acts as a space-occupying lesion, but other invading parasites produce mainly traumatic lesions with very little inflammatory reaction except for a few eosinophils. The lesions produced by nematodes are sometimes grossly visible as *hemorrhagic foci or narrow, slightly tortuous tracks*. Brown, hemorrhagic discoloration depends on the parasite hitting a vein or arteriole, and it appears that some worms have a tendency to migrate along veins. There may be only one or several such tracks in the CNS, and they occur quite at random. Microscopically, the lesion is an irregular focus or pathway of traumatic malacia into which some hemorrhage may have occurred. There may be slight cellular infiltration in the adjacent meninges or nerve roots. The track is liquefied, and its margins not sharp, and apart from lymphocytes, gitter cells, and a few eosinophils, there is no significant reaction in the damaged tissue or in the adjacent vessels. The disruption, which is not selective in the tissues destroyed, leads to *microcavitation*. The disrupted axons, swollen, tortuous and as globose fragments, persist for some time in the microcavitations (Fig. 3.134). Gemistocytic astrocytes may be present in older lesions.

Chlamydial disease

Sporadic bovine encephalomyelitis (SBE) occurs in calves less than 6 months of age, and is caused by ***Chlamydophila pecorum***. Identical disease is also reported due to infection with *Chlamydophila psittaci*. *Chlamydophila pecorum* also causes a wide range of other conditions in calves, including polyarthritis, metritis, conjunctivitis, and pneumonia. The disease occurs in the USA, Japan, Europe, and Australia; the agent probably has a worldwide distribution and most infections are asymptomatic. Encephalomyelitis is reported to occur naturally only in cattle and buffalo. As a rule, SBE is indeed sporadic, affecting only a few animals in a herd, however outbreaks of the disease with morbidity of 25% are described. Transmission appears to be by direct contact. The clinical syndrome is not particularly characteristic. It is composed of moderate fever and signs of catarrhal inflammation of the respiratory tract. There is some stiffness, weakness of the hindlimbs with staggering and knuckling of the fetlocks, and muscle tremors. There is some dullness; signs of excitement are not present. Death occurs in a few days to a few weeks.

The organism has a tropism for blood vessels, mesenchymal tissue and serous membranes, which make *vasculitis and polyserositis the hallmark of lesions*. Encephalitis is secondary to vascular damage. The gross morbid change that suggests a diagnosis of SBE is serofibrinous inflammation of serous membranes and synoviae. This is most consistently *peritonitis*, and in ~50% of fatal cases there is also *pleuritis and pericarditis*. The meninges appear congested and edematous and occasionally are covered with a few fibrin tags. Microscopically, there is a rather *severe and diffuse meningoencephalomyelitis* (see Fig. 3.60). The leptomeningitis is most severe about the base of the brain. The reactive cells are almost solely histiocytes and plasma cells, with only a few neutrophils. These cells infiltrate the meninges and perivascular spaces and mix with reactive adventitial cells of the vessel walls. The vascular endothelium proliferates secondary to lesions in the vascular walls, and ischemic changes may occur in the parenchyma. Reactive microglial nodules are widespread in the brain.

Cell culture of *Chlamydophila*, the gold standard diagnostic tool, is being displaced by detection by PCR. Elementary bodies produced by this organism occur in the cytoplasm of mononuclear cells in the exudates in the meninges and from serosal membranes and in microglia of nodules, but they are not numerous and their demonstration by special stains or immunohistochemistry is not usually rewarding.

Idiopathic inflammatory diseases

Necrotizing meningoencephalitis of Pug and other small breed dogs

Canine necrotizing meningoencephalitis (NME), formerly "Pug dog encephalitis," is an idiopathic disease affecting mainly Pug dogs, but also reported rarely in Maltese, Pekingese, Shih Tzu, and Chihuahua. A similar condition, but with lesions more prevalent in the white matter, is reported in Yorkshire Terriers (distinct from *Yorkshire Terrier necrotizing encephalopathy*, which affects brain stem), named necrotizing leukoencephalitis. The cause of NME is unknown; several etiologic agents have been suggested as causes, including alpha-herpesvirus, but none has been confirmed. An autoimmune reaction against canine brain tissue has been suggested as a possible mechanism. A wide age range is affected. Generalized convulsions and their aftermath dominate the clinical picture, which may include lethargy, ataxia, and progression to coma. The clinical signs refer essentially to cortical disease that progresses rapidly over a few weeks, but which may extend to several months.

The lesions are particularly in the cerebral cortex, and are bilateral but asymmetric, often confluent over large areas, and extend to the adjacent white matter with relative sparing of the deeper periventricular tissue. The geography of the lesions therefore helps to distinguish this disease from other encephalitides of the dog. Grossly, localized swellings in the cerebrum contribute to asymmetry, and malacic foci may be seen as typical yellow areas of softening (Fig. 3.138) or, in cases of longer duration, as tiny cystic cavities.

The histological changes are necrotizing and with an affinity for the hemispheres. Numerous foci of meningitis, characterized by infiltrations of lymphocytes, plasma cells, and monocytes (Fig. 3.139), diminish caudally and may be absent in the caudal fossa and spinal cord. These infiltrates breach the pial barrier and destroy the superficial cortex to an extent and severity that is unusual. The evidence of

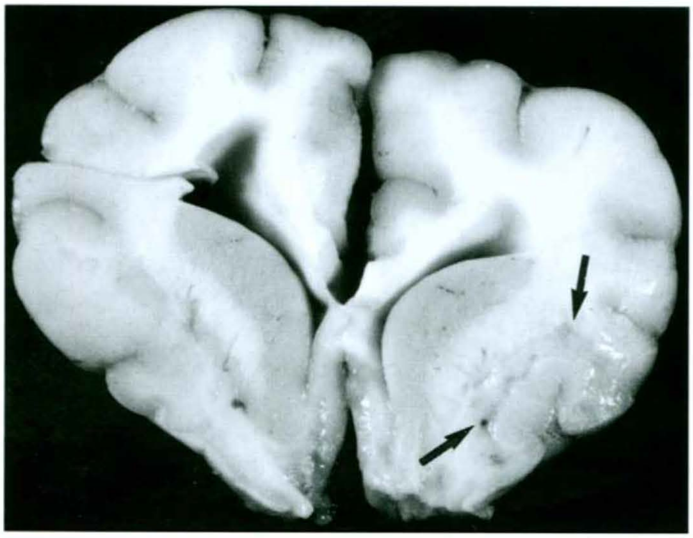

Figure 3.138 Malacic focus in ventrolateral cerebral hemisphere (arrows) in **Canine necrotizing meningoencephalitis**. (Reprinted with permission from Bradley GA. Vet Pathol 1991;28:91.)

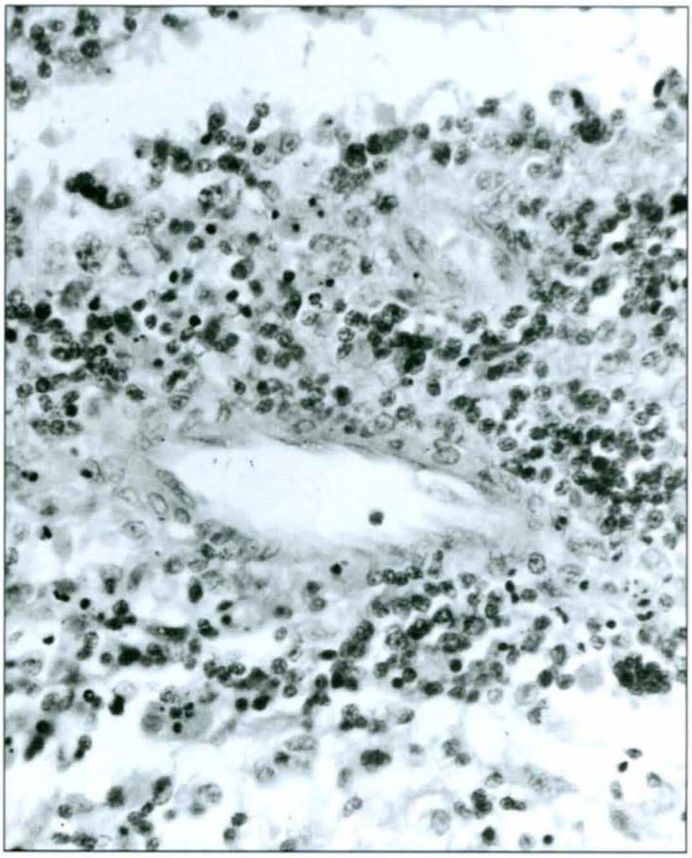

Figure 3.139 Meningeal arteriole surrounded by mixed mononuclear infiltrate in **Canine necrotizing meningoencephalitis**.

cerebral necrosis extends from selective neuronal necrosis to areas of malacia, the latter especially in chronic cases. Vascular endothelium in the cortex is reactive and associated with edema, occasional petechiae, and diffuse accumulation of mononuclear cells in parenchyma and vascular cuffs.

The differential features of this meningoencephalitis, in addition to its nonsuppurative nature, are the malacic degenerations and predilection for the cerebral cortex. This condition must be differentiated also from granulomatous meningoencephalomyelitis (GME). The inflammatory infiltrate in GME contains more histiocytes, which in the chronic stage transform to epithelioid cells that can form discrete cohesive sheets or granuloma-like lesions. Also, in GME, the reaction is predominantly in the white matter and is distributed in almost all parts of the CNS. In contrast, the reaction in NME is mostly in the cortical gray matter.

Granulomatous meningoencephalomyelitis

Granulomatous meningoencephalomyelitis (GME) is a sporadic disease of the CNS of dogs. GME appears to have a worldwide distribution and to occur mostly in *young to middle-aged dogs of small breeds*, e.g., terriers and toy breeds, however the disease can occur in any breed and in an age range of 6 months to 12 years. The cause of GME is unknown; several infectious causes have been suggested but not confirmed to be the cause of this condition. Based on the predominance of CD3+ T cells and MHC class II antigen-positive macrophages, an immune-mediated mechanism has been proposed.

Variations in the distribution and extent of the lesions result in a variety of clinical signs. Spinal lesions may be associated with ataxia, paresis, or paralysis (Fig. 3.140). Lesions in the brain stem frequently produce signs of vestibular dysfunction. Changes of behavior, forced movement and circling, depression and convulsions occur with supratentorial lesions. Macroscopic lesions, if evident, consist of gray-white discoloration of the white matter of the brain or spinal cord, and in those cases in which the cellular aggregations become confluent, there may be irregular areas of malacia (Fig. 3.141).

The histologic changes are patchy in distribution. There may be very few foci, or they may be disseminated, or they may be localized to one area and confluent, or there may, in the same animal, be both confluent and disseminated distributions. *The essential histologic feature is perivascular aggregation of cells rather selectively in the white matter.* The minimal lesion is cuffing of vessels by lymphocytes and plasma cells with small eccentric clumps of macrophages. The macrophages increase in number and may come to comprise the cuff, appearing as discrete granulomas, which, depending on the plane of section, may appear to be in the parenchyma. Occasional mitoses are present in these cells. Transformation to epithelioid cells occurs later. The perivascular aggregates expand in concentric arrangements and displace surrounding parenchyma (Fig. 3.142). Where the cuffing response is severe, edema and necrosis may occur in the adjacent white matter leading to a spillover of mononuclear cells into the parenchyma and to the usual reactive changes. Large malacic foci are unusual. In cases of prolonged duration, confluence of lesions occurs and reparative responses include the deposition of abundant reticulin and collagen in perivascular arrangements. Involvement of meninges is patchy and often related to lesions of white matter directly underlying.

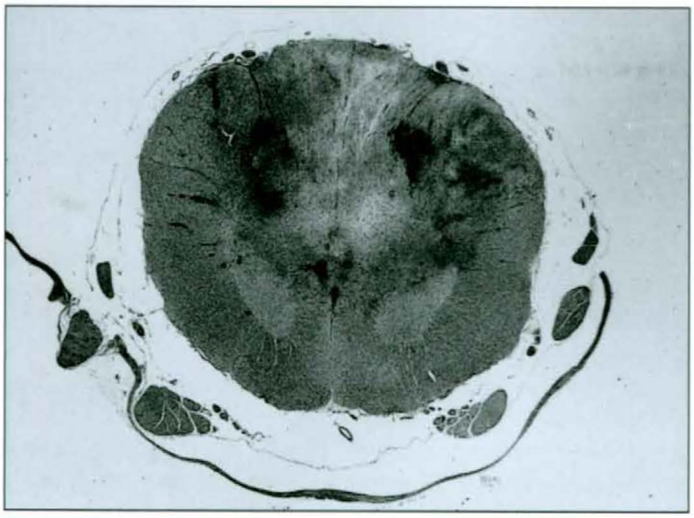

Figure 3.140 Focal lesions in the spinal cord of a dog with **granulomatous encephalitis**. (Courtesy of JB Thomas.)

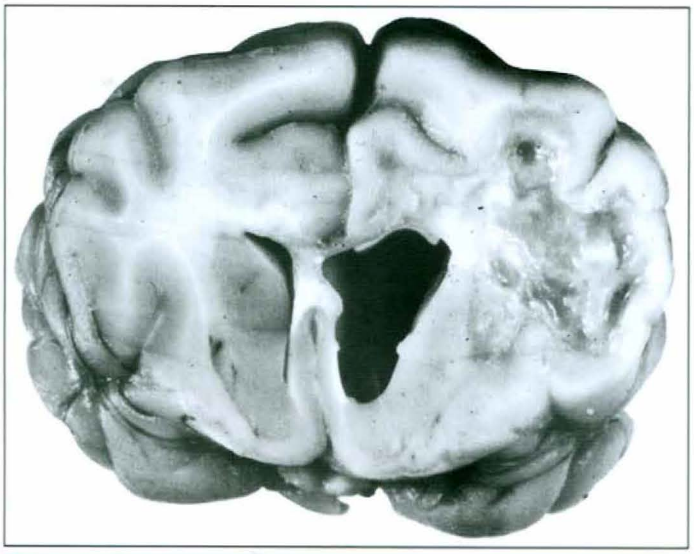

Figure 3.141 Malacia of cerebrum and hydrocephalus secondary to infarction in a dog with **granulomatous encephalitis**.

Cytological characterization of the cell aggregates can be difficult. In many, and perhaps most, cases, the cells are easy to classify, being well differentiated as lymphocytes, monocytes, plasma cells, and histiocytes (Fig. 3.143). Granulocytes may be present but are not numerous, and histiocytes often show epithelioid transformation and may form small syncytial masses. There may also be in some cases large immature cells of reticulohistiocytic type in which mitoses may be few or many. Differentiation between GME and brain malignant histiocytosis (BMH) can be problematic occasionally; BMH is frequently part of a multisystemic tumor and rarely occurs in isolation. Also, the absence of cellular atypia and the predominance of perivascular orientation should favor the diagnosis of GME.

Acute polyradiculoneuritis (coonhound paralysis)

Acute polyradiculoneuritis, or polyradiculoneuropathy, affects primarily dogs, occasionally cats, and rarely horses, and has many similarities to Guillain-Barré syndrome in humans. The condition was named coonhound paralysis to reflect the fact that some affected dogs had been bitten or scratched by raccoons, although cases may have no known exposure to raccoons. Within 7–10 days, ascending flaccid paralysis, starting in the hindlimbs and progressing cranially to involve the forelimbs, leads to quadriplegia and rapid atrophy of muscle. There are no cerebral signs. Some dogs die of respiratory paralysis, but most will recover slowly if nursing is adequate. Dogs that have

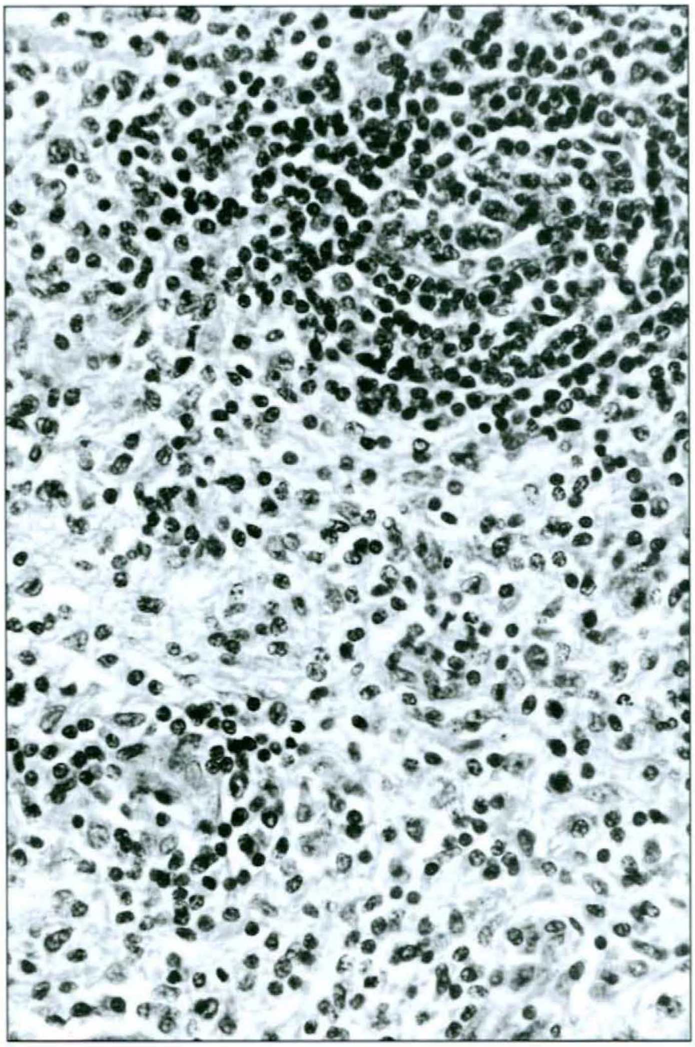

Figure 3.143 Detail of cellular infiltrate in brain in **granulomatous encephalitis** in a dog.

recovered appear to have increased sensitivity to subsequent exposure but may survive several bouts of paralysis. The disease has been transmitted using pooled saliva of raccoons, but the cause has not been identified; an autoimmune mechanism is suspected. Lesions are found in the *ventral roots of spinal nerves and in peripheral nerves*. Mononuclear and plasma cells infiltrate around venules, but the extent of the infiltrate is variable and not correlated with the course of the illness or the severity of nerve degeneration. There is primary and Wallerian degeneration afflicting ventral roots in particular, with axonal reaction in motor neurons and atrophy of denervation in muscle. This idiopathic polyradiculoneuritis is the most common inflammatory condition of peripheral nerves in dogs.

Neuritis of the cauda equina

Neuritis of the cauda equina of horses is a polyneuritis in which the presenting signs are referable to the sacrococcygeal nerves and include perineal anesthesia, tail paralysis, urinary incontinence, fecal retention, weakness, atrophy of coccygeal muscles and, in longstanding cases, atrophy of the muscles of the hindlimbs. The neuritis is progressive. The cause is unknown, but the nature of the reaction suggests immune mediation, which may follow viral infection. The condition has been compared to experimental allergic neuritis in laboratory animals. *Halicephalobus gingivalis* is reported as a novel cause of cauda equina neuritis in one horse.

Although the pathologic changes emphasize the *sacral and caudal spinal nerve roots*, there may simultaneously be asymmetric pareses of other nerves producing isolated limb pareses, and paresis or paralysis referable to cranial nerves. The lesions in these other nerves are similar in character to, but much milder than, those in caudal nerve roots. Inflammatory changes are present in sensory and some autonomic ganglia, but changes in the spinal cord are limited to those that reflect peripheral nerve injury.

The gross changes affect in particular the extradural parts of the sacral and coccygeal nerves and may extend through the intervertebral foraminae into the adjacent muscle. The roots are thickened and fusiform and usually discolored by recent or old hemorrhage. The intradural segments of affected nerves are discolored but not usually enlarged.

Microscopically there is *granulomatous inflammation with extensive fibrosis*. The thickening and discoloration are attributable to hemorrhage, proliferation of epineural tissue, and inflammatory cell infiltrates. The infiltrating lymphocytes, plasma cells and macrophages are frequently disposed as to form granulomas, often with central epithelioid and giant cells; granulocytes do not feature in the infiltrates. Degenerative and regenerative changes are present in the myelin and axons of affected roots and appear to be more closely associated with endoneurial and perineurial fibroplasia than with leukocytic infiltrates.

Steroid-responsive meningitis-arteritis (Beagle pain syndrome)

Steroid-responsive meningitis-arteritis (SRMA) is a *polyarteritis of possible immune-mediated origin affecting mainly small to medium-sized leptomeningeal and myocardial arteries*, but arteries in many organs can be affected. Beagles, especially those in laboratory-bred colonies, are at high risk, but the disease is reported in Boxers, German Shorthaired Pointers, Nova Scotia Duck-tolling Retrievers, and rarely in other breeds. Affected dogs have fever, hyperesthesia, severe pain on manipulation, cervical rigidity, and anorexia. The clinical course of SRMA is usually acute, but a chronic form exists. Gross lesions are minimal, but areas of subarachnoid hemorrhage may be present along the brain stem and the spinal cord, especially the cervical part. Histologically, small to medium-sized leptomeningeal arteries, especially of the brain stem and spinal cord, and to a lesser extent heart and cranial mediastinum, have moderate to severe perivascular and transmural infiltrates of lymphocytes, plasma cells, histiocytes, and fewer neutrophils. Occasionally, neutrophils predominate. Also, there is severe fibrinoid necrosis, thrombosis, and occasionally periarterial fibrosis. Mild lymphocytic and histiocytic leptomeningitis is also a constant finding.

Distinct from SRMA, an unusual case of idiopathic vasculitis resembling "*isolated angiitis of the CNS*" in humans has been reported in a mixed-breed dog. The necrotizing vasculitis, with cuffs of mixed cell types including multinucleated giant cells, resulted in localized cerebral necrosis.

Shaker dog disease

Shaker dog disease is an idiopathic condition characterized clinically by *tremors* that worsen after stress or excitement. The condition was described first affecting solely young adult white-haired small dogs (little white shakers), but now is recognized in dogs of any size or coat color. Histologically, *mild diffuse, nonsuppurative encephalomyelitis* is present. No myelin disease is present.

Sensory ganglioneuritis (sensory ganglioradiculitis)

Sensory ganglioneuritis (sensory neuronopathy) is a rare idiopathic disease of adult dogs characterized by *nonsuppurative inflammation of dorsal root (sensory) spinal ganglia and cranial sensory ganglia* with degeneration and necrosis of sensory neuronal cell bodies and proliferation of ganglionic satellite cells. The cause may be a cell-mediated immune mechanism. Secondary to sensory ganglion neuronal injury, Wallerian degeneration develops in the dorsal funiculi (fasciculus cuneatus and fasciculus gracilis) and the affected areas appear grossly as white V-shaped or triangular areas throughout the entire length of the spinal cord. Similar but milder lesions can be present in sympathetic ganglia, peripheral nerves, myenteric plexi, motor roots, and the spinal tract of the trigeminal nerve. Breed or sex predilection have not been observed. Clinical signs are variable and include generalized sensory ataxia, depression or absence of spinal reflexes, facial hypalgesia/paresthesia, megaesophagus, and dysphagia. Masticatory muscle atrophy is observed in a few dogs in association with this condition and is attributed to loss of motor fibers as they course through the trigeminal ganglion.

Post-infectious encephalomyelitis

Neurological disease that follows, after a variable period, common viral infections or vaccination exposure is well known in children as post-infectious or post-vaccinal encephalitis, or acute disseminated encephalomyelitis. The common pathologic basis is a *demyelinating inflammatory process dominated by mononuclear inflammatory cells with a distinctive perivenous distribution*. Examples that meet the criteria have occurred in relation to rabies vaccination in dogs when such vaccines were prepared in neural tissue, and the pathologic process is the same as that in experimental allergic encephalomyelitis. The histologic changes are widely distributed in the brain and cord and affect mainly the white matter. Perivascular infiltrates of lymphocytes, plasma cells, and monocytes/macrophages widely distend the space and spread into the surrounding parenchyma. Proliferation of adventitial cells may be prominent. Although much descriptive emphasis has been given to demyelination, this is restricted to the perivascular areas of infiltration and to surrounding areas showing the usual degenerative and reactive changes.

Eosinophilic meningoencephalitis

Recognized causes of eosinophilic meningoencephalitis include nematode and protozoan parasites. **Idiopathic eosinophilic meningoencephalitis** has been reported in dogs, with Rottweilers and Golden Retrievers over-represented, and one cat. The condition is characterized clinically by behavioral changes such as inappropriate urination and lack of response to commands. In severe cases, episodes of sternal or lateral recumbency without loss of consciousness are described. Clinical pathology findings are mild to moderate peripheral blood eosinophilia and CSF pleocytosis with predominance of eosinophils. Grossly, there is thickening and green discoloration of the meninges. Histologic changes are those of eosinophilic and granulomatous meningitis of the cortex and cerebellum, and the underlying neural parenchyma appears pallid, occasionally spongiotic, and has mild eosinophilic and histiocytic cuffing with rare areas of axonal swelling and neuronal degeneration. Spinal cord lesions are poorly documented. The condition is usually responsive to steroid treatment, suggesting an immune-mediated mechanism.

Granulomatous radiculitis of the seventh and eighth cranial nerves of calves

This is a rare condition affecting young calves and characterized clinically by facial paralysis and pathologically by the presence of multifocal granulomas affecting mainly the roots of cranial nerves VII and VIII. The etiology is unknown; however, *Mycoplasma bovis* was suggested as a cause because some affected calves had concurrent mycoplasmal otitis media.

NEOPLASTIC DISEASES OF THE NERVOUS SYSTEM

Primary neoplastic disease of the CNS of animals is rare in species other than the dog and cat. Neoplasms derived from virtually every cell type in the nervous system are recorded.

The tumors may be *congenital*, and these do not differ in their characteristics from similar tumors in adult animals with the possible exceptions of: medulloblastoma, which is thought to be derived from the residual cells of the external granular layer of the cerebellum; craniopharyngiomas, which are thought to arise from remnants of Rathke's pouch, which forms the adenohypophysis; chordoma, which is thought to arise from remnants of notochord; intracranial teratoma, which is probably derived from germ cells; and cystic epidermoid tumors, which are thought to result from the inclusion of surface ectodermal cells at the time of closure of the neural groove. The relatively high incidence of tumors in Boxers and Boston Terriers may indicate a hereditary predisposition, which these breeds also have for endocrine neoplasia. The introduction of computerized tomography (CT) and magnetic resonance imaging (MRI), in addition to the use of immunohistochemistry, have improved our understanding of CNS tumors in various domestic animals and have helped in reaching more accurate diagnoses. Neoplasms of the CNS rarely metastasize to extraneural tissue, and their clinical importance depends on their destructive effect on host neural tissue and the resulting neurologic deficits.

The conventional tumors of the CNS are discussed here and classified according to the current histological classification published by the Armed Forces Institute of Pathology (AFIP) in cooperation with the World Health Organization (WHO). Tumors of the pituitary and nonchromaffin paraganglia are discussed with the Endocrine system.

Tumors of neuroepithelial tissue

Astrocytoma

Astrocytoma is the most common primary intracranial tumor (Fig. 3.144A–E). Astrocytomas are found most commonly in dogs, but are reported also in cats and cattle, and may occur in the brain or cord but are more prevalent in cerebrum, thalamus, hypothalamus, and midbrain. In dogs, astrocytomas are common in brachycephalic breeds but can occur in any breed. Astrocytomas have no age predilection, but are more prevalent in middle-aged or older dogs. The gross appearance varies, depending largely on the degree of malignancy. These tumors can be very difficult to detect grossly, especially when they involve white matter or grow slowly. They are then white and, because of their firmness, may be more readily palpable than visible. Their presence may be suspected only by deviation of some architectural feature (Fig. 3.144B, D). Larger and more malignant tumors are prone to vascular accidents and necrosis, and they are then easy to see (Fig. 3.144E), but the margins are never discrete, especially not when they are surrounded by edematous tissue. The extent of the tumor is always much greater than can be appreciated grossly.

Histologically, these tumors are very diverse and are classified as *low-grade astrocytoma* (well differentiated), *medium-grade astrocytoma* (anaplastic), and *high-grade astrocytoma* (glioblastoma).

Low-grade astrocytoma appears as an unencapsulated expansile and subtly invasive mass that replaces pre-existing tissues and has low to moderate numbers of bland round to oval cells. In most cases, the neoplasm appears as an increased population of fibrous astrocytes that individually are not clearly malignant (Fig. 3.144A). Variants of this neoplasm include **fibrillary astrocytoma** (neoplastic cells have scant cytoplasm but abundant fibrillary processes and filaments), **protoplasmic astrocytoma** (neoplastic cells have scant cytoplasm and few short processes and filaments), **gemistocytic astrocytoma** (neoplastic cells have abundant acidophilic cytoplasm and eccentric oval to round nuclei; Fig. 3.144C). Another variant, the **pilocytic astrocytoma** (neoplastic cells are bipolar, elongated (piloid or hair-like) astrocytes and have few Rosenthal fibers), has been reported in both dogs and cats.

In **medium-grade astrocytoma**, the population is denser; the nuclei are a little larger and darker and show slight but definite variations in size and shape but no mitoses. The cells are recognizable as astrocytes. The walls of the vessels may be slightly thickened.

In **high-grade astrocytoma**, or *glioblastoma multiforme*, hemorrhage and necrosis are expected and the adventitial and endothelial cells of the vessels proliferate forming glomeruloid blood vessels. Generally, only a few cells are recognizable as astrocytes. Neoplastic cells have a tendency for pseudopalisading around necrotic areas. Pleomorphism, giant nuclei, and multinucleated giant cells are common. Mitotic figures are common and atypical.

Astrocytomas exhibit positive immunostaining for glial fibrillary acidic protein (GFAP), S-100 protein, and vimentin. The staining pattern for GFAP varies from sparse to abundant.

Oligodendroglioma

This is the easiest of the glial tumors to recognize even when growing rapidly. This tumor is reported in dogs especially in brachycephalic breeds and rarely in cats. Grossly, it usually appears well demarcated, being gray, soft, and almost fluctuating (Fig. 3.145A). Hemorrhage and necrosis occur but are unusual. The tumor is densely cellular with almost no stroma. The nuclei are remarkably uniform and like those of normal oligodendroglia in size and shape. The cytoplasm does not stain, but its membrane does, so that the nucleus seems to lie in a clear

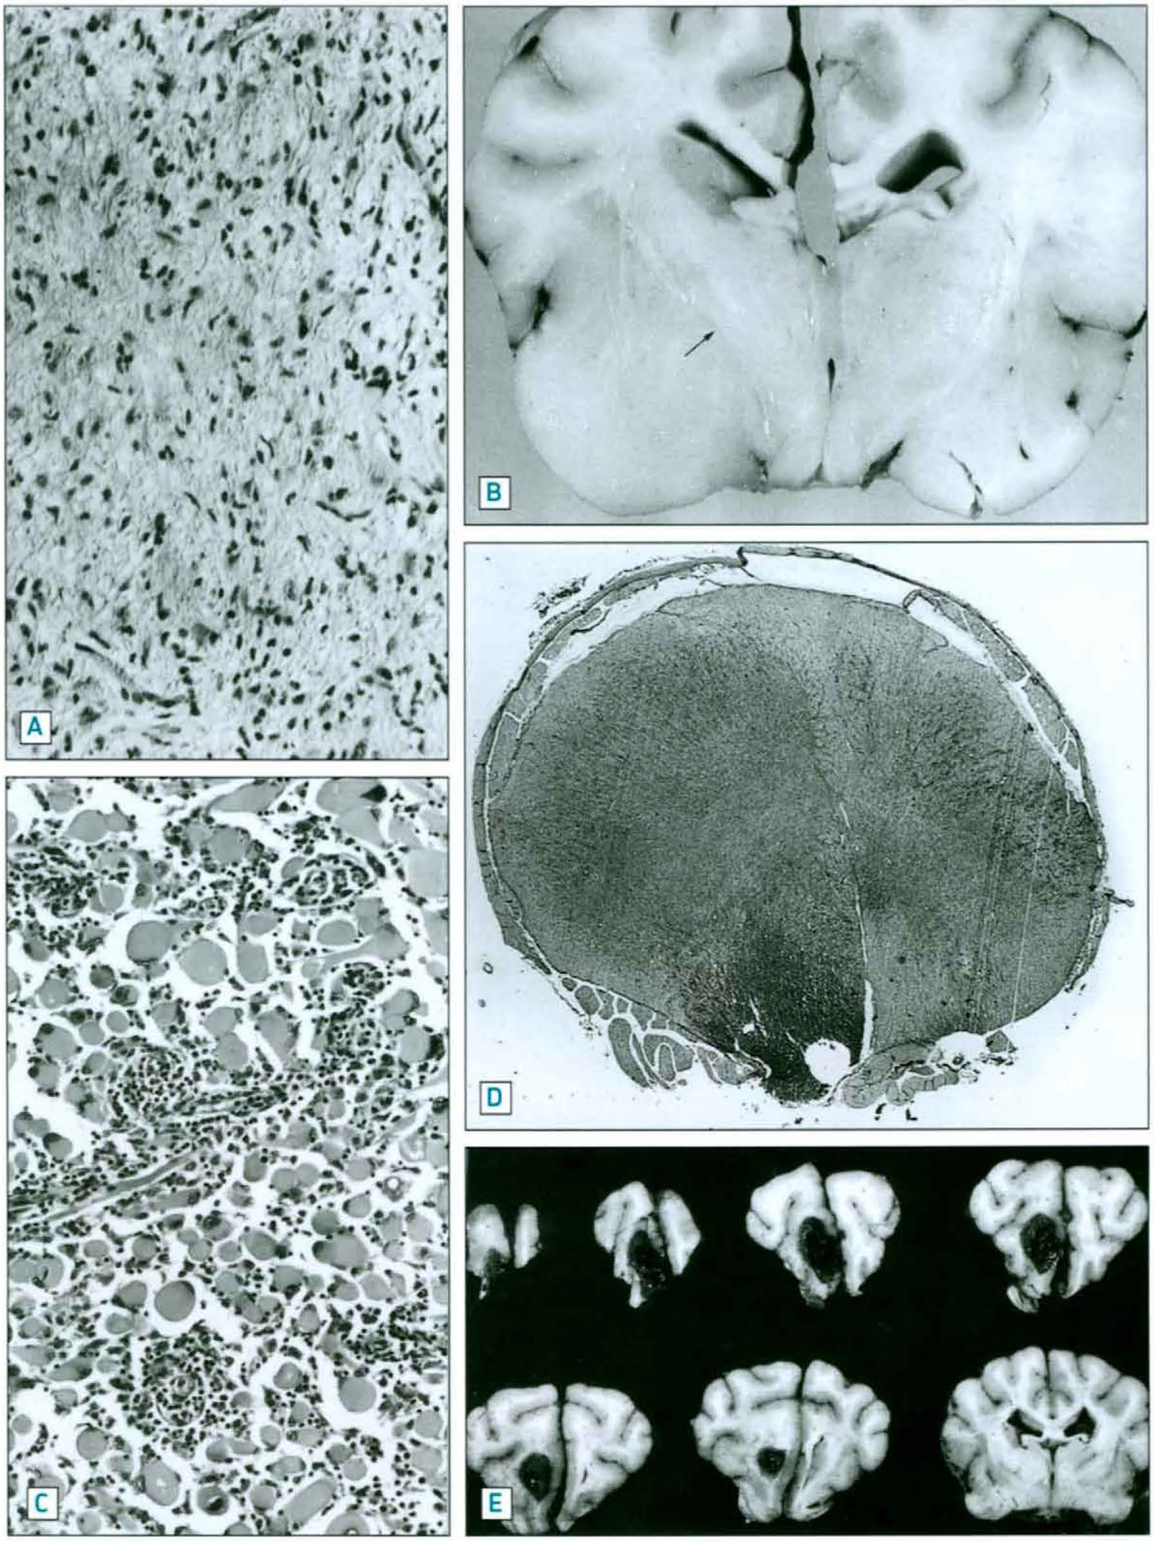

Figure 3.144 **A. Fibrous astrocytoma** in a dog. **B. Astrocytoma** in piriform lobe in a dog. Note lack of definition but displacement of internal capsule (arrow) by the homogeneous tumor. **C. Gemistocytic astrocytoma** in a dog. **D. Astrocytoma** of spinal cord in a dog. **E. Hemorrhagic astrocytoma** of left frontal lobe in a dog.

polyhedral or rounded halo (honeycomb cell pattern) (Fig. 3.145B). These tumors occur in white matter, and those near the third ventricle may contain areas distinguishable as astrocytoma or ependymoma. Blood vessels may proliferate especially at neoplasm margins to form glomeruli-like vessels. Mucinous degeneration and cyst formation may occur in these tumors and mineralization may occur in some of them. There are no clear indices of malignancy, although all must be regarded as malignant. Oligodendrogliomas do not stain with GFAP; however, the neoplastic cells are usually intermingled with some astrocytes that readily stain with GFAP.

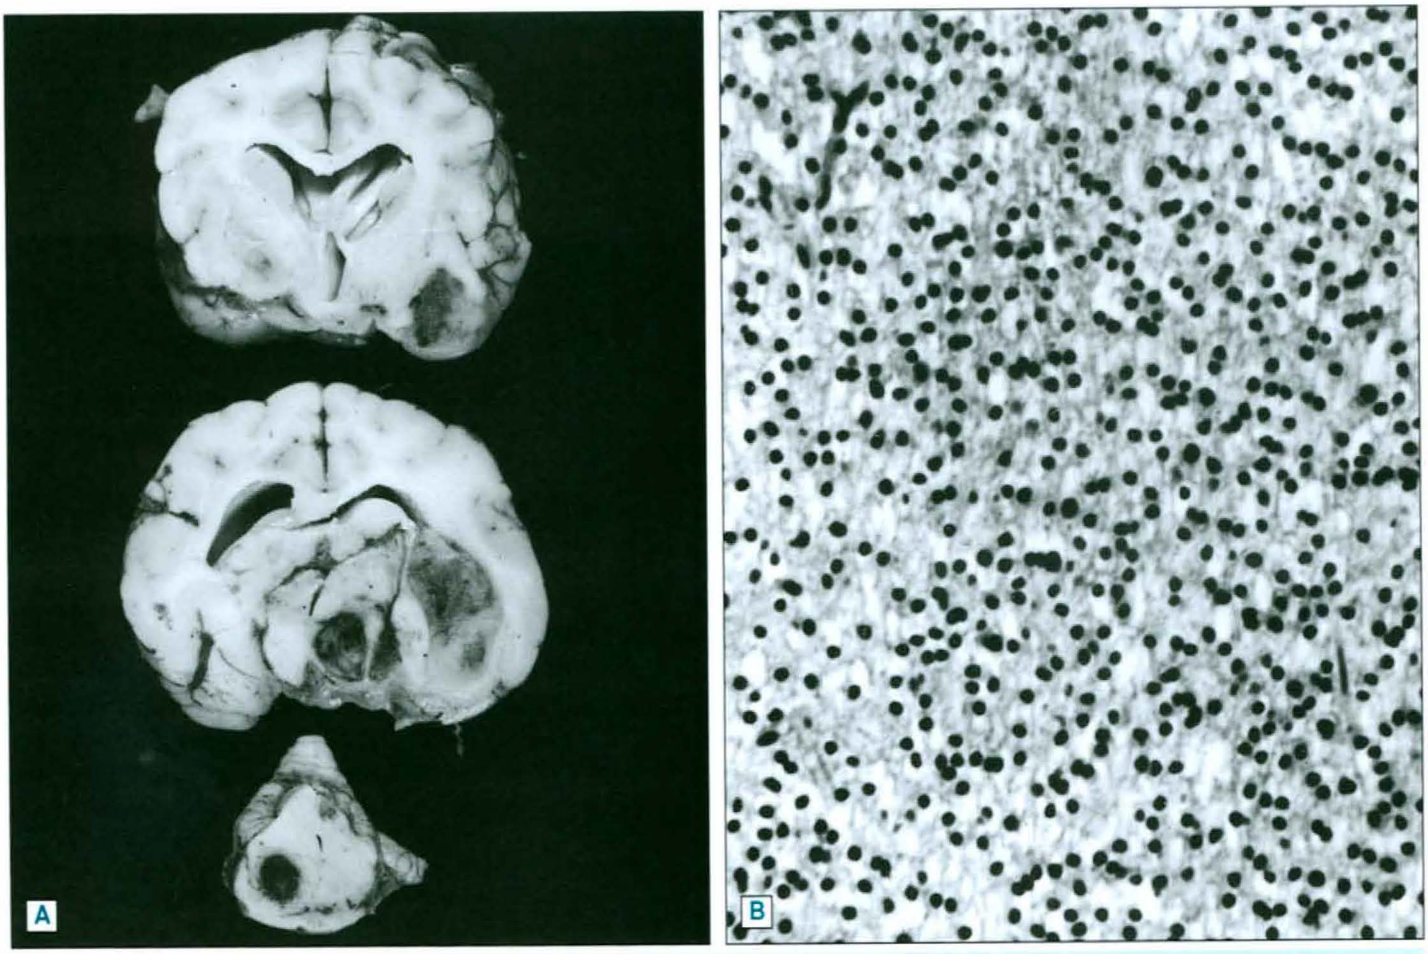

Figure 3.145 A. Oligodendroglioma involving right side of brain stem and piriform lobe in a dog. (Bottom section reversed to show caudal extension in brain stem.). **B.** Histologic pattern of oligodendroglioma.

Oligoastrocytoma (mixed glial tumor)

This glial neoplasm is composed of both neoplastic astrocytes and oligodendroglia.

Gliosarcoma

This rare glial tumor is composed of highly anaplastic glial cells with abundant sarcomatous components. Positive GFAP staining should differentiate this tumor from other spindle cell tumors, e.g., fibrosarcoma.

Gliomatosis cerebri

This is a diffuse infiltrating disease of dogs, predominantly of brachycephalic breeds, and humans characterized by an *infiltrative cell type reminiscent of astrocytes* rather than by the formation of a distinct tumor mass. The infiltrates involve the brain, often bilaterally but asymmetrically, with discontinuous areas also in the spinal cord. There is no tumor "mass," rather diffuse enlargement of affected regions, the cells insinuate among normal structures that remain intact with only slight damage to axons and neurons. Where the infiltrates involve the molecular layer of the cerebrum or the deep white matter, they spread in veils on leptomeninges and ependyma.

Gliomatosis cerebri is composed mainly of cells reminiscent of fibrillary astrocytic cells but there are also oligodendrocytes, cells of transitional character, and small unclassified cells (Fig. 3.146). The origin of the neoplastic cells in the canine cases is still controversial, as they do not stain with glial markers such as GFAP. The pattern of infiltration is unexplained, but involves participation of cell adhesion molecules.

Ependymoma

Ependymomas are neuroglial tumors derived from the lining epithelium of the ventricles and central canal of the spinal cord. Most arise about the third ventricle. They are gray and fleshy but may be dark from hemorrhage if they project into a ventricle. They are more prevalent in dogs and cats, but are reported in horses and cattle.

The tumors are usually densely cellular and those arising about the third ventricle may be difficult to distinguish from undifferentiated pituitary tumors. The nuclei are small, dark, and regular and the cytoplasm has no distinct boundaries. Pseudorosettes form around blood vessels, and are characterized by a perivascular nuclear-free zone. True rosettes are also present and appear as tubular cavities lined by cells of epithelial appearance. The cells forming true rosettes are bound together by desmosomes, have basally located nuclei, and

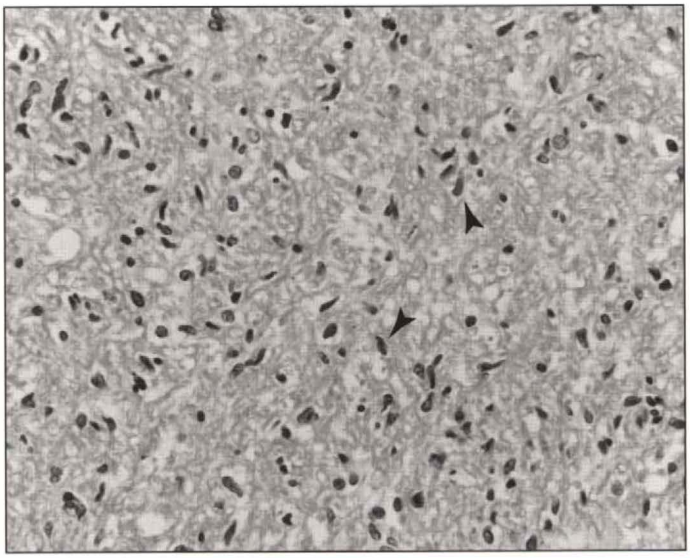

Figure 3.146 Gliomatosis cerebri appears as an increase in the cellularity of cerebrocortical white matter due to diffuse infiltration of neoplastic cells (arrowheads) that do not form a discrete mass or efface the pre-existing tissue (Boxer dog).

have surface cilia anchoring phosphotungstic acid hematoxylin (PTAH)-positive blepharoplasts. A **papillary variant** does exist and is characterized by branching papillary stroma covered by recognizable, usually ciliated, ependymal cells (Fig. 3.147). Ependymomas of the spinal cord may be more papilliferous than those in the brain, with tumor cells attached to fronds that are supported by a delicate stroma and embedded in mucinous intercellular stroma. A **clear cell variant** resembling oligodendroglioma is only reported in humans. **Malignant ependymoma** is characterized by increased cellular atypia and mitoses.

Most canine ependymomas stain negatively for GFAP; however, feline and equine cases are reported to stain positively for this marker. Most ependymomas show slight positive staining for vimentin and cytokeratin. Human ependymomas stain strongly with anti-epithelial membrane antigen antibody (EMA); however, information about immunoreactivity of domestic animal ependymomas to EMA is not available.

Choroid plexus tumors

These are rare, reported in cats, horses, and cattle, and occur with higher frequency in dogs. They may be papillomas or carcinomas. They are vascular papillary growths that implant widely on the meninges. The cells retain recognizable choroidal character (Figs 3.148, 3.149). According to cellular atypia and invasiveness, these tumors can be classified as papilloma or carcinoma. Internal or communicating hydrocephalus is a complication. They express epithelial markers, e.g., pancytokeratin, but not glial markers, e.g., GFAP.

Neuronal and mixed neuronal glial tumors

These tumors of adult animals are composed of neurons and/or neurons admixed with glial cells.

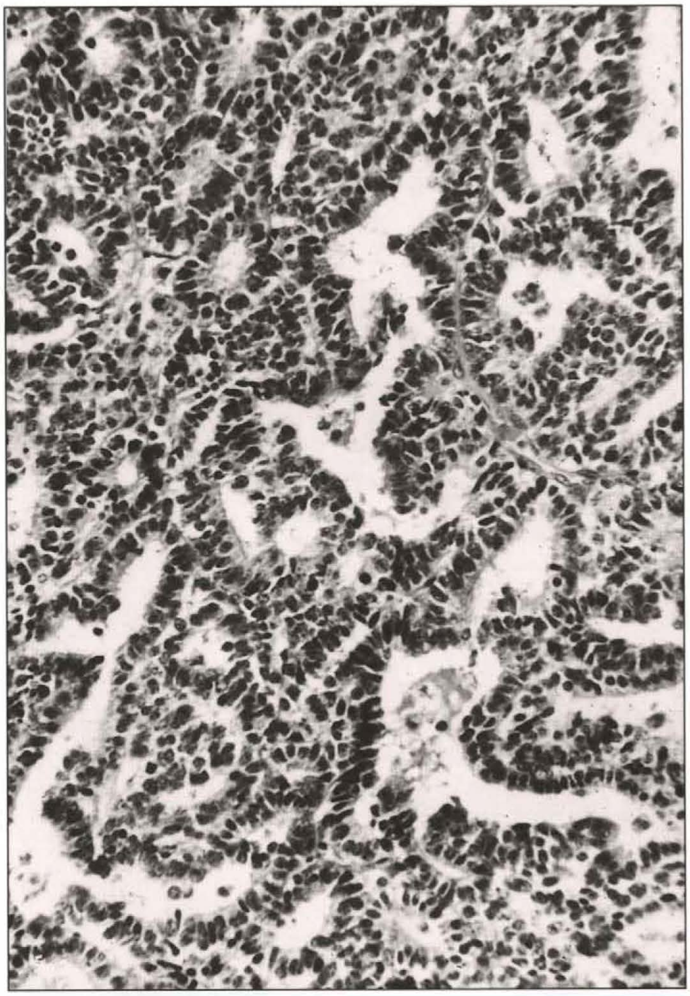

Figure 3.147 Typical branching papillary structure in an **ependymoma** in a dog.

Gangliocytomas

These are extremely rare tumors that are reported in dogs, a cow, and a horse. They appear to have a predilection for the cerebellum. The tumor is composed of cells reminiscent of large ganglion cells or mature pyramidal cells. Neoplastic cells do not stain with glial markers but show different reactivity with neuronal markers such as neuron-specific enolase (NSE) and synaptophysin.

Ganglioglioma

This is another rare bicellular tumor composed of neoplastic neuronal cells and neoplastic astrocytic cells. They have the same immunohistochemical staining pattern as gangliocytomas, but the astrocytic cells stain with GFAP.

Olfactory neuroblastomas (esthesioneuroblastoma)

This rare malignant tumor arises from primitive neurosensory cells present in the olfactory mucosa. They are uncommon but have been identified in various animal species, mainly dogs and cats. The olfactory epithelium is unique amongst neuronal structures in that the basal cells retain the ability to divide and differentiate to become

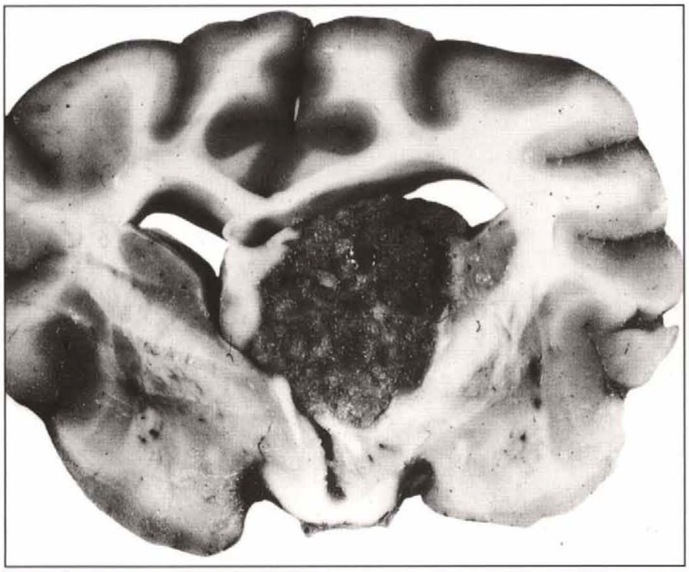

Figure 3.148 Choroid plexus papilloma in a dog.

sustentacular cells or bipolar neurosensory cells. The tumors are locally aggressive and may penetrate the cribriform plate. The dense cellular population is homogeneous, arranged in sheets or clusters but also forming true and pseudorosettes (Flexner-type rosettes and Homer Wright-type pseudorosettes). They may be palisaded on trabeculae, oval in shape with scant cytoplasm. Cytoplasmic processes may form an abundant, delicate fibrillary matrix. The detection of type C retroviral particles identified with feline leukemia in spontaneous olfactory neuroblastomas of cats is of interest. Neoplastic cells stain with different degrees of reactivity for both neuronal and epithelial immunohistochemical markers, e.g., NSE and cytokeratin respectively.

Embryonal tumors

These tumors arise from primitive or progenitor cells present in the nervous system and are capable of differentiating into different lineages including glial or neuronal cell lines.

Medulloblastoma (cerebellar primitive neuroectodermal tumor)

Medulloblastoma, well-known in children, is rare in animals, but occurs in the young of several species (Fig. 3.150), mainly calves and dogs. There is no such cell as a "medulloblast," the name invented for this tumor of unknown parentage. It is currently thought to arise from undifferentiated cells found in neonatal life beneath the cerebellar pia mater and thought to be the precursors of the cerebellar cortex. These tumors grow rapidly. Histologically, they are densely cellular with scant stroma and few vessels (Fig. 3.151A). The cells are small and classically "carrot-shaped" with oval or elongate nuclei and the cytoplasm tapering at one pole. They are also supposed to produce small perivascular palisades and pseudorosettes (Fig. 3.151B). These classical features are not always present, and then there is nothing by which this tumor can be identified except its location in the cerebellum. The term medulloblastoma should be limited to those embryonal tumors originated in the cerebellum. Tumors of this histological appearance in other sites in the brain of calves or other species are called *primitive neuroectodermal tumor* not medulloblastoma. Medulloblastomas stain positively for different neuronal markers including NSE and synaptophysin and some show positive staining for GFAP.

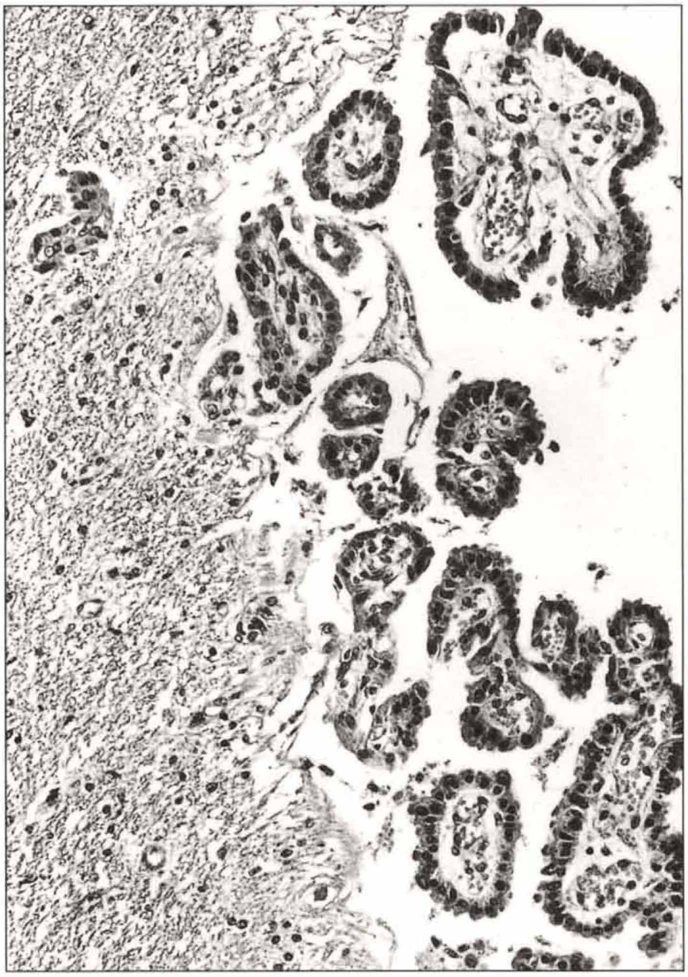

Figure 3.149 Invasion into the periventricular white matter of a dog by a **choroid plexus carcinoma**.

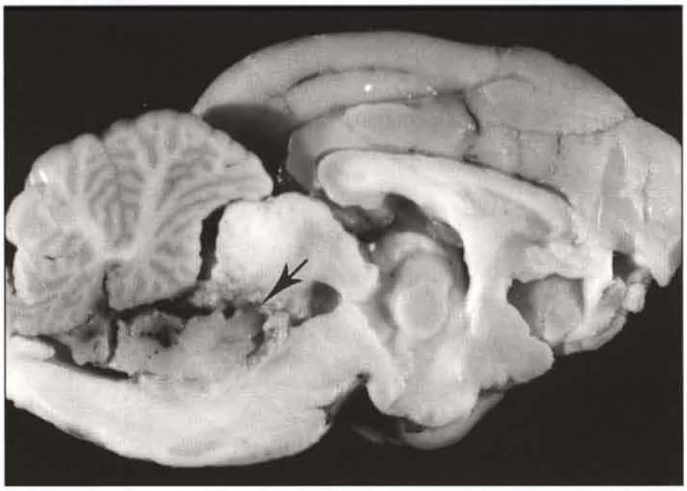

Figure 3.150 Medulloblastoma between cerebellum and fourth ventricle with extension into colliculus (arrow) in a cat.

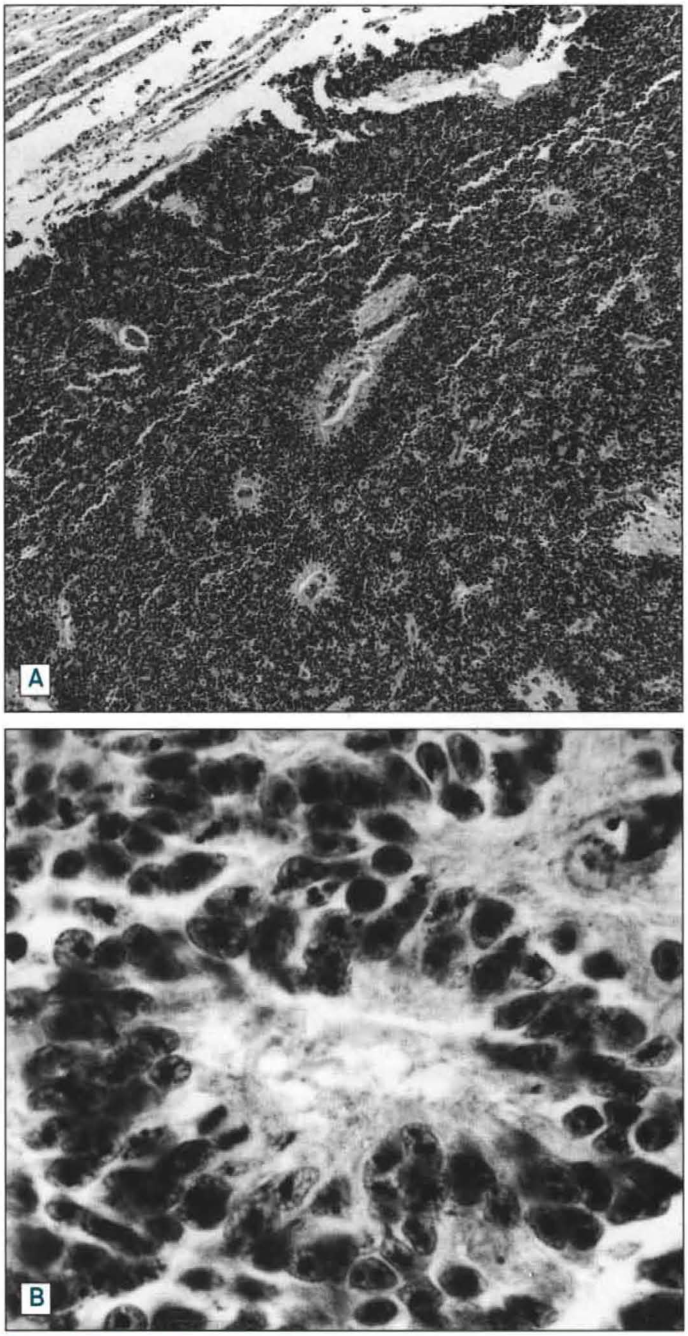

Figure 3.151 Histologic patterns of **medulloblastoma** in a calf. Pseudorosettes are visible in (**A**) and are detailed in (**B**), as circular groupings of dark tumor cells around a central pale area containing neurofibrils. (Courtesy of MD McGavin.)

Neuroblastomas

These tumors are rare and occur in any part of the CNS. Histologic criteria to distinguish them from other cellular neurogenic tumors are not satisfactory and identification must depend on other means. They are thought to arise from primitive neuroepithelial cells with differentiation towards postmitotic neuroblasts. The histologic appearances are similar to those of medulloblastoma, consisting of masses of small rounded cells that resemble lymphocytes, with hyperchromatic nuclei and scant cytoplasm. The presence of rosettes and pseudorosettes is helpful. Neoplastic cells stain positively with neuronal markers and negatively with glial markers such as GFAP.

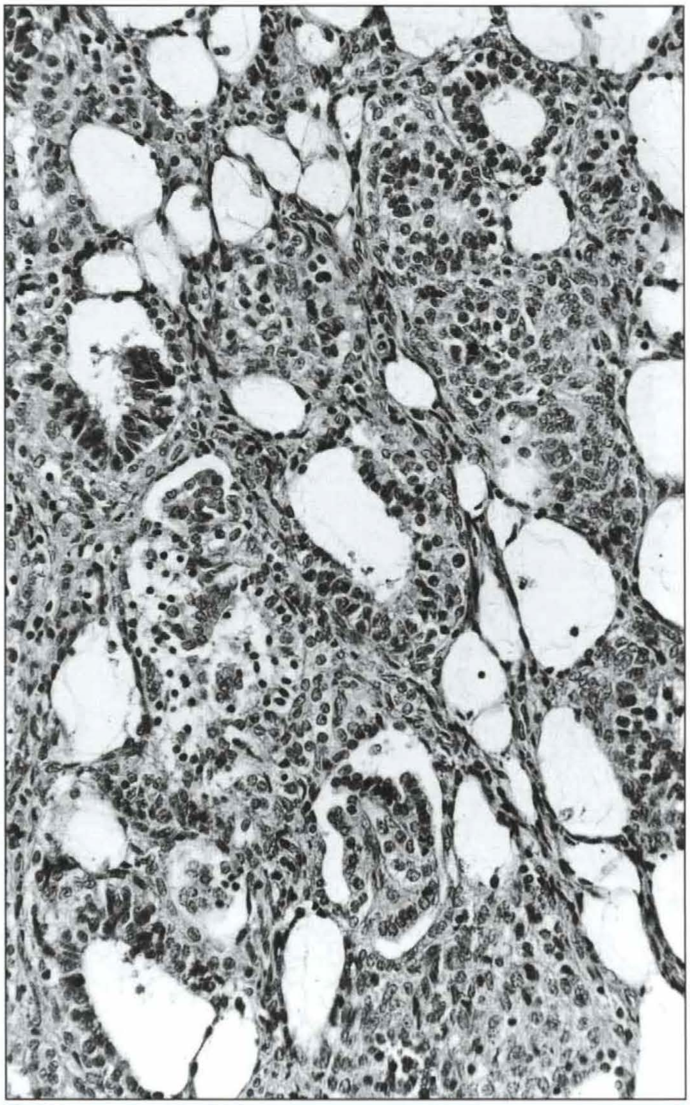

Figure 3.152 Neoplastic cells showing tubular structures with infoldings in **spinal nephroblastoma** in a dog.

Thoracolumbar spinal tumor of young dogs (spinal nephroblastoma)

These are single intradural masses occurring in young, large-breed dogs in the region between the tenth thoracic and second lumbar segments, and affected animals are presented with signs of cord compression. The tumor likely originates from the renal primordium, a renal ectopic embryonic remnant from which diverse nephron cell types are derived, present at this area. The histologic appearance is of glandular areas intermingling with cellular areas. The glandular areas consist of rosettes and tubules, the latter tortuous, branching and sometimes papilliferous, with infoldings reminiscent of embryonic glomerular capsules (Fig. 3.152). The cellular areas contain densely packed cells of blastema appearance with ovoid clear nuclei and indistinct cytoplasm. Some streaming is evident but muscle fibers are not present. In some of these tumors, glomerular structures can be recognized with confidence as can tubular cross-sections strongly

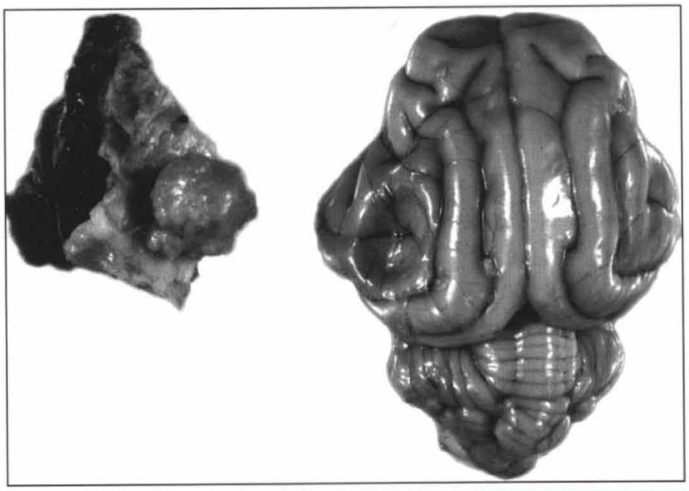

Figure 3.153 Meningioma attached to dura and calvaria (left), and leaving an indentation in the left parietal cerebral cortex of a cat. (Courtesy of RF Slocombe.)

suggestive of distal renal tubules. Presumably these tumors arise from ectopic embryonic remnants but notably the kidneys do not contain neoplasm although nephroblastomas are well recognized in dogs. From time to time, undifferentiated tumors of embryonic type and possibly derived from remnants of pronephros are seen in the cervical region of dogs and sheep. These tumors stain positive for cytokeratin and negative for glial and neuronal markers.

Pineal tumors

These tumors are rare. The benign variant is called *pineocytoma* and the malignant variant is called *pineoblastoma*. They are described in horses, cattle, and dogs. The diagnosis is based on the site of the tumor and its replacement of the pineal body. Other positive identifying characteristics are absent. Microscopically, there is a resemblance to medulloblastoma. The tumor may extend into midbrain and thalamus. Teratomatous tumors with characteristics of the gonadal teratomas are not described in the pineal gland of animals. Specific markers for tumors in animals are not reported.

Tumors of the meninges

These include the only tumor arising from meningothelial cells, **meningioma**, and those arising from nonmeningothelial cells, such as fibrosarcoma and sarcomatosis.

Meningiomas

Meningioma is the most common type of intracranial tumor in the cat and it is one of the commonest of the intracranial and intraspinal tumors in man, and is relatively common in dogs, rare in cattle, and not recorded in horses. It rises within the meninges, usually in close association with the dura, and grows expansively, compressing but seldom invading the brain (Fig. 3.153). Those in humans are presumed, by virtue of their site and structure, to arise mainly from the arachnoid granulations and also from islands of arachnoid cells that lie in the inner surface of the dura mater. A rare variant of meningioma is the **paranasal meningioma**, which arises from meningeal arachnoid cells that are trapped within or outside bone during development of the skull, and is reported in horses and dogs. The meningiomas observed in animals conform in histologic type to those observed in humans.

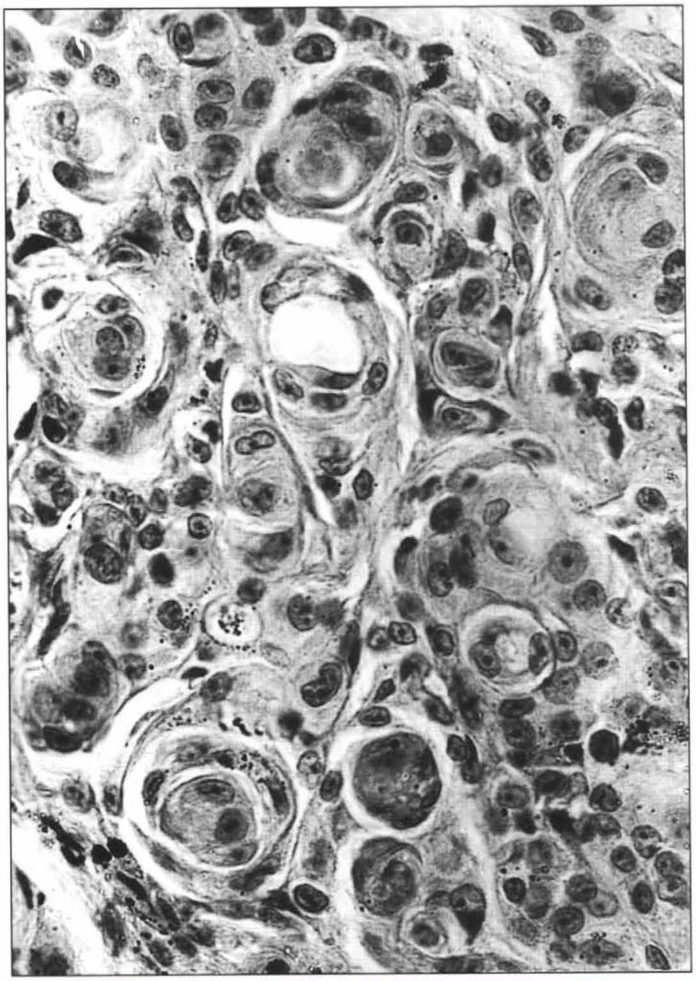

Figure 3.154 Histologic appearance of a **psammomatous meningioma.**

Meningiomas are globular, ovoid or tuberous, sometimes plaque-like, well circumscribed, and have a smooth surface. They are gray, sometimes yellow, on cut surface, firm, and may be gritty. Feline meningiomas are more easily separated from the brain parenchyma than are the canine ones, which are usually more interdigitated into the brain parenchyma. In cats, common locations include the tela choroidea of the third ventricle and the supratentorial meninges. They may be multiple in cats. There are several histologic varieties.

The **meningotheliomatous or epithelioid meningioma** is diffusely cellular with the cells in sheets or pseudo-alveoli. The stroma varies in amount, is richly vascular, and may contain much collagen. The cells are large with abundant finely granular pale cytoplasm without a distinct margin, and the nuclei are spherical or ovoid and rather vesicular. The **psammomatous meningioma** has the same general features as the foregoing, but the cells arrange themselves in whorls (Fig. 3.154). In the center of a whorl, lamellar hyaline tissue forms, derived possibly from cells, stroma, or a blood vessel. As the hyaline focus expands, it tends to be impregnated with salts of calcium and iron to form *psammoma bodies*. The **fibroblastic meningioma** is similar to fibroblastic tumors elsewhere. The **transitional or mixed type** has features of both epithelioid and fibroblastic meningioma.

Angioblastic meningiomas are highly vascular with prominent endothelial cells in formed vessels and lining vascular clefts. The vessels are surrounded by spindle cells giving a distinct resemblance to hemangiopericytoma. **Papillary meningiomas** are extremely rare in animals and composed of meningothelial cells arranged in papillary structures supported by fibrovascular cores. **Myxoid meningioma** is similar to myxoma elsewhere. There may be some difficulty in separating **hemangioma** from highly vascular meningiomas; both contain endothelial cells, pericytes, and stromal cells, the latter of uncertain parentage.

Granular cell meningiomas resemble granular cell tumors that occur elsewhere. They are included here because they do occur in the meninges and spinal nerve roots of dogs and the notion is attractive that some, at least, of the tumors are derived in common with cells of nerve sheaths and other neural crest mesenchyme. The tumors are usually small and well circumscribed but not well encapsulated. The cells are large and rounded, the cytoplasm clear apart from fine granules that may be few or numerous, and the nuclei small and rounded. The cytoplasmic granules are acidophilic and PAS-positive. Delicate stroma, in which amyloid may be deposited, separates the cells individually or in small groups. Stigmata of anaplasia are absent.

Most intracranial meningiomas are benign as indicated by low frequency of metastases and failure to invade the brain. By these criteria, ~2.5% are malignant and may metastasize. In contrast, extracranial meningiomas, which occur mainly in the paranasal region and orbit, are anaplastic and locally aggressive. Meningiomas stain positively for vimentin and negative for synaptophysin and GFAP. Staining for cytokeratin, NSE, and S-100 usually yield positive results but with sparse to moderate expression.

Fibrosarcoma

Fibrosarcomas may provide circumscribed or diffuse involvement of the meninges, or they may form local lesions of the brain or cord. They are not rare. Those of the brain and cord retain a perivascular orientation even though they are infiltrative. Histologically, some are acceptably fibrosarcoma but some are more pleomorphic and anaplastic spindle cell tumors. The histogenesis of these tumors is uncertain. They may arise from fibroblasts, pericytes, or resident reticuloendothelial cells of the monocyte-macrophage series. Some of the more anaplastic astroglial tumors provoke a remarkable degree of capillary endothelial hyperplasia and fibrosis of the vascular adventitia in brain and meninges. The proliferating fibroblastic cells are atypical, their appearance consistent with fibrosarcoma.

Meningeal sarcomatosis

Meningeal sarcomatosis is a rare condition reported only in dogs and characterized by diffuse infiltration of the leptomeninges, especially of the lumbar spinal cord, by pleomorphic neoplastic mesenchymal cells. Tumor may extend along the entire cerebrospinal axis from medulla to sacral cord. Neoplastic cells are present usually circumferentially in the subarachnoid space and may invade the subpial parenchyma of the spinal cord and to lesser extent the brain. Individual cells are pleomorphic, where the main neoplastic cells are large irregularly round cells (35–80 μm) with abundant cytoplasm and large round-to-ovoid hyperchromatic nuclei (20–65 μm). Neoplastic cells usually have a high mitotic rate and up to threefold anisokaryosis. In addition, several lymphoid, plasmacytoid, and histiocytic cells are present amid the neoplastic cells. A few multinucleated giant cells and intact neutrophils may also be present. The neoplastic large cells stain positively for vimentin. They usually stain positive, but with sparse to moderate expression, for CD18 and actin. They stain negatively for lymphocyte markers, S100, cytokeratin, and GFAP.

Hematopoietic tumors

Hematopoietic tumors such as lymphosarcoma, multiple myeloma, and malignant histiocytic tumors that originate in extraneural locations can metastasize to the CNS as part of their multisystemic metastasis, however in the following section we will describe those hematopoietic tumors that originate primarily in the CNS.

Lymphoma/lymphosarcoma

Primary CNS lymphomas are reported mainly in dogs and cats and sporadically in ruminants. They are mostly intraparenchymal and have an angiocentric (perivascular) pattern in contrast to lymphosarcomas metastatic from extraneural areas that are usually arranged diffusely in the meninges. Most primary CNS lymphomas are of T-cell type. Histologically, they follow the same morphology as extraneural lymphomas/lymphosarcomas.

Plasma cell tumor

A primary intracerebral intraparenchymal plasma cell tumor has been reported in a dog. An identical tumor was reported in a cat, but the diagnosis of primary neural plasma cell tumor was not confirmed due to incomplete postmortem examination.

Malignant histiocytosis

Primary neural malignant histiocytosis was reported in the right parieto-occipital lobe of a miniature Schnauzer as a poorly demarcated mass composed microscopically of histiocytic cells with many binucleate and multinucleate giant cells. Neoplastic cells stained positively for lysozyme.

Non-B, non-T leukocytic neoplasm (neoplastic reticulosis)

This controversial malignant neoplasm has a histologic resemblance to necrotizing meningoencephalitis (NME) of Pug dogs and granulomatous encephalitis (GME). The term "reticulosis" came into use because of aggregation of reticular fibers around neoplastic cells. Many cases diagnosed previously as reticulosis have been reclassified as lymphoma and a few as histiocytic tumors. The tumor may be single or multiple and can occur in any part of the CNS but is more prevalent in the cerebral white matter. The exact histogenesis of the neoplastic cells is yet to be determined, however, the neoplasm is composed histologically of angiocentric large (25–50 μm) round cells reminiscent of histiocytes and numerous non-neoplastic lymphocytes and macrophages. Multinucleate giant cells may predominate. Neoplastic cells usually show atypia and a moderate mitotic rate. The neoplastic cells stain positively with CD18 and negatively for lymphocyte markers, proving a leukocytic but non-lymphoid origin. The neoplasm has been reported in dogs and rarely in cats, cattle, and horses. The differentiation between neoplastic reticulosis and GME (formerly called inflammatory reticulosis) is difficult. The predominance of neoplastic histiocytic-like cells, cellular atypia, and high mitotic rate should favor the diagnosis of neoplastic reticulosis.

Microgliomatosis

The histogenic origin of the neoplastic cell in this rare neoplasm is controversial. The neoplasm diffusely infiltrates the cerebral white matter and brain stem with cells reminiscent of microglial cells. The infiltration in some cases can be limited to meninges or can be perivascular. In any case, this is a non-mass-forming neoplasm and the brain is almost unremarkable grossly. The neoplastic cells do not cause significant destruction of the pre-existing tissue. Neoplastic cells stain negatively for GFAP. There is strong overlap between microgliomatosis and gliomatosis cerebri. In human microgliomatosis, most neoplastic cells stain for CD18 and other monocyte/macrophage lineage markers. Similar studies on the immunohistochemical markers expressed by canine microgliomatosis are not available.

Tumors of the sellar region

Suprasellar germ cell tumors

Germ cell tumors are presumed to arise from ectopic embryonic germ cells which, intended for the developing gonad, may become widely distributed. They are responsible for a spectrum of tumors in humans, usually in the midline and according to histological features designated as *seminoma, choriocarcinoma, entodermal sinus tumor, and teratoma.* They are revealed early in life and the preferred locations in the cranial cavity are in the pineal region or in the hypothalamus above the sella. These are rare tumors in dogs. Their location and growth pattern is similar to that of pituitary adenomas and some may be misdiagnosed as craniopharyngioma.

The reported canine cases were suprasellar and classified on the basis of location, admixture of distinct cell types and patterns, and positive immunochemical staining for alpha fetoprotein. Sheets and nests of cells resembling seminoma were admixed with areas of vacuolated hepatoid cells, glandular formations similar to those in gonadal teratomas, and occasional foci of squamous epithelium.

Craniopharyngioma

Craniopharyngiomas are thought to arise from remnants of Rathke's pouch, which forms the adenohypophysis. Aberrant differentiation of Rathke's epithelium is common in dogs, expressed in cystic structures lined by respiratory-type epithelium. The craniopharyngioma, in contrast, consists of clumps of epithelial cells palisaded on collagenous stroma. Keratinization may be present to form pearls, as in well-differentiated squamous carcinoma. Degenerative foci contain cholesterol crystals and blood pigments. Neoplastic cells are positive for cytokeratin.

Other primary tumors and cysts

Epidermoid cysts

Epidermoid cysts in the brain are confined to the fourth ventricle and environs. They are rare, probably represent surface ectoderm misplaced at the period of closure of the neural groove, and are described only in humans, dogs, and a horse. The cystic structure is lined by squamous epithelium, and the cavities contain keratinaceous debris. They occur in young dogs and may develop to several centimeters in diameter. The clinical signs are determined by the location of the tumor.

Hamartoma or meningio-angiomatosis

Hamartoma or meningio-angiomatosis is a rare benign lesion, best regarded as a malformation or hamartoma producing circumscribed plaques on the surface of the brain. Blood vessels are in excess in the lesions and are cuffed by proliferating cells that are considered to be meningothelial. The lesion does extend into the underlying neural substance, which shows mixed degenerative and reactive changes.

Metastatic tumors

Secondary tumors can metastasize from extraneural tissue to the CNS. The most common examples include canine hemangiosarcoma, malignant histiocytosis, lymphosarcoma, and malignant melanoma of dogs and rarely other species.

Tumors affecting the CNS by extension or impingement

There are several tumors that do not arise directly from the CNS, but arise from structures adjacent to the CNS and sometimes impinge on the CNS, for example, vertebral osteosarcomas, nasal carcinomas, and chordomas.

Chordoma

Chordomas are rare tumors in animals with the exception of mink and European ferrets. In ferrets they are usually present at the tip of the tail. In humans, dogs, and cats, they are slow-growing persistent tumors mainly of the sacrococcygeal region with some occurring in paraspinal and cranial regions. On the basis of histological characters, *the tumor is presumed to arise from notochordal remnants*. Grossly, they are gelatinous, gray, friable, and lobulated. Histologically, the lobules are not encapsulated but are well defined by bands of connective tissue. The principal cell (physaliferous cells) types are large, clear, and vacuolated with a botanical appearance and some resemblance to cartilage (Fig. 3.155). The cytoplasm contains large clear vacuoles with distinct boundaries. At the periphery of the lobules there are smaller, stellate cells with eosinophilic cytoplasm; mitotic figures are rare in these but they may be the germinative cells. There may be islands of bone or cartilage. Mucinous substance can be demonstrated in the cytoplasmic vacuoles of the larger cells and between the cells; the smaller peripheral cells may contain PAS-positive granules. Differentiation from mucinous chondrosarcoma can be difficult without assistance of immunochemical methods. Chordomas will stain

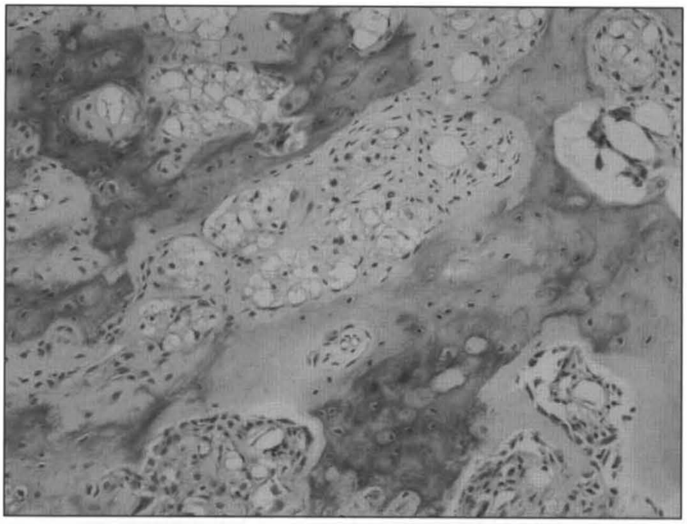

Figure 3.155 A **chordoma** in the tail of a ferret is composed of large, clear, vacuolated principal cells (physaliferous cells) in association with chondro-osteoid metaplasia.

immunohistochemically for cytokeratin, but chondrosarcomas will not. Chordomas also stain positively for vimentin and S-100.

Tumors of the peripheral nervous system

Ganglioneuroma and peripheral ganglioneuroblastoma

These rare tumors originate from the cranial and spinal ganglia and from sympathetic ganglia of the autonomic nervous system. They have been reported in cats, pigs, cattle, dogs, and horses. They can be solitary or multicentric. The few ganglioneuromas observed in cattle have developed in relation to the abdominal sympathetic plexuses. **Ganglioneuroma** is composed of ganglion cells and glial cells.

Ganglioneuroblastoma is composed of poorly to fairly well differentiated ganglion cells with more atypia and high nuclear-to-cytoplasmic ratio. The degree of differentiation of these tumors varies considerably, and they are a mixture of ganglion cells, Schwann cells, and nerve fibers. The ganglion cells show different degrees of differentiation from primitive neuroblasts to some that are remarkably mature. In the more primitive form, **neuroblastoma**, the neoplastic cells may form true or pseudorosettes. The adrenal medullary ganglioneuromas and ganglioblastomas are probably better regarded as hamartomatous malformations rather than as neoplasms.

Paraganglioma

This rare neuroendocrine tumor originates from extra-adrenal paraganglion chief cells associated with autonomic nervous system ganglia. The histologic picture resembles chemodectoma described in Vol. 3, Cardiovascular system. The neoplastic cells stain positive for neuroendocrine markers such as synaptophysin and chromogranin.

Peripheral nerve sheath tumors

These include the benign form (schwannoma, neurofibroma) or the malignant form (malignant schwannoma, neurofibrosarcoma) (Fig. 3.156A–E). The Schwann cell of the peripheral nervous system is accepted as the origin of these tumors. Most of these tumors are seen in the skin. The dermal tumors do pose problems of differentiation from fibrous and perivascular lesions (see the Skin and appendages). In skin, they do show some significant differences from the tumors of nerve trunks and roots.

Schwannomas may be largely solitary infiltrating lesions at any site on a nerve trunk. Those distant from the CNS are not encapsulated or well defined, are difficult to dissect cleanly, and have an ordinary fibrous appearance and texture. Schwannomas of nerve roots tend to be well-defined fusiform tumors. They probably arise from a single nerve and extend proximally and distally in conjunction with the nerve but external to it. In this way they may extend through the intervertebral foraminae and extend also to involve other nerves that have a plexus arrangement such as the brachial plexus. They may arise within and remain within the dura mater, and such tumors may be globose rather than fusiform and soft and discolored from hemorrhage. Expansive intradural growth may be slow and compress the brain or cord, but some of these tumors are malignant and invasive (Fig. 3.156D) and metastasize particularly to the lung.

Any cranial or spinal nerve root may be the site of growth, but in the dog, in which they are not rare, the brachial plexus is most frequently involved. In the thoracic region and on the acoustic nerve (Fig. 3.156A), the tumors tend to originate within the dura. The histologic appearance varies within and between tumors depending on the presence or absence of anaplastic change and the extent of hemorrhage, degeneration, fibrosis, and mineralization. Blood vessels are often prominent but ill formed. The anaplastic tumors consist of closely packed cells with oval or elongate nuclei that give an impression of interlacing streams not supported or guided by reticulin or collagen (Fig. 3.156B). In areas of tumors that are not anaplastic, two patterns are dominant and referred to as Antoni A and Antoni B. *Antoni A arrangements* are repetitive and give the tumor its character. Uniform, fusiform cells are arranged as bands, herring bones, whorls, or palisades (Verocay bodies) (Fig. 3.156C). *Antoni B tissue* is degenerative and may predominate in some sections. It is loose and myxoid, sometimes hyalinized and may be sparsely cellular (Fig. 3.156E). Microcysts may be present in areas of myxoid change. Cartilaginous and osseous metaplasia occur infrequently. A malignant variant is more invasive grossly and occasionally metastasizes to the lung and other organs. The neoplastic cells stain strongly for vimentin and usually stain positively but with varying intensity with S-100, GFAP, nerve growth factor receptor, and myoglobin. They stain negatively with α-smooth muscle actin, which stains hemangiopericytoma and rhabdomyosarcoma positively.

Neurofibromatosis of cattle is a well-recognized Schwannoma. It is common in abattoir material from old animals but has been observed in very young calves. The skin may be affected, but the lesions are usually restricted to deeper nerves of the thoracic wall and viscera. The brachial plexus, intercostal nerves, hepatic autonomic plexus, epicardial plexus, and autonomic nerves of the mediastinum are those most frequently affected in various collective patterns. Sympathetic ganglia, especially the stellate and others of the thorax, are also frequently involved. Affected nerves are thickened, firm, and gray, and may bear yellow-gray nodules. Affected ganglia may be enlarged to several centimeters and appear lobulated on section. The histologic appearances are as described above for Schwannomas, but anaplastic change is rare (Fig. 3.156C).

Eye

GENERAL CONSIDERATIONS

The role of the veterinary pathologist in the diagnosis of ocular disease is usually restricted to histologic examination. Gross pathology of the eye is the realm of the clinical ophthalmologist. The sophistication of ocular clinical examination, including imaging techniques like ultrasound and magnetic image resonance, represents a substantial challenge for the ocular histopathologist. Especially when dealing with globes submitted from ophthalmic specialists, we are being asked to provide very precise histologic counterparts for some very specific macroscopic lesions detected by these increasingly sophisticated clinical examination techniques.

The reluctance of many pathologists to embrace ophthalmic pathology stems from the disappointing quality of sections made from formalin-fixed globes processed by routine methods, from unfamiliarity with ocular anatomy and histology, and from fear of the complex terminology shared by clinical ophthalmologists and ophthalmic pathologists. At least equally daunting is the need to be familiar with the ever-growing list of specific ocular syndromes, the correct identification of which has huge significance in terms of therapy and prognosis. There are many examples in which a perfectly adequate description and general morphologic diagnosis will nonetheless fail to communicate the appropriate prognostic or therapeutic information, simply because the clinician reading the report cannot make the connection between the histologic description and the specific clinical-pathologic syndrome. This is also true when dealing with the histologic manifestations of the innumerable inherited ocular disorders that occur in purebred dogs, the species that indisputably dominates veterinary ophthalmology. In many instances, the correct diagnosis requires the correlation of the lesion with the age, breed, and specific clinical features of the disease.

Ocular fixation

The eye undergoes very rapid postmortem/postenucleation change that not only obscures subtle degenerative lesions but also mimics genuine developmental or degenerative diseases. Even with a globe obtained within minutes of death or surgical removal, improper handling of the specimen frequently results in a section of poor quality. The globe can be speedily and gently removed by grasping the third eyelid with forceps and applying traction to the globe whilst making a circumferential incision at the fornix. Blunt curved scissors inserted through this incision may be used to sever the extraocular muscles and optic nerve, and allow the globe to be removed from the orbit. All orbital fat and extraocular muscles should be gently removed from the sclera to permit rapid penetration of fixative to the retina.

The choice of fixative depends upon the disease suspected and upon the type of examination to which the eye will be subjected. *Formalin* has the advantage of ready availability, ease of shipment, little danger of overfixation, and adequate preservation of color and macroscopic detail for photography. Also, it permits localization in the bisected globe of lesions identified ophthalmoscopically, and the use of electron microscopy should such examination be warranted by the findings of light microscopy. However, formalin penetrates the sclera slowly and there are postmortem changes, including retinal detachment, even in globes fixed immediately after death or surgery. Injection of formalin into the vitreous (0.25 ml for a dog or cat, 2.0 ml for a horse) greatly improves retinal fixation and helps prevent the almost inevitable retinal detachment that follows routine formalin fixation. Rapid-penetrating fixatives such as *Zenker's, Davidson's or Bouin's* are preferred for globes in which preservation of histologic detail (especially retinal detail) is paramount. All render the globe and its refractive media opaque and less suitable for macroscopic assessment and photography than does formalin. All require strict attention to the duration of fixation. *Regardless of the method of fixation, all eyes benefit from hardening in 70% ethanol over about 24 hours to prevent retinal detachment when trimming the globe for embedding.* A mixture of equal parts cold 4% buffered glutaraldehyde and 10% neutral formalin has been recommended as an ocular fixative for both light and electron microscopy.

In all domestic animals, *the preferred section for histology is made from a midsagittal slab which includes optic nerve*, thereby allowing examination of both tapetal and nontapetal fundus in the same section. **Attempting to slice the fixed globe with a scalpel blade is**

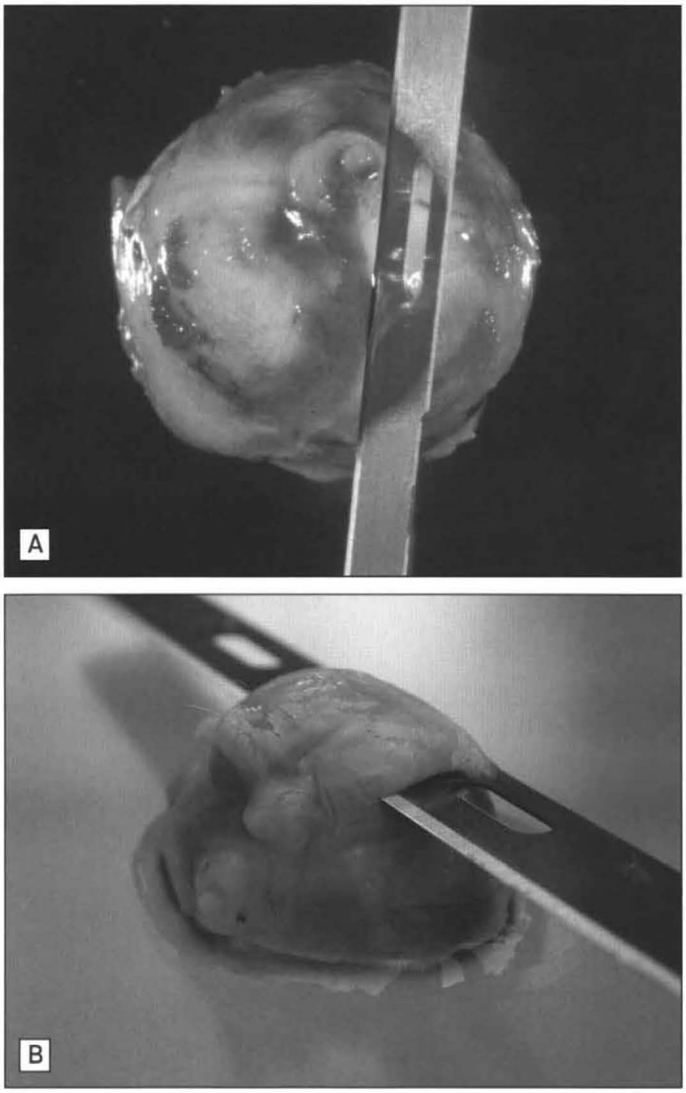

Figure 4.1 A. Trimming a fixed eye. The first incision is made from back to front, perpendicular to the posterior ciliary artery and just adjacent to the optic nerve. **B.** The second cut, made from front to back to avoid detaching the retina, is parallel to the first and far enough to the periphery to miss the lens.

perhaps the single biggest contributor to sections of poor quality. *The optimal cutting instrument is a new disposable microtome blade.* For small globes less than about 1 cm in diameter, an ordinary consumer razor blade is perfectly adequate.

Because there is no easily accessible instruction manual on how to obtain a good histologic section, those details are included here.

- The fixed globe, free of extraocular muscles and eyelids, is opened by a smooth sagittal incision beginning adjacent to the optic nerve and ending with the cornea.
- The correct 6:00–12:00 orientation, needed to capture tapetal and nontapetal fundus, is insured by making the incision at right angles to the orientation of the posterior ciliary artery (Fig. 4.1A).
- The open globe is then inspected for macroscopic lesions.
- A second cut, parallel to the first, is made from the cornea backward through the retina (Fig. 4.1B).
- That second cut should be far enough to the periphery to leave the already-bisected lens undisturbed (for a second cut through the lens will surely dislocate it).
- The resulting slab should be lifted carefully into a thick processing cassette or a tissue bag.
- Even though the piece of tissue is as much as 1 cm thick, it is hollow and thus presents no difficulty in terms of automated tissue embedding procedures.

DEVELOPMENTAL ANOMALIES

Ocular developmental defects are common in domestic animals, particularly in purebred dog breeds in which extensive linebreeding has been used to increase the predictability of the phenotype. Many of the defects involve the eyelids and result from accentuation of anatomic peculiarities of the breed, such as entropion from deliberate enophthalmos or misdirected hairs from overly prominent facial folds. Such anomalies are clinically obvious and amenable to surgery, and rarely require the attention of a pathologist.

Anomalies of the globe are usually multiple, which reflects the stepwise induction and interdependence of the various parts of the developing eye. Without proper consideration of ocular embryology, any discussion of the lesions found in anomalous eyes threatens to be just a catologue of observations rather than a roadmap to understanding that such lesions are all predictable results of a relatively small number of possible errors in organogenesis. It is also important to recognize the differences in normal ocular structure among the various species, and the different rates at which mature form is attained. For example, the retina of carnivore eyes continues to develop for about 6 weeks postnatally, whereas that of ruminants and horses is mature at birth. Thus, something like retinal dysplasia is necessarily an in utero event in ungulates, but may be in response to early postnatal injury in carnivores.

Review of ocular organogenesis

The primary optic vesicle is an evagination of the forebrain that, with differential growth of brain and surface ectoderm, becomes separated from the presumptive diencephalon by the *optic stalk.* The

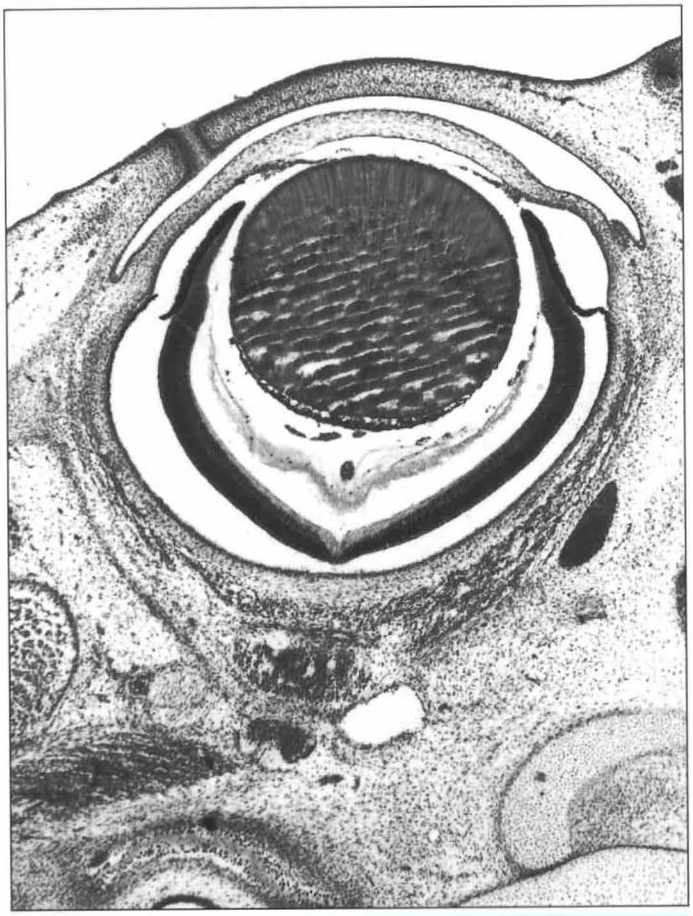

Figure 4.2 Canine embryo at 34 days gestation. Lids fused, cornea fully formed. Large lens surrounded by complete vascular tunic derived posteriorly from hyaloid artery and anteriorly from the future pupillary membrane. Iris not yet formed.

apposition of primary optic vesicle to overlying surface ectoderm induces a focal ectodermal thickening, the *lens placode*. The placode grows to form a primitive *lens vesicle*. It is the developing lens that orchestrates the invagination of the optic vesicle to form the bilayered *optic cup* and bring the lining neuroectoderm into the apposition that provides the future photoreceptor and pigment epithelial layers. Surrounding the optic cup is a mass of *mesenchyme*, derived from neural crest, which will form the vascular and fibrous tunics of the eye (iris and ciliary body stroma, corneal stroma and endothelium, choroid and sclera) under the induction of the differentiating neuroectoderm (Fig. 4.2). *Ocular adnexa and muscles* form independently and seem not to require normal development of the globe, as evidenced by the presence of normal lacrimal gland, lids, and extraocular muscles in most cases of severe microphthalmos.

Defective organogenesis

Failure of the eye to attain even the stage of optic cup is a rare occurrence and is usually of unknown cause. The defect is usually bilateral but asymmetrical, and the severity of the defect relates to the stage of organogenesis at which the insult occurred. Failure of formation of the primary vesicle, or its early and complete regression, is *true anophthalmos* and is very rare. Failure of optic vesicle invagination gives rise to the very rare *congenital cystic eye*. Incomplete invagination results in *congenital retinal nonattachment*. Failure of division (or subsequent fusion) of the optic primordium as it grows from the telencephalon results in *cyclopia*, or *synophthalmos*, a single dysplastic midline globe.

Anophthalmos and microphthalmos

Anophthalmos, total absence of ocular tissue, is a very rare lesion, and almost all cases described are more correctly termed *severe microphthalmos,* in that some vestige of eye is found in serially sectioned orbital content. The usefulness of distinguishing between the two is questionable, and *many authors have adopted the term "clinical anophthalmos" for all such cases*. Concurrent anomalies of skeletal and central nervous systems are common.

Macroscopic examination of orbital content usually reveals a normal lacrimal gland and vestigial extraocular muscles. The globe is usually recognized as an irregular mass of black pigment, with structures such as cornea or optic nerve variably recognizable. Histologically, there is almost always a mass of pigmented neurectoderm, reminiscent of ciliary processes, and some effort at retinal differentiation (Fig. 4.3). There is frequently some remnant of lens, a finding that suggests regression of an embryonic globe that had reached at least the stage of optic cup. One or more plates of cartilage, presumably derived from third eyelid analog, are common.

Cyclopia and synophthalmos

Damage to the prosencephalon prior to the outgrowth of the optic vesicles may result in improper separation of paired cranial midline structures, including eyes. *Cyclopia is a fetal malformation characterized by a single median orbit containing a single globe.* Most specimens have some duplication of intraocular structures, such as lens, iris, or hyaloid

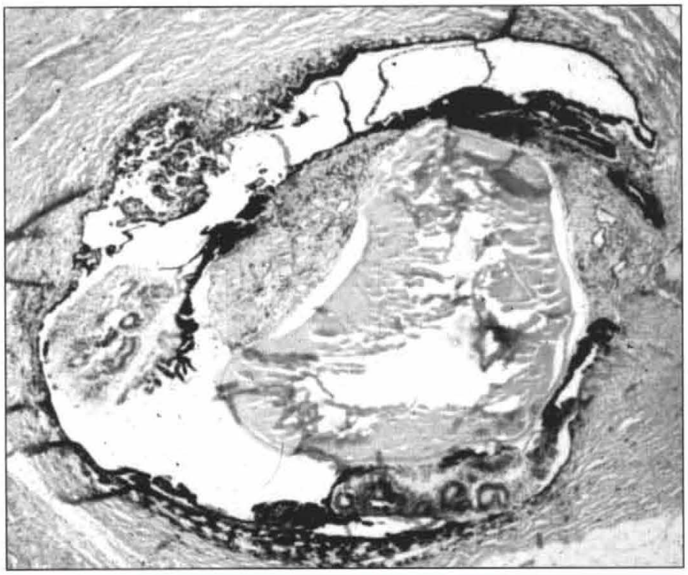

Figure 4.3 Secondary microphthalmia. The ciliary processes tend to be highly conserved even in the most disorganized globes.

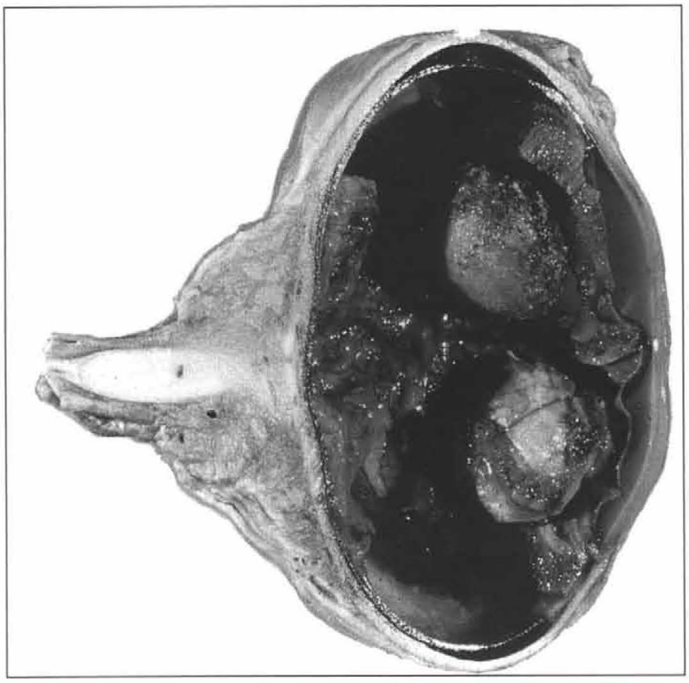

Figure 4.4 Globe from typical "cyclopian" calf. Duplication of lens and pupil indicates **synophthalmos** rather than true cyclopia.

vessels, and are thus more properly considered *incomplete separation or early fusion (synophthalmos)* (Fig. 4.4). Some specimens have two dysplastic globes within a single orbit. Severe cranial anomalies accompany cyclopia and synophthalmos, including absent or deformed ears, a median proboscis, cranioschisis, cleft palate, and brain anomalies ranging from microcephaly to hydranencephaly and hydrocephalus.

Cyclopian-like malformations have been reported in sheep, chickens, and dogs, and as inherited defects in cattle with the most thoroughly documented cases being in sheep grazing alpine pastures rich in the legume *Veratrum californicum*. Fresh and dried plants contain three steroidal alkaloids – jervine, cyclopamine, and cycloposine – capable of damaging the developing neural groove of the fetal lamb. Ewes eating the plant on gestational day 15 have lambs with the cyclopian malformation, for it is at that time that the neural groove has formed and the first cranial somites are forming. A similar syndrome has been produced in kids and calves by maternal feeding of the plant on day 14 of gestation. Ingestion of the alkaloids prior to day 15 in sheep may cause fetal death but no anomalies, and exposure soon after day 15 may cause various skeletal abnormalities but not cyclopia.

In naturally occurring outbreaks, affected lambs have deformities ranging from cyclopia with microcephaly to relatively normal lambs with harelip and cleft palate. Prolonged gestation is common in the case of severely malformed fetuses.

Cystic eye and retinal nonattachment

Failure of apposition of the optic vesicle to the cranial ectoderm results in failure of lens induction, which in turn removes the major stimulus for invagination of the optic vesicle to form the optic cup. *Persistence of the primary optic vesicle is seen as a cystic eye* (Fig. 4.5), consisting of a scleral sheet lined by neurectoderm of variable neurosensory and pigmentary differentiation. The absence of lens and of bilayered iridociliary epithelium distinguishes this rare lesion from the more common dysplastic eye of secondary microphthalmos.

Incomplete invagination of the optic vesicle allows persistence of the cavity of the primary optic vesicle and prevents attachment of the presumptive neurosensory retina to the developing retinal pigment epithelium. *In the postnatal globe, retinal nonattachment cannot easily be distinguished from acquired retinal separation.* In each instance, the retina is extensively folded and may have improper differentiation of neuronal layers. The diagnosis of retinal nonattachment is assisted if there is also lack of apposition between the two layers of neurectoderm covering the anterior uvea (destined to be iridal and ciliary epithelium) and if retinal rosettes are evident. In addition, since nonattachment is an early and fundamental error in organogenesis, such eyes usually lack a lens and probably will be microphthalmic with multiple anomalies.

Coloboma

The mildest and latest defect in organogenesis results from failure of complete fusion of the lips of the optic (embryonic) fissure, a slit-like but normal channel in the floor of the optic cup and stalk through which the vasoformative mesoderm and stromal mesenchyme enter the globe. Failure of closure of the fissure may occur anywhere along its length, but the channel persists most frequently as a notch-like defect of the caudal pole at, or just ventral to, the optic disk. Its exact location can vary substantially. It is lined by an outpouching of dysplastic neurectoderm. If the defect is sufficiently large, the outpouching of neurectoderm induces a similar bulge in the sclera, termed **scleral ectasia** (Fig. 4.6). Occasionally such ectasias are so large as to form a retrobulbar cyst as large as the globe itself (Fig. 4.7). Regardless of size, the lining of the scleral coloboma is formed by neurectoderm that bulged through the defect in the optic cup. Abortive neurosensory differentiation within the cyst wall is common and permits definitive

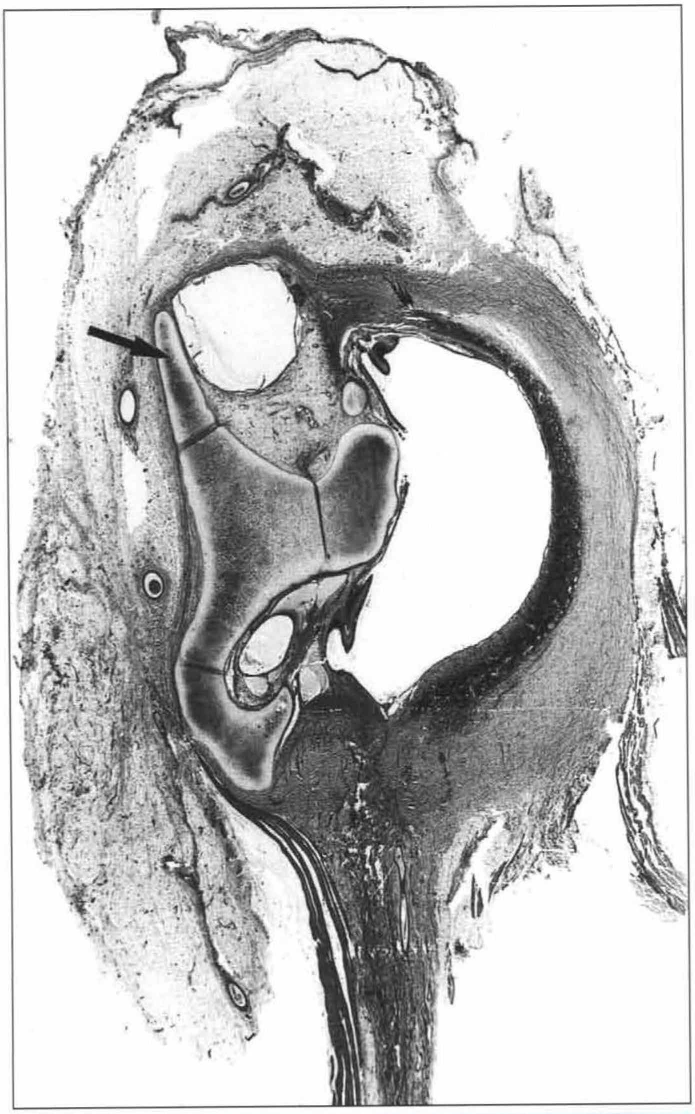

Figure 4.5 Severe **microphthalmos** in a foal. There is no lens, no apparent attempt at invagination, and no neurosensory retinal differentiation. Persistence of the cavity of the optic vesicle qualifies this as a cystic eye. Cartilage plate (arrow) is probably an analog of the third eyelid.

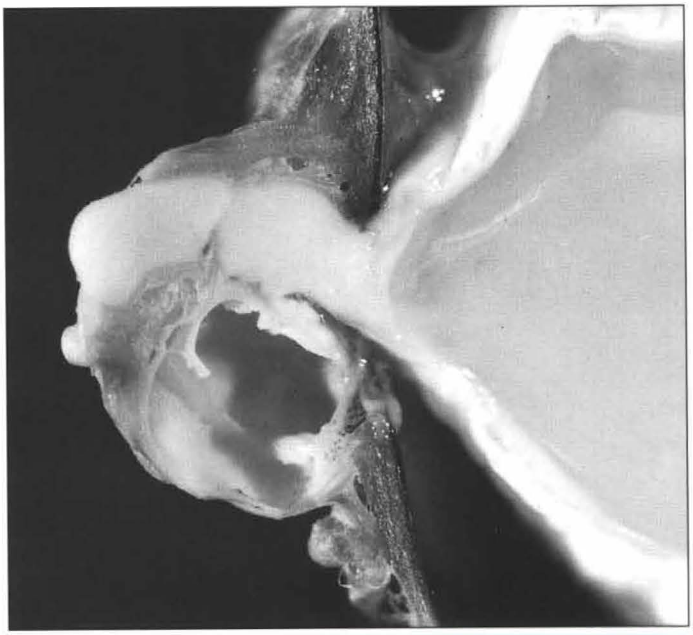

Figure 4.6 Coloboma adjacent to the optic disk, accompanied by retinal separation. Collie eye anomaly.

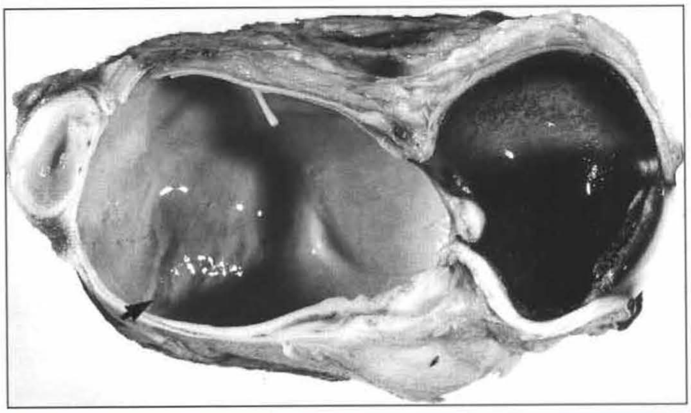

Figure 4.7 Retrobulbar cyst (arrow) formed by coloboma and massive scleral ectasia in a calf. The globe is small and the retina is completely separated.

identification of the retrobulbar cyst as being a **coloboma** (absence or defect of some ocular tissue) in terms of pathogenesis (Fig. 4.8).

Colobomas occur in all domestic species, but are especially frequent in Collie dogs as one manifestation of the Collie eye anomaly. In Collies, they usually arise within or just adjacent to the optic disk. They appear to arise as focal defects in maturation and/or induction of sclera and choroid by the retinal pigment epithelium (RPE) that is forming from the outer layer of the optic cup. Because the exact location of the embryonic fissure is somewhat variable, it is difficult to determine how many examples of coloboma are the result of delayed closure of that normal embryologic structure, and how many represent some more fundamental defect in the proper interaction of RPE and the developing periocular mesenchyme destined to form choroid and sclera. Proper maturation of the RPE, and in particular the normal acquisition of pigmentation, appears to be critical to the induction of normal mesenchymal migration and maturation. Its failure results in such varied anomalies as choroidal hypoplasia, segmental or diffuse iris and ciliary hypoplasia (known clinically as **iris coloboma**), and even microphthalmia. Because of its frequent association with the merle dilution defect in the coat color of dogs, the general syndrome is known as *merle ocular dysgenesis*. It is similar, but not identical, to Collie eye anomaly. The same defect occurs, with much less frequency, in color-dilute (incompletely albinotic) horses, cattle, non-merle dogs, and cats. A similar pathogenesis and spectrum of lesions, not proven to be associated with color dilution, occurs in Collie eye anomaly (see later). In Charolais cattle, colobomas of (or near) the optic disk are inherited as an autosomal dominant trait with incomplete penetrance. The lesion is bilateral but not necessarily equal in severity.

Defective differentiation

Subsequent to formation of the optic cup, ocular differentiation involves continued differentiation of neurectoderm into retinal and

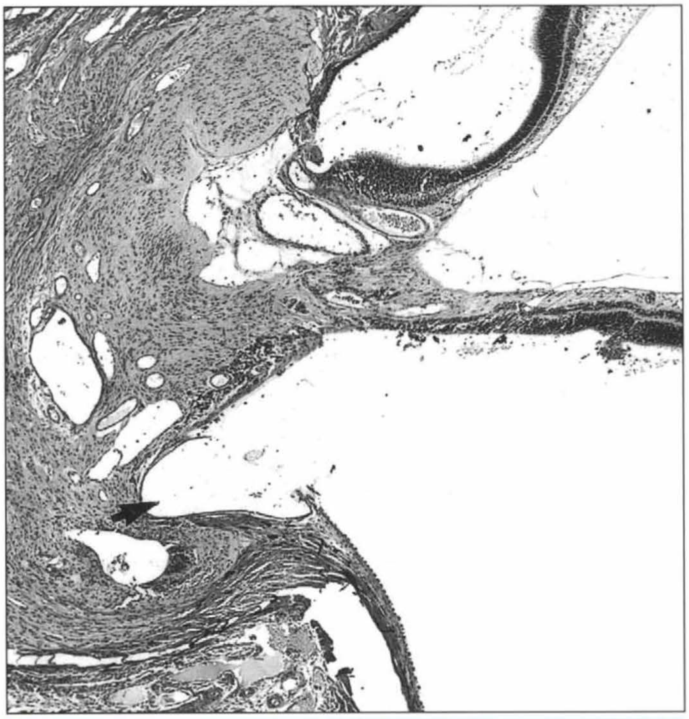

Figure 4.8 **Coloboma** (arrow) at the optic disk in a Collie pup with Collie eye anomaly. Dysplastic neurectoderm lines the defect and attempts to form sensory retina.

uveal neuroepithelium, and induction of primitive periocular neural crest mesenchyme to form the sclera and uvea. The normal development of retinal pigment epithelium from the neurectoderm of the posterior half of the optic vesicle seems prerequisite for these differentiations to occur.

It is traditional to present specific ocular anomalies as they relate to structures of the adult eye, and thus as anomalies of cornea, iris, lens, retina, and so on. This approach correlates well with the clinical examination of the eye but provides no understanding of the fundamental pathogenesis of the anomaly. *Here we will organize these "later" anomalies (occurring after the stage of optic cup formation) on the basis of the presumed pathogenesis: defective migration, proliferation, or remodeling of ocular mesenchyme, defective maturation of neurectoderm, and defective development of ectoderm.*

Anomalies of mesenchyme

After formation of the optic cup and separation of the lens vesicle, the periocular mesenchyme undergoes a complex series of migrations, differentiations, and atrophies that determines the final structure of the vascular and fibrous tunics of the globe. At the anterior edge of the optic cup, one or more waves of mesenchymal invasion form corneal endothelium, corneal stroma, and the anterior half of the transient perilenticular vascular network, including the pupillary membrane. The posterior half of this perilenticular vascular tunic is formed by invasion of mesodermal endothelial cell precursors and supporting perivascular mesenchyme through the optic fissure to form the extensive but transient *hyaloid artery system* (see Fig. 4.2). Another mesenchymal wave accompanies the ingrowth of the neurectoderm at the anterior lip of the optic cup to form the iris stroma, although it is unclear which layer acts as the primary inducer. Its peripheral portion later atrophies to form the porous *filtration angle* of the anterior chamber, a process that may not be completed in carnivores until 6–8 weeks after birth. The choroid and sclera are induced by the developing retinal pigment epithelium to form from the mesenchyme surrounding the caudal half of the optic cup.

Anomalies of mesenchyme may result from defective ingrowth or differentiation, as with choroidal and iris hypoplasia, incomplete atrophy of the tunica vasculosa lentis or hyaloid artery system, or incomplete remodeling of the filtration angle to cause primary glaucoma.

Choroidal hypoplasia

This is a relatively common lesion in the eye of dogs by virtue of its prevalence in the Collie breed as the hallmark of Collie eye anomaly, and a very similar syndrome occurs in Australian Shepherd dogs and Shetland Sheepdogs. It is also seen in a variety of dog breeds in association with genes for color dilution (merle, dapple, and harlequin). *The hypoplasia is thought to result from induction failure by a defective retinal pigment epithelium.* The basic defect is not clearly established but may be related to defective pigmentation, a suggestion supported by the prevalence of iris and choroidal hypoplasia in white animals of all species, especially those with blue irises. Other anomalies linked to the choroidal hypoplasia/hypopigmentation include optic nerve coloboma, microphthalmia, and (with the merle ocular dysgenesis) cataract and segmental iris hypoplasia. Some degree of retinal dysplasia is also common. At least in theory, all of these defects are predictable outcomes of improper mesenchymal induction by a defective, inadequately pigmented retinal pigment epithelium. Even in otherwise normal (nonwhite) animals with a blue iris, there is usually hypoplasia of the tapetum and choroid.

Collie eye anomaly

This is a common disease of smooth and rough Collies, first reported in 1953 and at one time estimated to have affected 90% of North American Collies. During the period 1975–1979, the defect was still present in over 70% of 20 000 Collies examined in a voluntary screening program. Prevalence in Europe and the United Kingdom is lower (30–60%). *The basic defect, patchy to diffuse choroidal hypoplasia, is inherited as an autosomal recessive trait*, but the numerous associated defects are more unpredictable in their familial pattern. Similar syndromes are reported in Border Collies, Shetland Sheepdogs, and Australian Shepherd dogs, and are probably of similar pathogenesis. The prevalence in these breeds, as in rough Collies, has marked geographic variation.

The *ophthalmoscopic findings* include one or more of retinal vessel tortuosity, focal to diffuse choroidal and tapetal hypoplasia, optic nerve coloboma, and retinal separation with intraocular hemorrhage. Other observations that are occasionally made in eyes of affected dogs are enophthalmos, microphthalmos, and corneal stromal mineralization. The disease is always bilateral but not necessarily equal. Even the mild, visually insignificant lesion of focal choroidal hypoplasia is genetically significant.

Macroscopic examination of the bisected globe reveals abnormal pallor of the posterior segment of the globe. If the globe is transilluminated, the sclera and choroid are focally or diffusely more translucent than normal. The pallor and translucency imply choroidal hypoplasia. Within or adjacent to the optic disk there may be a colobomatous pit of variable size, the lining of which is continuous with the retina. Accompanying the larger type of pit is a bulge in the overlying sclera, called **scleral ectasia** or **posterior staphyloma.** If there is retinal separation, it is usually complete, with the only sites of attachment being at the abnormal optic disk and at the ora ciliaris (Fig. 4.9). In such cases, there may be extensive intravitreal hemorrhage and retinal tears. Almost all Collie eyes with retinal separation have large optic disk colobomas. Detachment from the ora ciliaris (so-called *retinal disinsertion*) may also occur, leaving the folded retina on the floor of the globe (Fig. 4.10).

The fundamental histologic lesion found in all affected eyes is choroidal hypoplasia. It is always diffuse, despite ophthalmoscopic observation of a lesion that may appear only to be focal within the dorsal temporal quadrant of the fundus. The choroid is thin and poorly pigmented, and the tapetum is thinner than normal or even absent (Fig. 4.11A, B). Retinal pigment epithelium is poorly pigmented, even in nontapetal fundus, and may be vacuolated. Because the choroid and tapetum in the normal dog do not reach adult thickness until about 4 months postpartum, age-matched control eyes are essential if overinterpretation of normal choroidal immaturity is to be avoided.

Histologic examination of eyes with optic disk colobomas reveals the bulging of dysplastic neurectoderm, continuous with retina, into the pit in the nerve head. The neurectoderm may show jumbled differentiation into ganglion cells, photoreceptor rosettes, glial cells, or pigment epithelium. Rosettes are common in the neurosensory retina adjacent to affected disks or embedded in the optic disk itself. In some specimens, there are degenerative retinal lesions overlying severely hypoplastic choroid. Edematous clefts are seen in the nerve fiber layer, and ganglion cells may be severely vacuolated.

Other retinal lesions include retinal folds and detachment. The folds are seen on histologic section as tubes of fully differentiated retina cut in cross-section or tangentially, and are thought to represent folds in a neurosensory retina that at least temporarily has grown in excess of the space available for it within the optic cup. These folds correspond to the clinically detectable vermiform streaks in the fundus, and gradually disappear as the dog (and eye) matures, allowing the growth of scleral shell to catch up with that of retina. Presumably it is a similar growth imbalance, but in the opposite direction, that causes retinal separation in about 10% of eyes with this syndrome. In this situation, a retina that is too small attempts to stretch from optic disk to ora ciliaris by the shortest route, rather than following the curvature of the scleral shell.

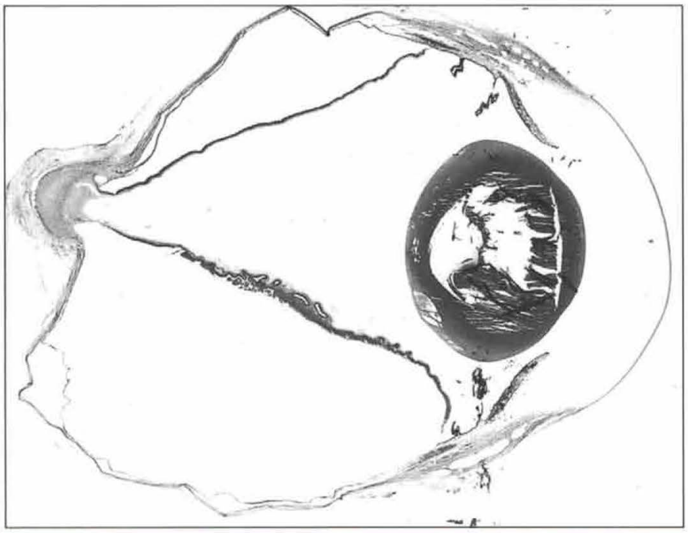

Figure 4.9 Retinal separation in Collie eye anomaly. There is coloboma at the optic disk. Choroid and sclera are thin. Retinal folding does not constitute dysplasia.

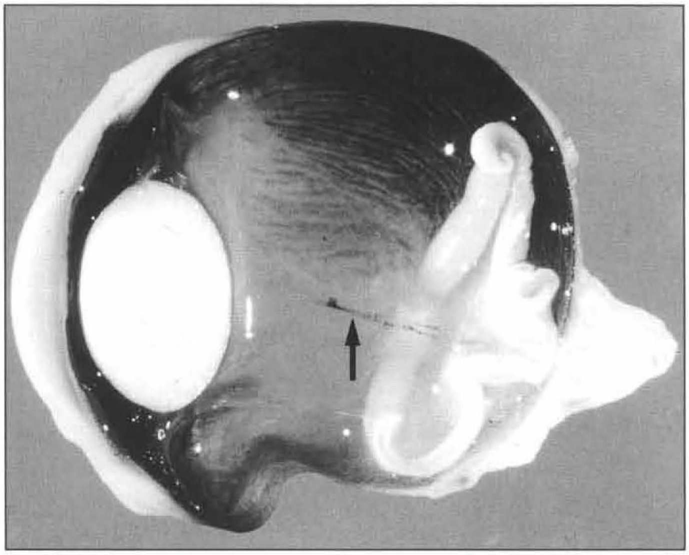

Figure 4.10 Retinal separation from ora ciliaris in Collie eye anomaly. Note hypopigmented choroid and prominent hyaloid artery (arrow).

Focal fibroblastic metaplasia and mineralization are occasionally seen in the subepithelial corneal stroma of dogs with Collie eye anomaly, but a similar defect is seen in anomalous eyes of other breeds; a genetic link to the Collie eye defect is not established. Tortuosity of retinal veins, a controversial clinical lesion sometimes considered part of Collie eye anomaly, has no described histologic counterpart.

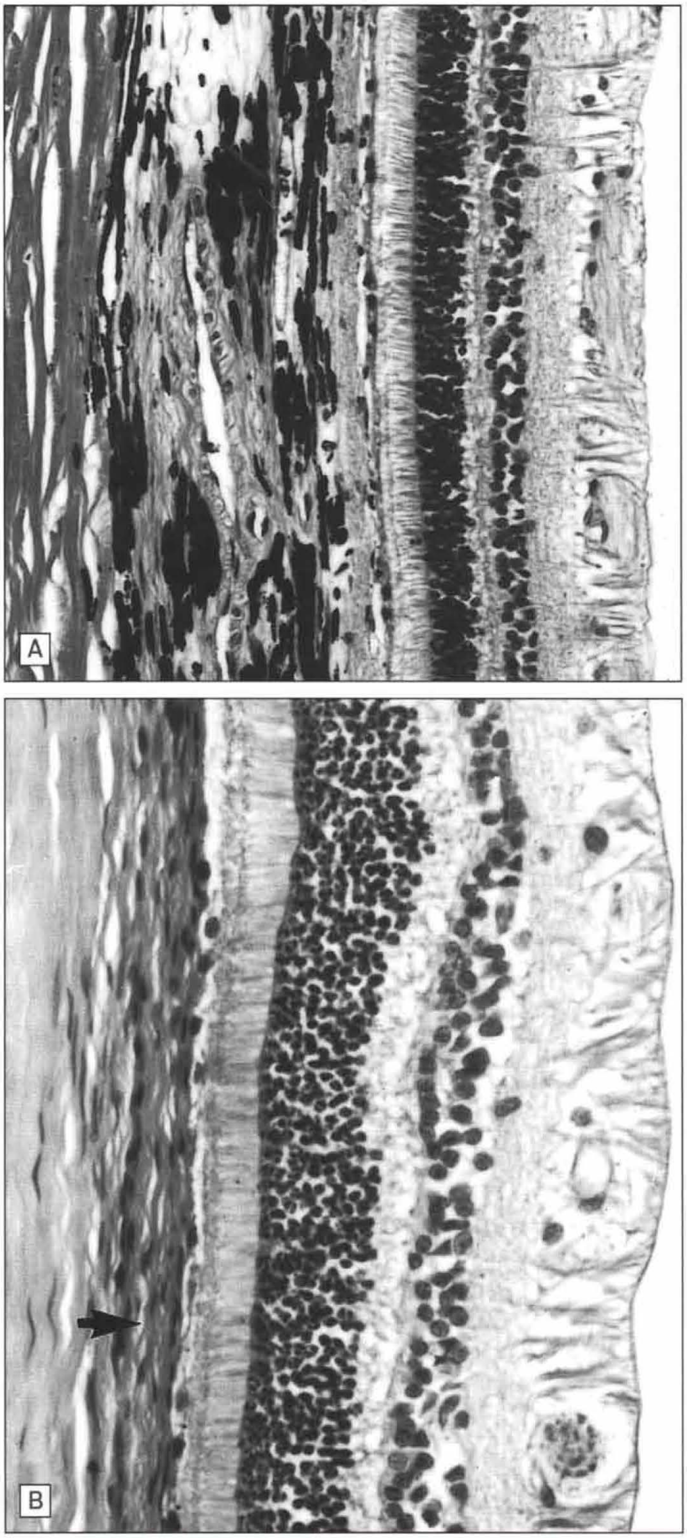

Figure 4.11 A. Normal posterior pole of the globe of a 13-week-old puppy. Tapetum present but thin (normal for puppy). Choroidal thickness approximates that of retina. **B.** Posterior pole just dorsal to the optic disk of a 13-week-old Collie with **Collie eye anomaly**. Tapetum is absent. Choroid (arrow) is severely hypoplastic.

The earliest lesion of this anomaly is defective differentiation of primitive retinal pigment epithelium to form rosette-like structures near the optic disk. Proper differentiation of both pigment epithelium and neurosensory retina requires obliteration of the lumen of the primary optic vesicle, which allows the two neurectodermal layers to come into apposition. Whether the earliest lesion of Collie eye anomaly results from inherently defective differentiation of pigment epithelium or from imperfect apposition of the two neurectodermal layers has not been resolved, but the central role of the pigment epithelium in determining ocular morphology suggests that the primary defect is in maturation of the presumptive retinal pigment epithelium. Anomalous development of choroid and sclera, including coloboma, is not seen in fetuses up to 45 gestational days, but is seen in neonates. This suggests that the defect is in choroidal maturation rather than in initial induction.

Another manifestation of mesenchymal maldevelopment in Collie eye anomaly, rarely noted clinically, is delayed atrophy and remodeling in the anterior chamber. The filtration angle may be closed, iris stroma may be attached to the corneal endothelium by a mesenchymal bridge, and remnants of anterior perilenticular mesenchyme are unusually prominent. Pigmentation of iridal neurectoderm is sparse. As these neonatal anterior segment lesions are not seen later in life (8–20 weeks) when puppies are examined ophthalmoscopically, it is presumed that they reflect only a minor delay in mesenchymal remodelling.

Defects primarily in anterior chamber mesenchyme

Hypoplasia of the iris *is a rare defect that may occur alone or in conjunction with multiple ocular defects.* It is relatively most frequent in horses, where it may be inherited and associated with cataract and conjunctival dermoids. The defect presumably results from incomplete inward migration of the anterior lip of the optic cup, with resultant lack of a neurectodermal scaffold to guide the subsequent migration of mesenchyme destined to form the iris stroma. The hypoplasia is usually severe and most cases are clinically described as *aniridia*. Histologic examination of such eyes usually reveals the vestigial iris as a triangular mesenchymal stump covered posteriorly by normal-appearing pigmented epithelium (Fig. 4.12A). The trabecular meshwork within the filtration angles may be malformed, but the ciliary apparatus is usually normal. The lens often is cataractous (Fig. 4.12B) and sometimes ectopic or hypoplastic. Glaucoma has been described as a sequel in horses (but not in other species), but it should be an expected sequel in severely affected eyes in any species because of the inevitable concurrent trabecular hypoplasia (Fig 4.12A).

Hypopigmentation of the iris may be unilateral or bilateral. When the loss of pigment is patchy in one or both irises, it is known as *heterochromia iridis*. The pigmentation may be diffusely absent in the iris stroma but present in the posterior iris epithelium (*subalbinotic*), or absent in both stroma and epithelium (*true albinism*). The iris is normal except for absence of visible pigment granules in the cytoplasm of otherwise normal stromal melanocytes and epithelial cells. Tapetum and, less reliably, choroid of affected eyes usually are hypoplastic as well as poorly pigmented.

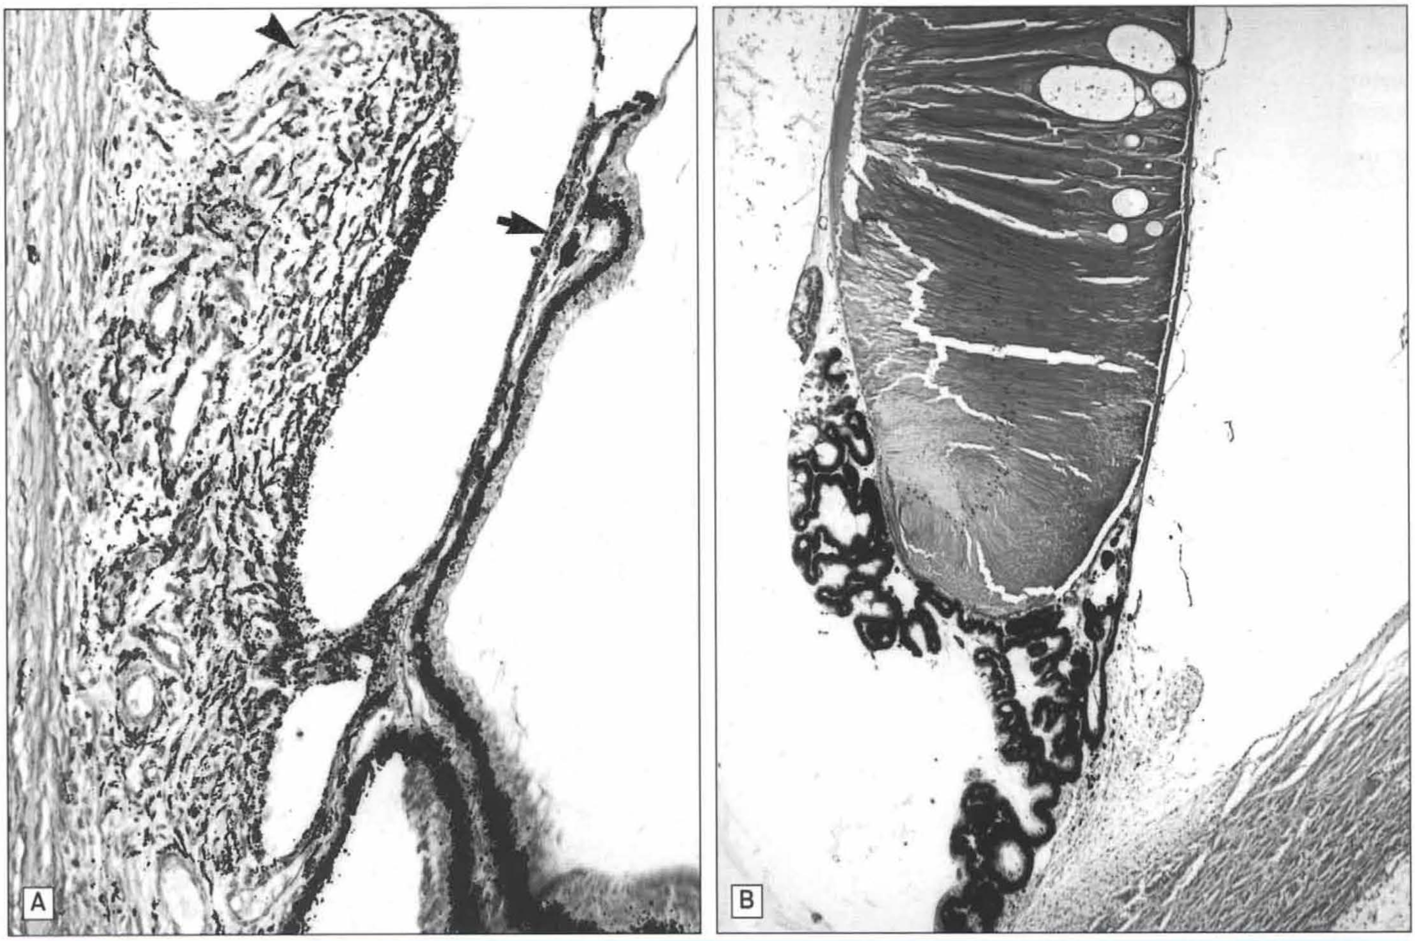

Figure 4.12 A. Iris hypoplasia (arrowhead) with hypoplasia of the trabecular meshwork in a dog. The ciliary processes (arrow) have developed normally. **B. Iris hypoplasia**, congenital cataract and dysplasia of ciliary processes in a piglet; one of three affected. The adherence of ciliary processes to the lens represents an arrest in remodeling rather than improper development.

Incomplete atrophy of the anterior chamber mesenchyme is relatively common in dogs and occurs occasionally in other domestic species. During organogenesis, waves of mesenchyme migrate between the surface ectoderm and the anterior rim of the optic cup. Some of the ingrowing mesenchyme forms corneal endothelium and stroma, while other portions of mesenchyme form the iris stroma and trabecular meshwork. Some of that mesenchyme occupies the anterior chamber and, as it matures, it forms a fibrovascular sheet stretching across the face of the lens and developing iris, known as the *pupillary membrane*. Its vascular component creates the anterior portion of an embryonic perilenticular vascular plexus, known as the *tunica vasculosa lentis*. Both the pupillary membrane and the tunica vasculosa lentis normally disappear late in gestation or in the early postnatal period. Failure of this anterior chamber fibrovascular mesenchyme to atrophy results in the very common anomaly of **persistent pupillary membrane** (persistence of the tunica vasculosa lentis alone is discussed later).

Atrophy of the pupillary membrane is frequently incomplete at birth and, in dogs, persistent remnants are common up to about 6 months of age. These insignificant and usually bloodless strands are seen as short, thread-like protrusions from the area of the minor arterial circle (iris collarette) and they may insert elsewhere on the iris, cross the pupil, or extend blindly into the anterior chamber (Fig. 4.13A). Persistent pupillary membranes achieve clinical significance in two ways. First, the size and number of strands crossing the pupil may be such that vision is obstructed. Second, strands that contact lens or cornea are associated with focal dysplasia of lens or corneal endothelium, clinically seen as opacity (Fig. 4.13B). Because the normal pupillary membrane never contacts the cornea, strands of pupillary membrane that extend from iris to cornea are considered to be minor versions of anterior segment dysgenesis (see below).

Histologic descriptions are mainly from studies in *Basenji dogs*, in which persistent pupillary membrane occurs as an autosomal recessive trait of variable penetrance. In this breed, atrophy of the pupillary membrane is abnormally slow even in dogs free of the defect in adult life, and remnants in puppies up to 8 months old are common. The membranes are seen as thin endothelial tubes, invested with a thin adventitial stroma, extending from vessels in the iris stroma near the collarette. The tubes are usually empty, but in severely affected eyes may contain erythrocytes, and the adventitia may contain melanin. The tubes weave in and out of the plane of section en route to corneal, iridic, or lenticular insertions. At sites of corneal insertion, corneal endothelium is either absent or dysplastic, with the latter manifested as fibrous metaplasia. Descemet's membrane is malformed or absent in the areas of attachment and there is associated deep stromal corneal edema to account for the clinically observed, minute

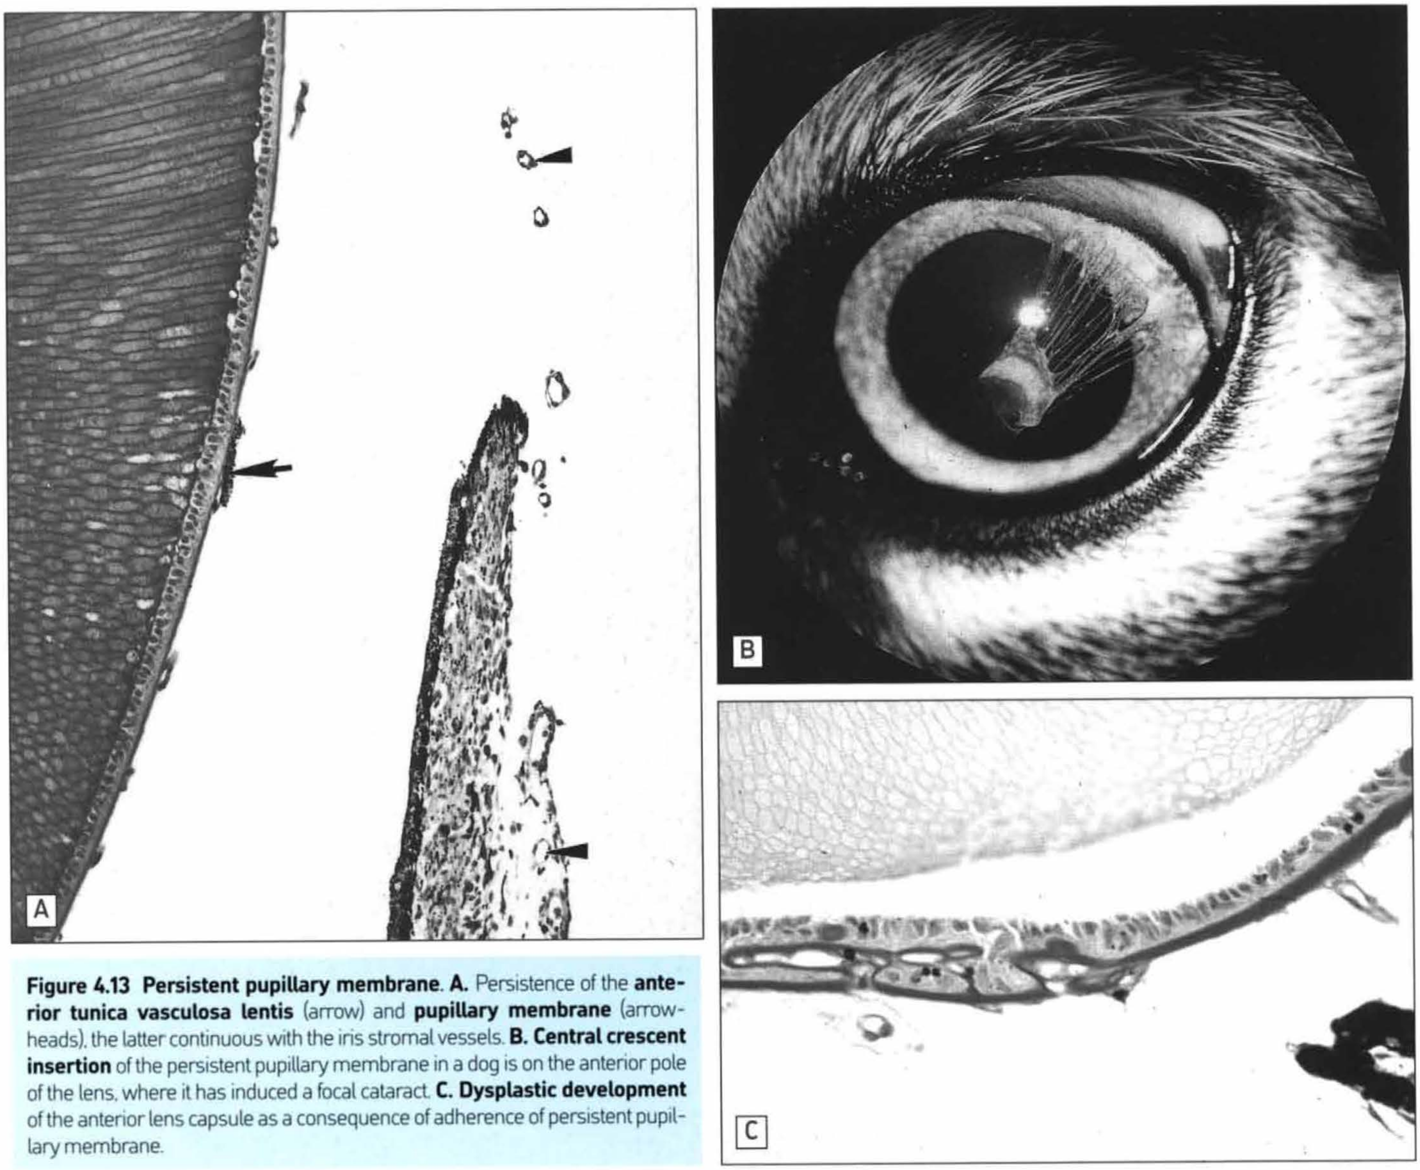

Figure 4.13 Persistent pupillary membrane. A. Persistence of the **anterior tunica vasculosa lentis** (arrow) and **pupillary membrane** (arrowheads), the latter continuous with the iris stromal vessels. **B. Central crescent insertion** of the persistent pupillary membrane in a dog is on the anterior pole of the lens, where it has induced a focal cataract. **C. Dysplastic development** of the anterior lens capsule as a consequence of adherence of persistent pupillary membrane.

gray stromal opacities. *Contact with the lens is accompanied by similar epithelial and basement membrane dysplasia, resulting in one or more epithelial, subcapsular, or polar cortical cataracts* (Fig. 4.13C). Some would classify this latter, more severe form of persistent pupillary membrane as a mild version of anterior segment dysgenesis (see below).

Much less common than persistent pupillary membrane are those defects grouped under the general category of **anterior segment dysgenesis** (or **anterior segment cleavage syndrome**). This group includes multiple anomalies of cornea, lens, and anterior uvea that stem from disordered development of anterior segment mesenchyme and/or improper separation of the developing lens from the overlying corneal mesenchyme. Such eyes are commonly microphthalmic and usually have microphakia, cataract, and congenital corneal opacities at sites of congenital anterior synechiae. The most severe cases have fusion of iris with corneal stroma without observed corneal endothelium or Descemet's membrane (forming a so-called "internal corneal ulcer"), and thus have no detectable anterior chamber (Fig. 4.14). *Most examples in dogs and cats probably result from perinatal corneal perforation from trauma or from progression of suppurative bacterial keratoconjunctivitis (ophthalmia neonatorum).* The

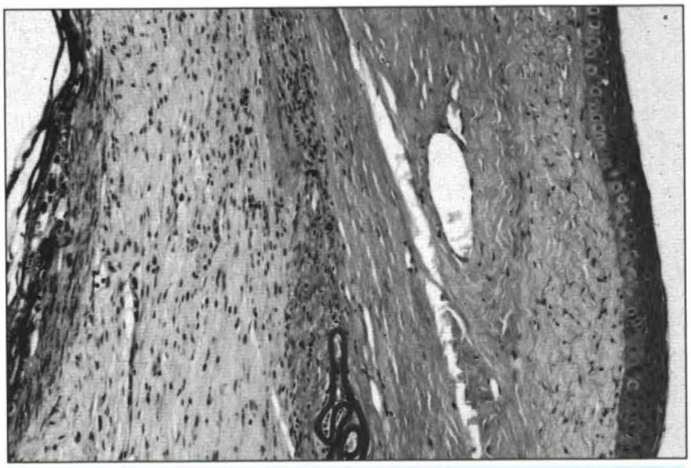

Figure 4.14 Anterior segment dysgenesis. Improper remodeling of anterior segment mesenchyme results in failure of formation of the anterior chamber. The iris is then fused to the cornea.

result is iris prolapse and incorporation of the iris into the developing cornea resulting in obliteration of the anterior chamber. Since the globe of dogs and cats continues to develop for many weeks after birth, this is yet another example of how difficult it can be to precisely distinguish idiopathic developmental disorders from those resulting from postnatal traumatic or inflammatory diseases.

Maldevelopment of the filtration angle (goniodysgenesis) occurs as a prevalent, inherited condition in dogs and in severely anomalous eyes of animals of any species. The defect may result from incomplete atrophy of mesenchyme that normally fills the fetal iridocorneal angle, or from inadequate posterior migration of the iris root. The defect is much more common in dogs than any other species. In the most severe cases, the trabecular meshwork may appear as a solid mesenchymal mass indistinguishable from the adjacent iris stroma (Fig. 4.15A). This rare lesion, known us *trabecular hypoplasia*, is a cause for truly congenital glaucoma. It is often accompanied by iris hypoplasia. Much more commonly, the error in remodeling is less profound and the lesion is seen as an imperforate or inadequately perforated mesenchymal sheet separating anterior chamber from a relatively normal trabecular meshwork (Fig. 4.15B). The only lesion may thus be a pectinate ligament that is thicker, more heavily pigmented and less fenestrated than normal. This has sometimes been referred to as *"pectinate ligament dysplasia."* (For a more complete discussion, see Glaucoma.)

Clinically noted ocular features of **bovine Marfan syndrome**, which are similar to human Marfan syndrome, are ectopia lentis, microspherophakia, and myopia. The human disease is caused by mutations in the fibrillin-1 gene; affected cattle have abnormal fibrillin metabolism. Eyes of affected cattle are characterized by megaloglobus, increased circumlental distance, asymmetrical ciliary processes, intact but fragile zonular fibers, and ectopia lentis. Affected animals have moderately hypoplastic ciliary bodies, compact filtration angles, and long thin irises with decreased fibrous stroma.

Incomplete atrophy of posterior segment mesenchyme

Incomplete atrophy of posterior segment mesenchyme may result in the mild and common lesion of **persistent hyaloid artery,** or in the much rarer but clinically more significant lesions of **persistent posterior perilenticular vascular tunic** with or without concurrent persistence of the primary vitreous. There is a tendency in clinical literature to group all of these defects under the umbrella of **persistent hyperplastic primary vitreous**, but histologically there is quite a wide range in the nature of the defect. Only the most severe qualify as true persistent hyperplastic primary vitreous.

The hyaloid artery and its branches are formed from mesenchyme and pre-endothelial mesoderm that enter the optic cup through the optic fissure prior to its closure. The vessel traverses the optic cup from optic disk to lens, where it ramifies over the posterior lens surface (posterior tunica vasculosa lentis). It joins with the vascular portion of the pupillary membrane (anterior tunica vasculosa lentis) to form a complete perilenticular vascular tunic. *As with its anterior chamber counterpart, the hyaloid system undergoes almost complete atrophy before birth.* Persistence of some vestige into adult life is common and clinically insignificant. In ruminants, the most common remnant is *Bergmeister's papilla*, a cone of glial tissue with a vascular core that extends from optic disk for a few millimeters into the vitreous (Fig.4.16). In calves up to about 2 months of age, the vestigial hyaloid system may still contain blood. In carnivores, it is the pupillary membrane that normally persists for several weeks postnatally. Bloodless remnants of the anterior termination of the hyaloid artery on the posterior lens capsule are known as *Mittendorf's dot*; it is a harmless anomaly, common in dogs and ruminants up to several years of age.

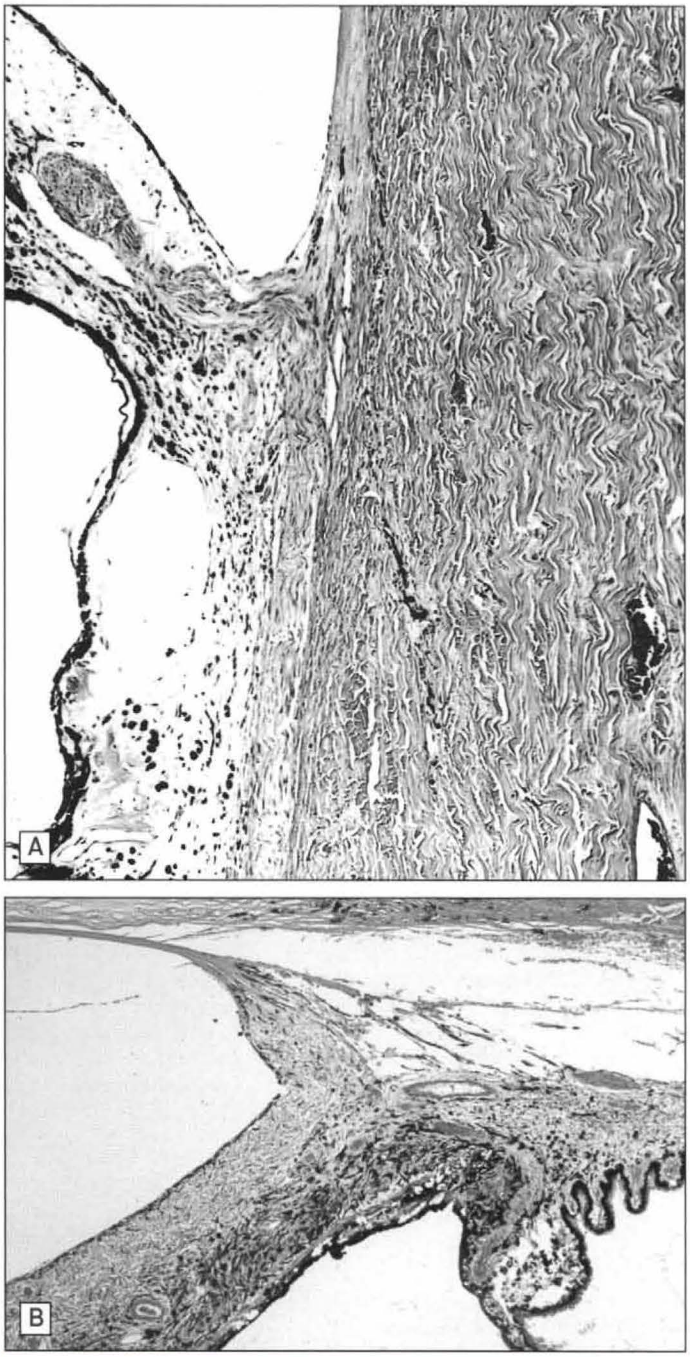

Figure 4.15 A. Goniodysgenesis. A primitive example (**trabecular hypoplasia**) with little maturation of the embryonic mesenchyme destined to form pectinate ligament and trabecular meshwork. **B.** A solid sheet of mesenchyme extends from the termination of Descemet's membrane into the iris stroma, with no obvious pectinate ligament. Other portions of the trabecular meshwork are relatively normal.

Much less common is undue persistence and even hyperplasia of the anterior end of the hyaloid system (**posterior tunica vasculosa lentis**). The normal tissue is a combination of blood vessels and

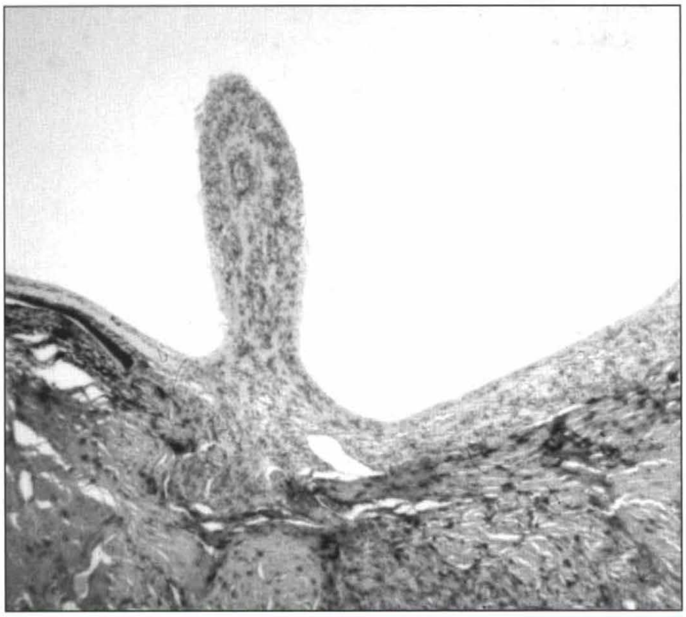

Figure 4.16 **Bergmeister's papilla**, the minimal histologic presentation of persistent hyaloid artery.

perivascular mesenchyme. Surrounding the hyaloid system is some primitive collagen, poorly characterized extracellular matrix, and a few macrophages. The combination of blood vessels and surrounding stroma is known as the *primary vitreous*. At least theoretically, *anomalous retention of the hyaloid artery and/or primary vitreous could therefore be separated into distinct entities of persistent hyaloid, persistent posterior tunica vasculosa lentis, persistent primary vitreous, and persistent hyperplastic primary vitreous*. Of these, the one most frequently reported (perhaps just because it is the most spectacular and significant) is **persistent hyperplastic primary vitreous**. In people, this rare anomaly is typically unilateral and is accompanied by microphthalmos, microphakia, retinal detachment, shallow anterior chamber, and embryonic filtration angles. The many reports of this anomaly in dogs have described a unilateral or bilateral retrolental vascular or fibrovascular network, usually without any other reported anomalies other than the expected posterior polar cataract. Such lesions are better described as *persistent posterior tunica vasculosa lentis*. In Doberman Pinschers, Bouviers and Staffordshire Bull Terriers, the classification as hyperplastic primary vitreous is more credible. In these breeds, the defect is inherited and forms a spectrum that includes persistent pupillary membrane, cataract, lenticonus, and microphthalmia as well as persistence of variable amounts of primary vitreous and posterior tunica vasculosa lentis (Fig. 4.17 A, B). The defects are detected as early as gestational day 30, at which time hyperplasia of posterior tunica vasculosa lentis is already obvious. Posterior polar cataracts and preretinal membranes are observed by day 37. The one report of two cases in cats was not supported by histopathology and its correct classification remains unknown.

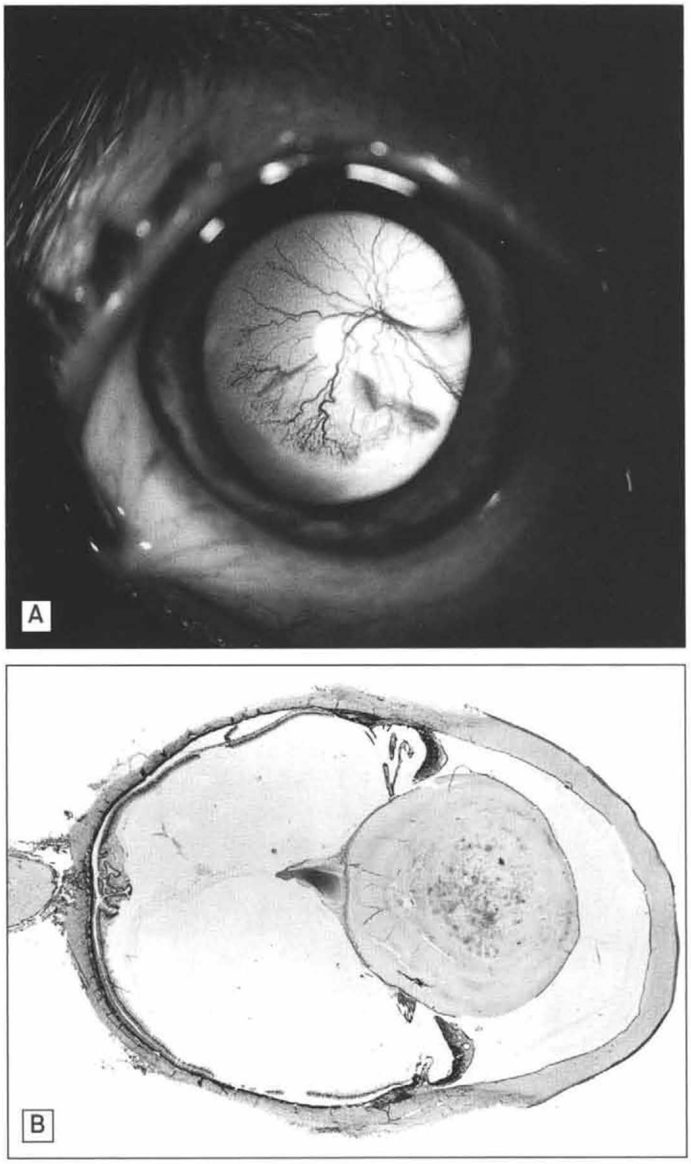

Figure 4.17 **A. Persistence of hyaloid artery and posterior tunica vasculosa lentis** in a dog. Posterior polar cataract is the almost inevitable consequence, as seen here. **B. Persistent hyperplastic primary vitreous.** A fibrocartilaginous plaque adheres to an elongated lens (lenticonus) and extends to the posterior pole. Retina is dysplastic near the optic disk, and the ciliary processes have not retracted from the lens capsule.

Anomalies of neurectoderm

Included under this heading are anomalies of retina, optic nerve, and of neuroepithelium of iris and ciliary body. Of these, *retinal anomalies are by far the most frequent and most significant.*

Retinal dysplasia

Retinal dysplasia *is a general term denoting abnormal retinal differentiation characterized by jumbling of retinal layers and by glial proliferation.* In clinical practice, the term has been used incautiously to include genuine retinal dysplasia, postnecrotic retinal scarring of the developing retina, and retinal folding. Genuine retinal dysplasia results from failure of proper apposition of the two layers of the optic cup or from failure of proper induction by an inherently defective retinal pigment epithelium. Those examples clinically classified as retinal dysplasia that reflect disordered wound healing of developing retina, or just folding of retina that is otherwise perfectly formed, should not be considered examples of true retinal dysplasia. While there is no formal agreement on the issue, it seems most logical to divide so-called retinal dysplasia into three different categories: *retinal folds* within an otherwise normal retina, *postnecrotic dysplastic retinal wound healing*, and rare *"true" retinal dysplasia* that is a sequel to some fundamental developmental error in retinal induction or maturation.

Those examples of retinal dysplasia in which the only abnormality is **retinal folding** are by far the most common, and are seen primarily in dogs. The anatomic location, ophthalmoscopic appearance, and effect on vision vary from breed to breed but tend to be uniform within each breed, a fact used by clinical ophthalmologists when attempting to distinguish inherited dysplasias from those occurring as isolated anomalies or as sequelae to in utero infections. The most severe examples occur in dogs with retinal nonattachment. These have extensively folded retinas since the distance to be traversed from optic disk to ora ciliaris in a straight line is shorter than the convex route taken by attached retina, and redundant retina is therefore obliged to fold upon itself. Less severe examples, which are seen much more frequently and in the greatest variety of breeds, probably reflect inequity in growth rate between the retina and the outer layer of the optic cup (choroid and sclera). *The most common example is probably seen in Collie eye anomaly and in American Cocker Spaniels*, in which the defect may be transient. Presumably, the folds become flattened and disappear as continued choroidal and scleral growth eventually create a globe that can accommodate the retina. At least in Collies (and other related breeds with syndromes similar to Collie eye anomaly), *the retinal lesion is probably secondary to defective RPE.* Since the other defects of choroidal/scleral formation and maturation are attributed to faulty induction by a defective RPE, it is reasonable to attribute the retinal folding to the same mechanism (Fig 4.18).

A histologically similar retinal folding that may not depend on retinal:scleral growth imbalance is seen in English Springer Spaniels. Changes are seen as early as gestational day 45 and always by day 55. Focal infolding of the neuroblastic layer away from the retinal pigment epithelium and focal loss of the junctions between the neuroblasts (the outer limiting membrane) are the early changes, followed by overt focal retinal separation and extensive retinal folding. In all breeds in which this type of dysplasia has been adequately studied, it is inherited as a simple autosomal trait.

Retinal dysplasia as a sequel to **retinal necrosis** can occur as a sequel to a wide variety of viral and physical-chemical insults to the embryonic eye; naturally occurring examples are almost exclusively viral. Since the carnivore retina continues to develop for about 6 weeks after birth, the opportunity is great for postnatal injury in

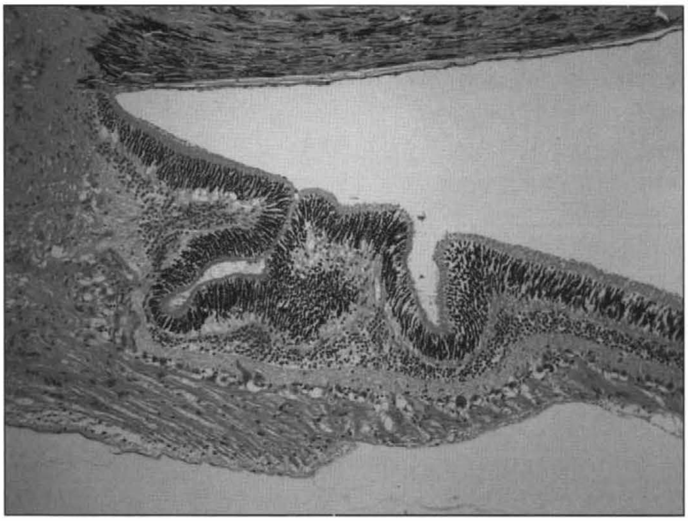

Figure 4.18 Retinal folding, presumably as a result of retinal redundancy that may eventually self-correct as the scleral shell grows to accommodate the retina. Retinal histologic organization is normal, distinguishing this from true retinal dysplasia.

puppies and kittens to produce retinal maldevelopment. Retinal maturation is most rapid in central (peripapillary) retina and progressively less towards the periphery, so that occasionally dysplastic lesions may be encountered only in peripheral retina – suggesting a viral (or other) injury quite close to the 6-week-old limit for dysplasia of this pathogenesis. Mature retina will scar but will not develop lesions of dysplasia.

The specific viruses implicated in domestic animals are *Bovine viral diarrhea virus* in cattle, *Bluetongue virus* in sheep, herpesvirus in dogs, and both parvovirus and leukemia virus in cats. The histologic lesion is similar for all diseases, with variation in lesions caused by the same virus in one species as great as the variation caused by different viruses in different species. *The most significant clue suggesting viral rather than genetic cause is the presence of residual inflammation and postnecrotic scarring in retina, optic nerve and, perhaps subtly, in choroid.* Injured retinal pigment epithelium undergoes one or more of reactive hyperplasia, migration into injured retina as discrete pigmented cells in areas of scarred retina, or metaplastic formation of multilayered fibroglial plaques in place of normal simple cuboidal epithelium (Fig. 4.19A, B). Disorganization of nuclear layers and rosette formation are seen as in other types of dysplasia.

Infection of calves with *Bovine viral diarrhea virus* between 79 and 150 days gestation is the most frequently encountered and thoroughly studied retinal dysplasia of known viral etiology. Work with other viruses has been too limited to allow definition of the susceptible period in fetal development or of the full range of resultant lesions. The limited descriptions of the other viral-induced retinal lesions suggest that the sequence of events is probably quite similar for all such agents.

The initial ocular lesion is nonsuppurative panuveitis and retinitis with multifocal retinal and choroidal necrosis. The acute inflammatory disease gradually subsides over several weeks, and most cases of spontaneous abortion or neonatal death retain scant vestige of previous inflammation. Those ocular structures already well differentiated at the time of the endophthalmitis (cornea, uvea, optic nerve) may undergo atrophy and scarring or be left virtually untouched. Other tissues, such as retina, are actively differentiating and exhibit a combination of the above atrophy and scarring as well as abortive regeneration and arrested differentiation. Retinal pigment epithelium in most examples (*Bluetongue virus* being an apparent exception) is infected and subsequently injured. *The result is a patchy alternation of abortive retinal regeneration, hyperplastic pigment epithelium, and postnecrotic glial scarring* (Fig. 4.19C). The lesions are usually more severe in nontapetal retina and are bilateral but not necessarily symmetrical. It seems reasonable to speculate that those naturally occurring cases in which the dysplasia is confined to peripheral retina represent late viral infection when only peripheral retina is still differentiating.

Because the virus has affinity for other neural tissues, *all calves with retinal dysplasia induced by Bovine viral diarrhea virus also have cerebellar atrophy, and some have hydrocephalus or hydranencephaly.* A similar association with hydrocephalus and other brain anomalies has been described for *Feline panleukopenia virus* infection in cats, *Bluetongue virus* infection in sheep, and in a possibly hereditary syndrome in white Shorthorn and Hereford cattle. In the latter two instances, the involvement of virus could not be excluded based upon published information.

Experimental irradiation of neonatal puppies (and, presumably, kittens) results in retinal necrosis and scarring virtually indistinguishable from postviral retinal dysplasia.

True retinal dysplasia, not associated with exogenous infection or teratogen, is rare. *It is characterized by retinal folds, retinal rosettes, patchy to diffuse blending of nuclear layers, loss of retinal cells and glial scars.* The folds and rosettes are the histologic counterparts of the vermiform streaks seen on the fundus with the ophthalmoscope. *The hallmark of retinal dysplasia is the rosette*, composed of a central lumen surrounded by 1–3 layers of neuroblasts. The three-layered rosette is the most common in naturally occurring cases in animals, and shows more or less complete retinal differentiation. Most such rosettes are probably retinal folds cut transversely (and, as mentioned above, should not be considered true dysplasia if no additional lesions are present). The lumen contains pink fibrils resembling photoreceptors and is bounded by a thin membrane resembling the normal outer limiting membrane. One- and two-layered rosettes are encountered infrequently and consist of a lumen surrounded by undifferentiated neuroblasts.

True retinal dysplasia occurs in combination with chondrodysplasia in several dog breeds, but particularly in Labrador Retrievers and Samoyeds. Cataract and persistent hyaloid remnants may accompany the retinal lesion. In Labradors, all the defects are the result of a single gene, with recessive effects on the skeleton and incompletely dominant effects on the eye.

Optic nerve hypoplasia

Hypoplasia is the most common anomaly of the optic nerve. The defect may be unilateral or bilateral, and usually occurs in eyes with other anomalies and particularly in eyes with retinal dysplasia. *In most instances, the so-called 'hypoplasia' is more likely to be atrophy* as the inevitable result of the destruction of ganglion cells in glaucomatous, viral, toxic, genetic, or idiopathic retinal disease (Fig. 4.20). The only clear example of an alternative pathogenesis is that associated with *maternal deficiency of vitamin A in cattle,* in which atrophy of the developing optic nerve results from failure of remodeling of the optic nerve foramen and subsequent stenosis. A similar lesion occurs in *pigs*, but in that species hypovitaminosis A seems more indiscriminately teratogenic, and optic nerve hypoplasia is accompanied by diffuse ocular dysplasia and multiple systemic anomalies. Hypoplasia is a relatively frequent clinical diagnosis in *toy breeds of dogs*, without apparent visual defects (and thus rarely receives histologic examination). Most examples are probably hypomyelination of the optic disk, which results from premature halt of myelinated nerve fibers at, or posterior to, the lamina cribrosa. The opposite, with myelin extending too far into the nerve fiber layer of the peripapillary retina, is also seen in dogs and is a frequent but insignificant occurrence in horses.

Inherited optic nerve hypoplasia is documented in one strain of laboratory mice, although it may accompany inherited retinal dysplasia or multiple inherited anomalies in any species. Histologic examination of affected eyes reveals few if any ganglion cells and a thin and moth-eaten nerve fiber layer.

Anomalies of surface ectoderm

From fetal surface ectoderm are derived corneal epithelium, lens, lacrimal apparatus, and the epithelial portions of the eyelids and associated adnexa. Seldom are anomalies of the extraocular structures the subject of histopathologic study inasmuch as they are clinically obvious and of significance only if they result in corneal irritation, impaired vision, or unacceptable appearance.

Excessively large or small palpebral fissures are part of current fashion in some dog breeds. *Micropalpebral fissure frequently leads to entropion* as the lid margin curls inward, and resultant corneal abrasion necessitates surgical correction. Congenital entropion also occurs as sporadic flock epizootics in lambs, but whether this is a structural deformity or the result of eyelid spasm is unclear. Entropion associated with microphthalmos occurs in all species. Other eyelid defects include colobomas, which are focal to diffuse examples of eyelid agenesis, and delayed separation of the eyelid fusion, which is the normal state during organogenesis.

Disorders of cilia are very common in dogs, but uncommon in other species. Congenital defects include one or more of ectopic cilia, misdirected but otherwise normal cilia (**trichiasis**), the occurrence of a second row of cilia from the orifice of normal or atrophic Meibomian glands (**distichiasis**), and excessively large cilia (**trichomegaly**). In each instance, the significance of the anomaly depends on the presence or absence of corneal irritation.

The lacrimal gland and its ducts develop from an isolated bud of surface ectoderm and, while anomalies must surely exist, they have not been investigated. *Failure of patency of the lacrimal puncta* occurs in dogs and horses and manifests as excessive tearing. Ectopic or supernumerary openings have been reported in dogs and in cattle.

Corneal anomalies

Primary corneal maldevelopment is rare in all species. The category may be expanded to include *corneal dystrophies*, defined as bilateral, inherited, and usually central corneal opacities that, despite their typically adult onset, presumably have a congenital basis. These rare lesions will be discussed with degenerative diseases of the adult cornea.

Corneal anomalies may be ectodermal or mesenchymal, and may affect one or more of corneal size, shape, or transparency. **Microcornea** refers to a small but histologically normal cornea in an otherwise normal globe. A small cornea occurring in a microphthalmic globe is expected and does not merit a separate description. Mild microcornea of no clinical significance is reportedly common in certain dog breeds. **Megalocornea** has not been reported in domestic animals, except in predictable association with congenital buphthalmos.

Dermoid is a congenital lesion of cornea or conjunctiva characterized by *focal skin-like differentiation*, and as such is properly termed a **choristoma.** They occur in all species. There is one report of a geographically high prevalence of multiple, and sometimes bilateral, dermoids as an inherited phenomenon in polled Hereford cattle in the American midwest, but ordinarily they seem to occur as single, random anomalies of unknown pathogenesis. Defective induction (skin instead of corneal epithelium) by the invading corneal stromal mesenchyme is the most popular speculation.

The *degree of differentiation varies,* but most consist of stratified squamous keratinized and variably pigmented epithelium overlying an irregular dermis containing hair, sweat glands, and sebaceous glands. Very rarely, cartilage or bone is seen. The degree of adnexal differentiation varies widely but may approach that of normal skin (Fig. 4.21A, B, C). At the edge of the dermoid, the dermal collagen reorients to blend with the regular stroma of cornea, and the epidermis transforms itself to corneal epithelium. Surgical removal may be for cosmetic reasons, or may be required if dermoid hairs irritate cornea, or if the position of the dermoid interferes with vision. In most instances of corneal dermoid, the choristoma is attached to the surface of a corneal stroma of normal thickness, so excision of the dermoid should not risk perforation of the globe.

Congenital corneal opacities are *usually caused by anomalous formation of the anterior chamber, particularly congenital anterior synechiae and persistent pupillary membranes.* Adherence of anterior chamber structures to the corneal endothelium, or perhaps their interposition during ingrowth of the corneal endothelium, results in focal absence of the corneal endothelium and disorganization of adjacent corneal stroma. Grossly, the affected cornea has deep stromal opacity caused by stromal edema or fibrosis in the area of the defective endothelium. Pigment, originating from adherent uveal strands, may be found in the corneal stroma. The opacity may be diffuse or focal, depending on the extent of uveal–corneal adhesion. Many examples are part of a more widespread anterior segment dysgenesis (see under Defects primarily in anterior chamber mesenchyme).

Diffuse, congenital corneal opacity occurs in Holstein-Friesian cattle in England and Germany. The histologic lesion is diffuse corneal edema but its pathogenesis is unknown. The cornea remains permanently opaque.

Corneal opacity caused by noncellular depositions occurs in dogs and is usually of adult onset despite an apparently genetic basis. The exception is multifocal, subepithelial deposition of basophilic, PAS-positive material in the corneas of puppies with Collie eye anomaly or other mesodermal dysgeneses. The material is of unknown origin and may be the histologic counterpart of the transient, multifocal, subepithelial opacities seen quite commonly in 2–3-week-old puppies whose eyes are otherwise normal and thus unavailable for histologic examination.

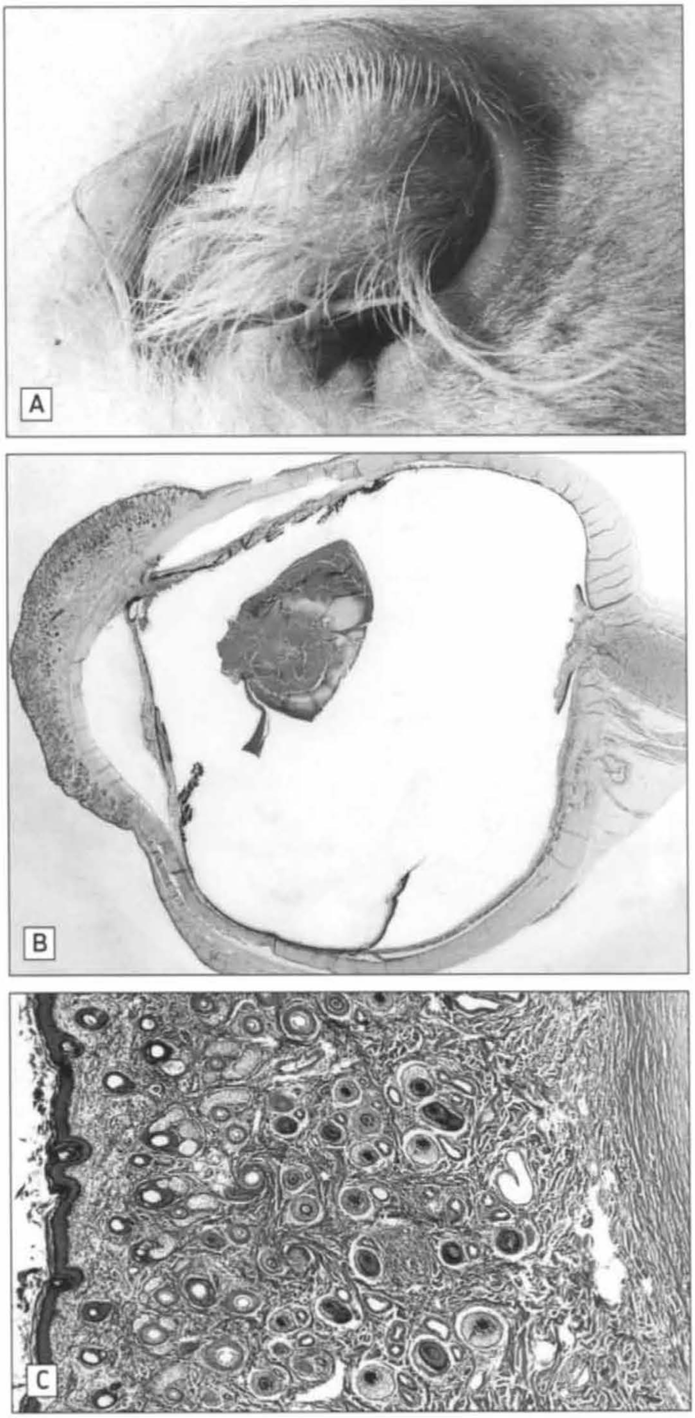

Figure 4.21 Corneal dermoid in a calf. **A.** Notch-like defect in lower lid is a coloboma. **B.** Anterior rupture of lens capsule with well-organized anterior synechia, probably from foreign-body perforation. **C. Corneal dermoid** in a calf; same eye as in **(A)** and **(B)**. Development approaches that of normal skin. Note abrupt transition to dense regular corneal stroma at deep margin of the dermoid.

Anomalies of lens

The lens may be abnormally small, abnormally shaped, ectopic, or cataractous. Of these, *only ectopia and cataract are common.*

Aphakia *is the congenital absence of lens, and it may be primary or secondary.* It is claimed that primary aphakia is possible only in a rudimentary globe because of the central role of lens in the induction of invagination of the primary optic vesicle. Any globe with the structure of optic cup, regardless of how dysplastic, must have had a lens early in organogenesis and its absence later must be the result of degeneration. This assumption is an extrapolation from work done many years ago in chicken embryos; while no work has been published to refute this contention, there is no work in mammals to confirm it. In the one report of aphakia in modern literature that includes histologic examination, several other puppies had small lenses and all had invaginated optic cups with iris and retina. There was no conclusion about the nature of the injury to the developing eyes or the timing of such injury.

Microphakia, *or congenitally small lens*, is reported in dogs, calves, and cats, but is nonetheless rare. Most such reports describe the defect in association with ectopia lentis, microphthalmos, and anterior chamber mesenchymal anomalies. Such lenses are spherical and almost always are cataractous.

Lenticonus and **lentiglobus** *are rare defects of lens shape* characterized by an abrupt change in capsular configuration so that the lens acquires a globular or conical protrusion. The defect is usually polar and, in animals, usually posterior. From scattered and very old descriptions, it is difficult to define the "typical" histology of such lesions or their pathogenesis. The defect usually appears as a focal overgrowth of cortical lens fibers covered by thin posterior lens capsule and retained posterior epithelium. Of four relatively recent descriptions, all of canine eyes, all had congenital cataract but only in one did the cataract involve the protruding lens fibers themselves. Other ocular lesions reported include hyperplasia of tunica vasculosa lentis, rupture of the lens protrusion, and dysplasia of ciliary epithelium. At least in Doberman Pinscher dogs, the posterior lentiglobus or lenticonus accompanying hyperplastic tunica vasculosa lentis appears to be an acquired defect caused by the abnormal fibrovascular elements adherent to lens.

Congenitally ectopic lenses occur in all species, but are relatively common only in dogs and horses. *Much more common than congenital luxations are spontaneous luxations in adult dogs*, which may be associated with acquired lesions of the zonule. The reason for the particular susceptibility of small terriers and Poodles to spontaneous lens luxation is unknown.

Congenital cataract occurs in most severely anomalous eyes, but may occur as an isolated ocular lesion. When cataract is present in eyes with multiple anomalies, it usually results from persistence of some part of perilenticular vasoformative mesoderm, but may also result from intraocular inflammation or toxic degeneration. Persistence of pupillary membrane or hyaloid system frequently results in multiple epithelial defects and subcapsular opacities at the sites of mesodermal contact with the lens.

In dogs, congenital primary cataracts are frequently hereditary but, as with corneal and retinal diseases, most hereditary cataracts are not congenital. Subtle, nonprogressive nuclear or cortical opacities are common but clinically insignificant in dogs and are of unknown pathogenesis. Primary, and usually diffuse, cataract is the most common ocular anomaly of horses. The pathogenesis is unknown, but there is usually no other ocular lesion. Congenital nuclear cataracts have been described as an inherited lesion in Morgan horses in the United States.

Congenital cataract is rare in cattle, swine, sheep, and goats. In cattle, hereditary congenital cataract occurs in Holstein-Friesians and in Jerseys and is thought to be an autosomal recessive trait. It is also seen as an infrequent result of fetal infection with *Bovine viral diarrhea virus*.

There is a single report of bilateral, complete cataracts in a litter of Persian kittens, but there are no examples in swine or small ruminants except in association with multiple ocular defects.

The pathology of congenital cataract is the same as acquired cataract, and is discussed later. It may be nuclear, cortical or capsular, focal or diffuse, stationary or progressive depending upon the timing and pathogenesis of the original injury.

Ocular adnexa

The adnexa include eyelids, nictitating membrane, lacrimal and accessory lacrimal glands. Developmental, degenerative, inflammatory, and neoplastic diseases of these structures are commonly encountered in clinical practice, but only the neoplasms and proliferative inflammatory lesions are regularly submitted for histologic examination.

Eyelids

Disorders of size and configuration of the palpebral fissure are common in purebred dogs, as are anomalies of number or placement of cilia. None requires histologic evaluation.

Blepharitis is *inflammation of the eyelid. Ordinarily, it refers to inflammation of the haired skin that covers the outer surface of the eyelid.* Diseases primarily affecting the palpebral conjunctiva that lines the bulbar surface of the eyelid would ordinarily be classified as conjunctivitis and are considered later. The diseases of the eyelid skin are, in general, exactly the same as diseases of skin elsewhere, and

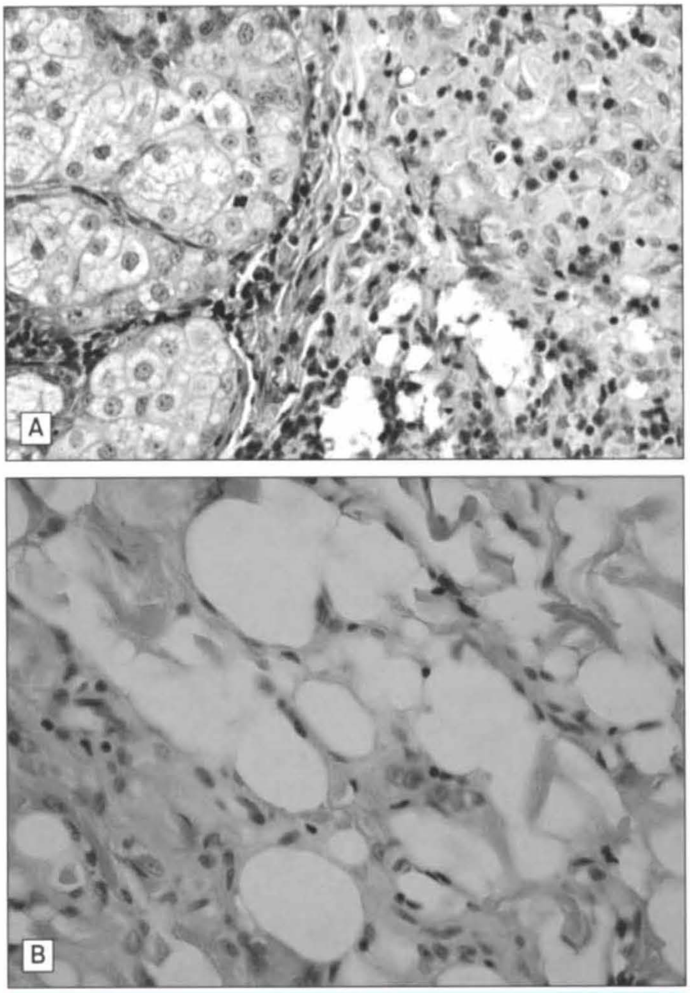

Figure 4.22 Chalazion **A.** Leaking Meibomian gland or, more often, Meibomian adenoma surrounded by foamy macrophages. **B.** In this variant (particularly common in cats), the leaking secretion forms **lipid lakes** with a relatively inconspicuous granulomatous reaction.

are thus not considered here in any detail. Inflammatory lesions more or less unique to eyelid include hordeolum, chalazion, and idiopathic granulomatous marginal blepharitis.

External hordeolum or **stye** is *suppurative adenitis of the adnexal glands of Zeis or Moll.* **Internal hordeolum** is *suppurative inflammation of the Meibomian gland.*

Chalazion is *sterile granulomatous inflammation in response to the leakage of Meibomian secretion into the surrounding dermis.* While it can theoretically occur in response to any type of injury to the Meibomian gland, almost all cases are found adjacent to Meibomian adenomas. The histologic lesion is distinctive and comes in two forms that may occur independently or in conjunction with one another. The more common is an accumulation of large foamy macrophages and multinucleated cells around the abnormal Meibomian gland. The macrophages contain distinctive refractile intracellular slender elongated crystals that have a bright silvery-white appearance when examined with polarized light. Alternatively, the reaction may consist of a mixture of these macrophages and lakes of free lipid. In routine sections, these appear as clear empty spaces that could be confused with dilated lymphatics (Fig. 4.22A, B). This latter variant was originally described in cats as idiopathic lipogranulomatous conjunctivitis (see below), but current opinion is that it is just a feline version of chalazion.

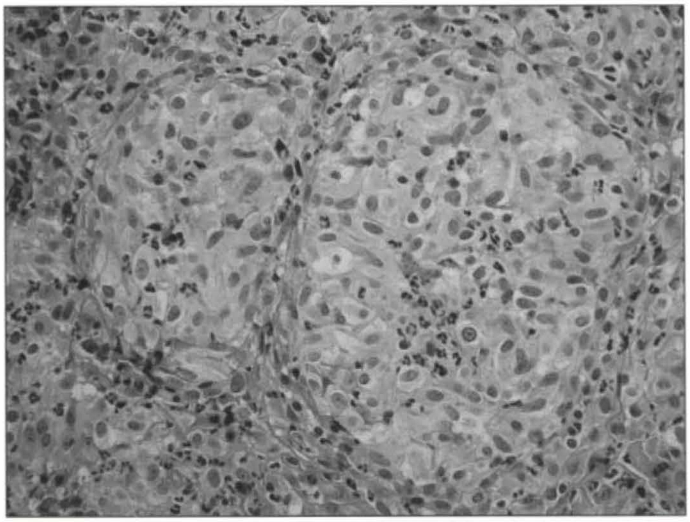

Figure 4.23 Granulomatous marginal blepharitis. Granulomas form around clear lipid vacuoles, sometimes with neutrophils. The location along the palpebral surface of the eyelid margin is critical to the diagnosis.

Idiopathic granulomatous marginal blepharitis is a uniquely canine lesion. The macroscopic lesion varies from a single nodule to a series of coalescing nodules that create virtually diffuse thickening of one or both eyelid margins. *The histologic lesion is a coalescence of suppurating granulomas in the subconjunctival tissue of the eyelid margin, without any proven association with adnexal structures and without any identifiable etiologic agent.* The granulomas often form around a clear central lipid vacuole, with or without neutrophils at the interface between the vacuole and the surrounding macrophages (Fig. 4.23). The lesion bears considerable similarity to cutaneous sterile pyogranuloma syndrome and other idiopathic granulomatous panniculitis syndromes, all of which are equally mysterious in terms of pathogenesis. *The lesions differ from those of chalazion in that the latter does not form discrete granulomas, does not involve neutrophils, and is always found adjacent to Meibomian glands.*

Lacrimal system

Acquired disease of the lacrimal system is probably quite common in dogs if one includes keratoconjunctivitis sicca (see Keratitis) and eversion of the gland of the third eyelid.

Dacryoadenitis *is inflammation of the lacrimal gland,* and may result from involvement in orbital cellulitis or orbital trauma, spread from severe intraocular inflammation, incidental involvement in systemic diseases such as malignant catarrhal fever, feline infectious peritonitis, and canine distemper; or apparently specific immunologic assault. Specific dacryoadenitis caused by a coronavirus is extremely common in laboratory rats in which acute necrotizing inflammation of lacrimal, Harderian and salivary glands results in eventual fibrosis and squamous metaplasia of affected glands. Residual lesions in mildly affected rats are multiple lymphoid aggregates in the glandular interstitium. Similar changes are often seen in dogs with keratoconjunctivitis sicca, and in the absence of demonstrated viral cause, are assumed to represent autoimmune lacrimal adenitis. The analogous lesion in people with Sjögren's syndrome is associated with influx of numerous T-helper cells into the gland, but no studies have yet been published to prove this immune pathogenesis for canine lacrimal adenitis and atrophy. However, the efficacy of cyclosporine, which acts primarily by suppression of T-helper cells, in reversing canine lacrimal adenitis provides evidence for such a pathogenesis.

Protrusion of the nictitans gland is quite common in dogs, and is thought to reflect a congenital laxity in the connective tissue anchoring the gland to the cartilage of the third eyelid. Because the resultant eversion is unsightly and resembles a neoplasm, these lesions frequently are excised even though the membrana nictitans may be normal except for overlying conjunctival inflammation from exposure and abrasion. Since this gland sometimes supplies a significant proportion of total lacrimal secretion, its surgical removal may be followed by keratoconjunctivitis sicca in dogs that have less than optimal function of the primary lacrimal gland. In dogs with keratoconjunctivitis sicca, the gland may suffer the same lymphocytic interstitial adenitis, fibrosis, and atrophy as affects the lacrimal gland itself.

Conjunctiva

At the orifice of the Meibomian glands, the epidermis of the lid undergoes abrupt transition to the pseudostratified columnar mucous membrane typical of the palpebral conjunctiva. Goblet cells increase in number from the lid margin to the fornix, but ordinarily are absent in that portion of conjunctiva that extends from the fornix to the corneoscleral junction (bulbar conjunctiva). Lymphoid aggregates are common in the subepithelial connective tissue, particularly below the bulbar conjunctiva and the inner aspect of the nictitating membrane. These aggregates are more prominent in the conjunctiva of horses than other domestic species. Whether this is normal or a reflection of increased antigenic stimulation of the conjunctiva in the dusty environment of many horse stables is unknown. The transition from conjunctival to corneal epithelium occurs at, or slightly central to, the corneoscleral junction, and is marked by gradual loss of pigment, rete ridges, subepithelial blood vessels, and lymphoid tissue.

The general pathology of the conjunctiva is similar to that of other mucous membranes. Acute conjunctival injury, whether physical, chemical, or microbial, results in hyperemia and severe edema. Evacuation of goblet cells and cellular exudation from the very labile conjunctival vessels add to the excessive lacrimation caused by any ocular irritation. The ocular discharge progresses from serous to mucoid and perhaps purulent with increasing severity of insult. *Chronic irritation* results in epithelial hyperplasia, hyperplasia of goblet cells and lymphoid aggregates, or even squamous metaplasia progressing to keratinization. The goblet cell hyperplasia is a very uncommon lesion when compared to squamous metaplasia and lymphoid hyperplasia. Lymphoid hyperplasia may be so marked as to result in grossly visible white nodules that may require surgical or chemical removal to reduce irritation of the adjacent cornea. Although characteristic of a number of etiologically specific conjunctival diseases, *lymphoid hyperplasia is best considered a nonspecific response to any chronic antigenic stimulation.* Conjunctivitis frequently accompanies other ocular disease, notably keratitis, uveitis, and glaucoma. Conversely, conjunctival inflammation may spread to cornea, uvea, and orbit, although only secondary corneal involvement is common.

The causes of **conjunctivitis** *include every class of noxious stimulus, including allergy and desiccation.* Because conjunctival biopsy is rarely performed until all therapeutic measures have failed, it is rare to identify an etiologic agent associated with conjunctivitis. The etiologic significance of bacterial, fungal, and even viral agents should be considered very carefully in light of the normal bacterial flora, and the high prevalence of conjunctival carriage of several viral agents in clinically normal animals. At least in dogs, the isolation of gram-negative organisms, especially coliforms, *Pseudomonas* and *Proteus*, should be considered significant in light of the almost exclusively gram-positive flora of normal conjuctiva. Conjunctivitis occurs in a wide variety of multisystem diseases, such as canine distemper and ehrlichiosis, equine viral arteritis and babesiosis, bovine viral diarrhea, malignant catarrhal fever, classical swine fever, rinderpest, African swine fever, and others. Conjunctivitis accompanies most viral and allergic diseases of the upper respiratory tract. Only those diseases in which conjunctivitis is particularly prominent are discussed here.

Infectious bovine rhinotracheitis (IBR) is usually accompanied by serous to purulent conjunctivitis, which can be confused clinically with *infectious bovine keratoconjunctivitis* ('pinkeye') caused by *Moraxella bovis* (discussed below). However, corneal involvement with IBR is uncommon and is never the central suppurating ulcer typical of infectious keratoconjunctivitis. In an unpredictable number of animals, multifocal white glistening nodules, 1–2 mm in diameter, may be seen on the palpebral or bulbar conjunctiva. They appear as early as 3 days after instillation of *Bovine herpesvirus 1* into the conjunctival sac, and represent hyperplastic lymphoid aggregates. Overlying conjunctiva may be ulcerated and the defect filled with fibrin. IBR is discussed in Vol. 2, Respiratory system; Vol. 2, Alimentary system; Vol. 3, Female genital system.

In contrast to the situation in dogs, most cases of conjunctivitis in *cats* are probably caused by infectious agents. The agents incriminated include mycoplasma, chlamydia, or herpesvirus. The diagnosis is usually made based upon clinical characteristics, the presence of other clinical signs, and demonstration of the infectious agent via PCR or culture. Histologic lesions are not etiologically specific, and demonstration of the specific infectious agent in histology or cytology samples (even with the aid of immunofluorescence) becomes progressively more difficult as the lesions age.

Felid herpesvirus 1 causes a combination of conjunctivitis, keratitis, and upper respiratory disease when it first infects young cats, but it may cause conjunctivitis alone as a recurring infection in older cats that had recovered from the initial disease.

Mycoplasma felis and *M. gatae* have been reported to cause conjunctivitis unassociated with other signs in immunosuppressed cats, but instillation of organisms into the conjunctival sac of healthy cats without prior corticosteroid administration does not cause disease. In addition, many of the cats with putative mycoplasma conjunctivitis have had concurrent infection with herpesvirus or with chlamydia. It is likely that the mycoplasma, which is a member of the normal feline conjunctival flora, acts as a medically significant opportunist rather than as a primary pathogen. The conjunctivitis is pseudodiphtheritic and initially is unilateral. Histologically there is nonspecific erosive and suppurative conjunctivitis. Diagnosis requires the demonstration of coccoid bodies in the periphery of conjunctival epithelial cells.

Chlamydophila psittaci usually causes unilateral conjunctivitis in cats of any age, without any other associated disease. The conjunctivitis is initially neutrophilic, but rapidly becomes a nonspecific mixed infection with subepithelial neutrophils, macrophages, lymphocytes, and plasma cells. Early in the disease (between days 7 and 14), typical intracytoplasmic inclusion bodies can be seen, and their detection is enhanced by immunofluorescent staining. Because the clinical signs are characteristic and disease is easily treated with tetracycline, histologic assessment is rarely required. In cases that are resistant to therapy, the disease is usually chronic and histologically nonspecific by the time biopsy is eventually done.

Parasitic conjunctivitis

Parasitic conjunctivitis is relatively common worldwide and may be caused by members of the genera *Thelazia, Habronema, Draschia, Onchocerca,* and several members of the family Oestridae. Of these, only *Thelazia* is truly an ocular parasite; the others cause eyelid, conjunctival, or orbital disease incidentally in the course of larval migration.

Members of the genus ***Thelazia*** are thin, rapidly motile nematodes 7–20 mm in length that inhabit the conjunctival sac and lacrimal duct of a variety of wild and domestic mammals worldwide. Their prevalence is much greater than the prevalence of conjunctivitis, suggesting that their number must be greater than usual before signs of conjunctival irritation are observed. The species most commonly associated with conjunctivitis in domestic animals are *T. lacrymalis* in horses; *T. rhodesi, T. gulosa, T. skrjabini* in ruminants; *T. callipaeda* in carnivores and humans; and *T. californiensis* in many species including dog, cat, bear, coyote, deer, and man. Female worms are viviparous, and larvae free in lacrimal secretions are consumed by flies of the genus *Musca* in which they develop for 15–30 days. The third-stage infective larvae migrate to the fly's proboscis and are returned to the conjunctival sac as the fly feeds.

Ocular habronemiasis results from deposition of larvae by the fly intermediate host, usually *Musca domestica* or *Stomoxys calcitrans*, in the moisture of the medial canthus of horses. Larvae of *Habronema muscae, H. microstoma,* or *Draschia (Habronema) megastomum* are the culprits. The burrowing larvae cause an ulcerative, oozing lesion about 0.5–1.0 cm in diameter at the medial canthus, which becomes progressively more nodular as a granulomatous reaction to the larvae mounts. Mineralized granules may be found within the lesion along with caseous debris, liquefaction, and viable larvae. The histologic lesion is similar to that of cutaneous habronemiasis, namely chronic eosinophilic and granulomatous inflammation surrounding live or dead larvae and eosinophils (Fig. 4.24).

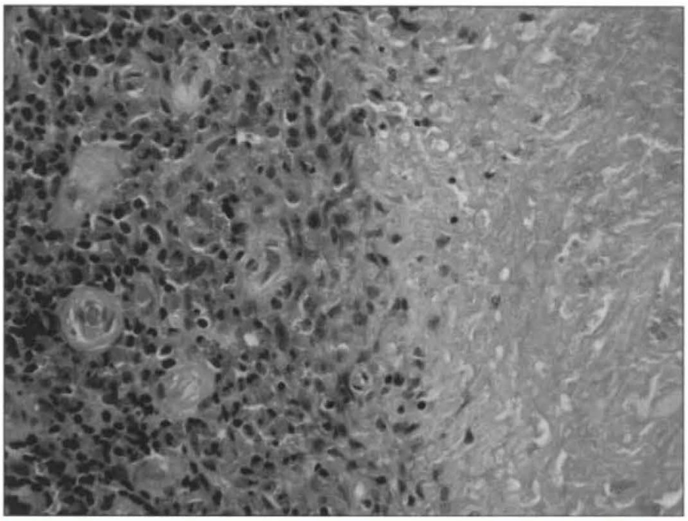

Figure 4.24 Conjunctival habronemiasis. Only rarely would fragments of larvae be detected within the center of these eosinophil-rich granulomas.

Ocular onchocerciasis results in the formation of granulomas and suppurating granulomas around fragmented or viable adult filarids within the sclera and subconjunctival lamina propria of dogs. Dogs are considered abnormal hosts for this parasite, which is much more commonly found in horses, cattle, and other ungulates. In horses, the infection causes a more diffuse eosinophilic and granulomatous conjunctivitis and peripheral stromal keratitis with a character similar to that in skin. Adults and microfilariae can be identified within the reaction.

Ophthalmomyiasis

A syndrome of periocular and even intraocular invasion by *fly larvae* occurs in various species including man. Its various manifestations are known collectively as ophthalmomyiasis. Specific *oculovascular myiasis*, "*uitpeuloog*," or "*gedoelstial myiasis*" is a disease of domestic ruminants and horses caused by invasion and migration of larvae of ***Gedoelstia*** spp. of Oestridae. The *Gedoelstia* are parasites of the blue wildebeest and hartebeest, the larvae being deposited in the eye, rather than in the nares as is the habit of *Oestrus ovis*. The most important member of the genus in terms of frequent aberrant parasitism in domestic species is *G. hassleri*, which in its natural antelope host migrates to the nasal cavity via the vascular system and cerebral meninges and subdural space. The parasitism is not clinically significant in the antelope, but in domestic species that are aberrant hosts, severe ocular and neural disease occurs, sometimes on a large scale. The disease is seasonal and occurs particularly in domestic ruminants in contact with wildebeest.

The ocular lesions vary from *transient mild conjunctivitis to destructive ophthalmitis* with orbital or periorbital edema or abscessation affecting one or both eyes. Neurological signs of varied pattern are common in sheep, partly due to the larvae directly and partly to thrombophlebitis marking their route of invasion. Thrombosis may be very extensive, may involve the jugular vessels and endocardium, and may cause sudden death when coronary vessels are affected.

Larval migration may be into the conjunctival sac, orbital tissues or into the eye itself. In the last instance, *ophthalmomyiasis interna*, the globe is often destroyed by the larval penetration. However, a syndrome of relatively harmless larval migration in the subretinal space or within vitreous has been reported in people. The characteristic subretinal linear tracks may be accompanied by focal retinal separation, preretinal and subretinal hemorrhage, and focal proliferations of retinal pigment epithelium. Two reported cases in cats had similar subretinal tracks, hyperplasia of pigment epithelium, and retinal hemorrhages. In one, the live motile larva was detected either on the face of, or just within, the retina. Subsequent examination failed to detect the larva, and the eye lesions resolved except for the subretinal tracks and pigment clumps.

The penetration is usually by a single larva despite numerous eggs or larvae within the conjunctiva. The larva may die within the globe or continue its migration by uneventful exit from the globe via sclera, optic nerve, or vessel adventitia.

Ophthalmomyiasis interna anterior has also been reported in a cat in association with infection with a first instar larva of ***Cuterebra*** spp. Severe anterior uveitis resolved after prompt surgical removal of the larva, but retinal degeneration and blindness ensued.

Immune-mediated conjunctivitis

Presumed allergic conjunctivitis occurs in all species but is most likely to be investigated in dogs (most examples of conjunctivitis in cats are assumed to have an infectious pathogenesis). Rarely is a specific allergen identified and, like its counterparts in allergic skin diseases, the diagnosis is based upon the failure to demonstrate infectious or mechanical causes, response to corticosteroid therapy, and sometimes a convincing association with environmental changes. Biopsy is rarely warranted, but when taken during the acute disease may show epithelial changes ranging from erosion to hyperplasia to squamous metaplasia, with eosinophils around dilated subepithelial blood vessels and percolating throughout the epithelium. Eosinophils are much more likely to be identified in cats than in dogs, a species difference that is also true of allergic skin disease in general. More chronic lesions, which are the more usual to be biopsied, have squamous metaplasia and lymphocytic-plasmacytic subepithelial infiltrates and the formation of lymphoid nodules.

There are a few histologically distinctive examples of conjunctivitis that are assumed to represent immune-mediated disease, mostly because they respond only to aggressive immunosuppressive therapy. In some dogs with chronic conjunctivitis (perhaps particularly German Shepherd Dogs), the infiltrate sometimes becomes particularly plasmacytic, diffuse, and thick in a fashion resembling an interface dermatitis. The bulbar surface of the third eyelid is the favorite location, and many believe this lesion (sometimes referred to as "*plasmoma*") to be the conjunctival variant of pannus keratitis.

Cats and horses may develop a severe **eosinophilic conjunctivitis** that is thought, by some, to be a conjunctival counterpart of the eosinophilic keratitis syndrome. Lesions may be unilateral or bilateral, and at least in cats there is almost always a concurrent ulcerative marginal blepharitis. Histologic changes include ulceration, epithelial hyperplasia, squamous metaplasia, and a heavy lymphocytic infiltration with a large proportion of eosinophils. Lesions in cats contain no detectable infectious agent, and no herpesviral DNA can be detected (the role of herpesviral infection in the pathogenesis of histologically similar eosinophilic keratitis in cats remains controversial). The clinical syndrome is rapidly responsive to topical corticosteroid administration.

Ligneous conjunctivitis is a distinctive clinical and histologic entity, thus far described only in Doberman Pinscher dogs. The clinical disease is bilateral and characterized by marked thickening and opacity of the palpebral conjunctiva and conjunctiva of the third eyelid. Histologically, the conjunctival lamina propria is thickened by massive deposition of hyaline material and a diffuse scattering of mononuclear leukocytes. Most of the leukocytes are T-lymphocytes, and the hyaline material stains weakly for IgG and IgA.

Feline lipogranulomatous conjunctivitis is probably the feline counterpart of canine chalazion. The lesion occurs almost exclusively in the lamina propria of the palpebral conjunctiva adjacent to the margin of either the upper or lower eyelid. The histology is very repeatable, consisting of a nodular accumulation of clear lipid lakes intermingled with large foamy macrophages and a few small or mononuclear leukocytes. Although the original report contained no mention of adjacent Meibomian lobules, the similarity between this entity and some cases of canine chalazion (or granulomatous dermatitis adjacent to injured cutaneous sebaceous glands) is striking and impossible to ignore (see Fig. 4.22B).

CORNEA

The cornea of domestic mammals is a horizontal ellipse varying from 0.6–2.0 mm in thickness among the various species. In general, the larger and older the animal, the thicker is the cornea. It appears as a structural and physiologic modification of sclera, and when chronically injured may lose the specialized features of cornea and resemble sclera both ophthalmoscopically and histologically. Embryologically, the epithelium is derived from surface ectoderm; the stroma and corneal endothelium are from neural crest mesenchyme.

The major attribute of cornea is its clarity, and it is the loss of clarity that is the most obvious indicator of corneal disease. The clarity results from several highly specialized anatomic and physiologic features: an unusually regular, nonkeratinized and nonpigmented surface epithelium; an avascular, cell-poor stroma composed of very thin collagen (mostly type I) fibrils arranged in orderly lamellae separated by a critical distance to allow the uninterrupted passage of light (620–640 Angstroms); and a high degree of stromal dehydration maintained by the presence of epithelial tight junctions, endothelial tight junctions, and a Na-K-dependent ATP-ase pump in the cell membrane of the corneal endothelium (Fig. 4.25A).

The cornea exists in a privileged environmental niche, bathed in the nurturing and antimicrobial saline of the tear film and protected from other irritation by the movable eyelids. Within this protected niche, the cornea does therefore not require the protective attributes of skin (keratinization, leukocytes, blood vessels) to protect itself from the harsh external environment. If there is rapid deterioration in any component of this protective environment, the cornea is most likely to respond with ulceration and subsequent wound healing. If, on the other hand, the shift is of gradual onset, then the more likely response is adaptive metaplasia in which the cornea reaches into its embryologic cutaneous heritage and becomes skin-like.

Corneal injury may result from physical or chemical trauma, microbial agents, increased intraocular pressure and, rarely, from inborn errors of metabolism. Specific features of some of these injuries will be discussed later, but the general reactions to most corneal injuries are presented here.

Corneal edema

Corneal edema occurs rapidly following injury and results from imbibition of lacrimal water through damaged corneal epithelium, absorption of anterior chamber water at a site of corneal endothelial damage, or failure of electrolyte (and thus water) extrusion by the corneal endothelium. If the epithelial or endothelial defect is focal, the resultant edema is limited to the stroma adjacent to the defect. The edematous cornea is clinically opaque, and may be up to five times its normal thickness (Fig. 4.25B). At least experimentally, edema subsequent to endothelial damage tends to be more severe than edema secondary to epithelial injury. Edematous stroma stains less intensely than normal, and collagen lamellae are separated into a fine feltwork of pale-staining fibrils by excessive hydration of the glycosaminoglycan ground substance (principally keratan sulfate and chondroitin sulfate). Percolation of stromal fluid into the epithelium results in the intercellular and intracellular edema known as *bullous keratopathy* (Fig. 4.25C).

Edema may also be part of more chronic corneal disease. Corneal vascularization in response to severe injury is accompanied by edema, as the porous new capillaries leak fluid into the interstitial spaces. A small amount of perivascular corneal edema frequently accompanies the deep stromal vascularization seen in chronic anterior uveitis of any cause. Sometimes the edema is unexpectedly diffuse, severe, and may persist even after the uveitis itself has subsided. Such eyes have a neutrophilic or lymphocytic destructive endothelialitis, with leukocytes interspersed among the vacuolated, pyknotic endothelial cells (see later section Uveitis). Other examples of corneal edema are seen in glaucoma and anterior segment anomalies. In the former, it is assumed that the high aqueous pressure drives fluid into the hydrophilic corneal stroma to a degree that overcomes the endothelial ion pump that dehydrates the stroma under normal conditions. In anterior segment anomalies, persistent pupillary membranes or congenital anterior synechiae cause focal defects in endothelial continuity.

Persistent corneal edema seems to predispose to stromal vascularization and fibrosis, but numerous experimental models show that

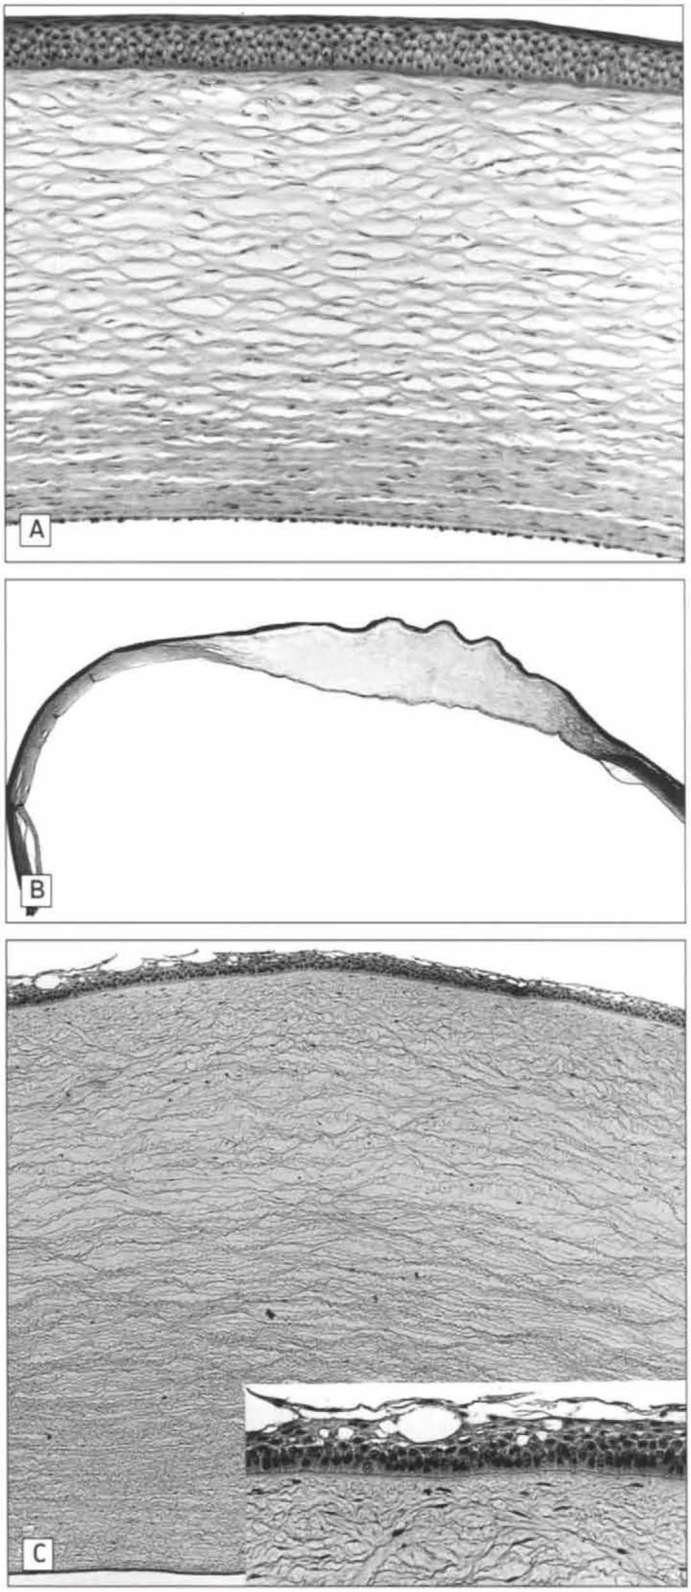

Figure 4.25 A. Normal canine cornea. Uniform, nonkeratinized epithelium without pigmentation or rete ridges. Stroma is poorly cellular. The clefts among the stromal fibers are unavoidable formalin fixation artifacts. **B. Central corneal edema** from abrasion of the corneal endothelium by lens. Figure 4.26 Corneal cutaneous metaplasia as a result of chronic keratoconjunctivitis sicca.

edema itself is not the stimulus. Instead, it is probably the infiltrating neutrophils that provide most of the angiogenic and fibroblastic cytokines. Damaged epithelium and stromal fibroblasts are alternative sources. A natural example of virtually permanent corneal edema, without accompanying vascularization, occurs in Boston Terrier and Chihuahua dogs with endothelial dystrophy.

Corneal cutaneous metaplasia

Injury to the corneal surface that exceeds the homeostatic ability of that epithelium resulting in corneal ulceration is described below. Less drastic change to the local environment that results in sublethal injury to the surface epithelium (qualitative or quantitative inadequacy of tears, irritation from misdirected eyelashes or from entropion) will result in adaptive cutaneous metaplasia. *The chronically irritated epithelium undergoes reactive hyperplasia with the appearance of rete ridges, melanin pigmentation, and surface keratinization.* The adjacent stroma undergoes dermis-like irregular fibroplasia and acquires vascularization via capillary migration from the limbus. These changes, while they enable the cornea to survive in a hostile environment and to combat the inflammatory stimulus, also deprive it of its transparency (Fig. 4.26).

Corneal wound healing

Corneal ulceration represents a loss of the surface epithelial barrier. It causes rapid osmotic imbibition of the tear film water, resulting in corneal edema. Neutrophils may be absorbed as well, and if present in large numbers they may initiate stromal lysis as they release their cytoplasmic enzymes. Persistent recruitment of neutrophils is usually a manifestation of sepsis, and is discussed further in the sections dealing with keratitis. In any corneal wound, however, there will be at least a few neutrophils.

The mechanisms of healing of corneal wounds vary with the severity of the injury, and involve an extremely complex interaction of epithelium, stroma, and innumerable cytokine growth factors derived from tear film, infiltrating leukocytes, and resident epithelium and stroma. Only the major elements will be described here, with an emphasis on histologically detectable events rather than on chemical mediators.

It is probably true that virtually any corneal injury results in at least some degree of both epithelial and stromal injury, but *from a purely histologic perspective one can sort corneal injuries into those involving primarily the epithelium and those involving a combination of the epithelium and underlying stroma. Those nonseptic defects involving epithelium alone, or epithelium and superficial stroma, heal by epithelial sliding followed after about 24 hours by mitosis.* One cannot claim that depth alone is the deciding factor, since even very deep wounds will sometimes heal just with epithelial sliding and eventual mitotic rebuilding, as long as the epithelium is satisfied with the quality of the underlying stroma. The sliding begins within a few hours, initially from wing cells from the immediately adjacent, viable cornea. Migration by basal cells rapidly follows. The sliding is preceded by lysis of the hemidesmosomes. Adhesion of the sliding epithelium is initially to adhesion molecules like fibronectin and laminin deposited along the exposed stromal surface. Reformation of the hemidesmosomes and their anchoring filaments may take weeks or even months, during which time epithelial adhesion remains precarious. Healing of shallow, uninfected corneal ulcers is rapid; experimentally induced 7-mm ulcers in horses heal within a mean of 11 days.

Persisting or reoccurring ulcers that cannot be healed just by sliding and replication of adjacent corneal epithelium may require the recruitment of cells from the epithelium at the corneoscleral junction, which is the site of the permanent replicative population. Such cells, when recruited for corneal wound healing, seem prone to retaining a conjunctival phenotype that includes pigmentation and a tendency to form rete ridges. One of the characteristics by which we recognize *chronic, stubborn corneal ulceration* is to observe this *conjunctival "metaplasia" of the surface epithelium.* Another is to recognize a *thickened basement membrane*, as the regenerating epithelium always seems to produce its own new basement membrane even if preexisting basement membrane still seems available. If the injurious stimulus disappears, the conjunctival character of the epithelium slowly fades, being replaced within a few weeks by a normal corneal epithelial configuration. Epithelial adhesion to the underlying stroma remains fragile for 6–8 weeks until the hemidesmosomal attachments of epithelium to basal lamina reform, and until the new epithelium secretes type VII collagen fibrils that anchor the basal lamina to the stroma. In the interim, the cells adhere to a mixture of fibrin and fibronectin derived from the inflamed conjunctival vessels via the tear film or from the injured cornea itself. In many cases, the only evidence of previous shallow ulceration is a thickened basal lamina resulting from secretion by the regenerating epithelium, and gentle undulation of the normally flat epithelial–stromal interface.

Stromal damage may be a direct result of the severity of the initial injury, but more often it is the result of neutrophil-mediated stromal lysis in those corneal injuries that were initially, or later became, septic. Shallow nonprogressive defects in the superficial stroma may be ignored, or may become filled by a thickened plaque of epithelial cells that create an epithelial facet. *Deeper defects that include more than the outer third of stroma will usually require rebuilding of the damaged stroma before epithelial sliding and regeneration can occur.* Within a few hours of the insult, neutrophils enter the wound via the tear film. They migrate into the stroma and control bacterial contamination, degrade damaged collagen, and stimulate both fibroplasia and vascularization via production of various cytokines, especially basic fibroblast growth factor derived from injured epithelium, stromal neutrophils, and injured stromal fibroblasts themselves. Viable stromal cells (keratocytes) adjacent to the wound undergo fibroblastic metaplasia and secrete large amounts of sulfated ground substance, particularly chondroitin sulfate. Most of the new stroma is usually produced by fibroblasts recruited from the limbus. Their ingrowth is always accompanied by a similar ingrowth of new blood vessels. This ingrowth begins about 4 days after substantial corneal injury, and migrates from the limbus centrally at a maximal rate of about 1 mm per day. This 4-day lag time is, presumably, a period of grace in which small or shallow defects can heal with epithelial regeneration alone, without the visual impairment that inevitably follows stromal fibroplasia. Once the epithelium seals the defect, there is immediate cessation of neutrophilic influx and, presumably, a similarly abrupt drop in the production of fibroblastic/angioplastic stimulatory cytokines. *The scarring and vascularization that are the manifestations of stromal rebuilding are permanent*, even though the fibrous tissue gradually becomes less cellular, the collagen fibrils reorient to resemble more closely the parallel arrays of normal stroma, and the ground substance gradually reverts from an embryonic configuration dominated by chondroitin sulfate to the normal predominance of keratan sulfate. Complete restitution of normal stroma, however, never occurs, although the residual scar may be subtle and better detected by clinical examination than by histology. Undesirable though such scarring may be, it is certainly better than the alternative of ineffective corneal healing and inevitable corneal rupture.

Healing of a corneal perforation involves the same events as does healing of a deep corneal ulcer, but there are some added challenges and complications. The cut edges of Descemet's elastic membrane retract from the wound and the transcorneal gap is initially plugged with fibrin and, sometimes, by prolapsed iris. If the gap is not closed by suturing or by a provisional matrix supplied by fibrin and/or iris stroma, there is the risk that the surface epithelium will grow downward along the cut surface of the stroma and into the anterior chamber (Fig. 4.27A). Its migration will be inhibited only by contact with viable corneal endothelium. If it does not encounter that endothelium, there is nothing to stop the epithelium from growing as a layer of stratified squamous epithelium all over the inside of the globe (Fig. 4.27B, C). Obstruction of the filtration angle inevitably causes glaucoma.

As with the surface epithelium, the corneal endothelium at the deep edge of the perforation attempts to bridge the defect by sliding over the fibrin scaffold to restore endothelial continuity. Replacement by mitosis begins within about 24 hours in some experimental models, but *the regenerative capability of the corneal endothelium in adult animals of most domestic species is very limited, and repair occurs by endothelial sliding and hypertrophy.* So potent is this capability that normal stromal dehydration can be maintained even in the face of a 50% reduction in endothelial cell density. The cut ends of Descemet's membrane make no apparent effort at regrowth, but rather the endothelium gradually secretes a new membrane that may eventually fuse with the old or remain separated from it by a layer of fibrous tissue.

The sequence of epithelial sliding and regeneration, remodeling stromal fibrosis and endothelial repair is not uniformly successful. Large gaping wounds fill with proliferating epithelium and stromal fibrous tissue that may protrude into the anterior chamber. The fibroblasts, most of which are probably derived from keratocytes but which may also evolve via endothelial metaplasia, tend to grow along the posterior surface of Descemet's membrane. Regenerating or sliding endothelium is then separated from the coiled remnants of the

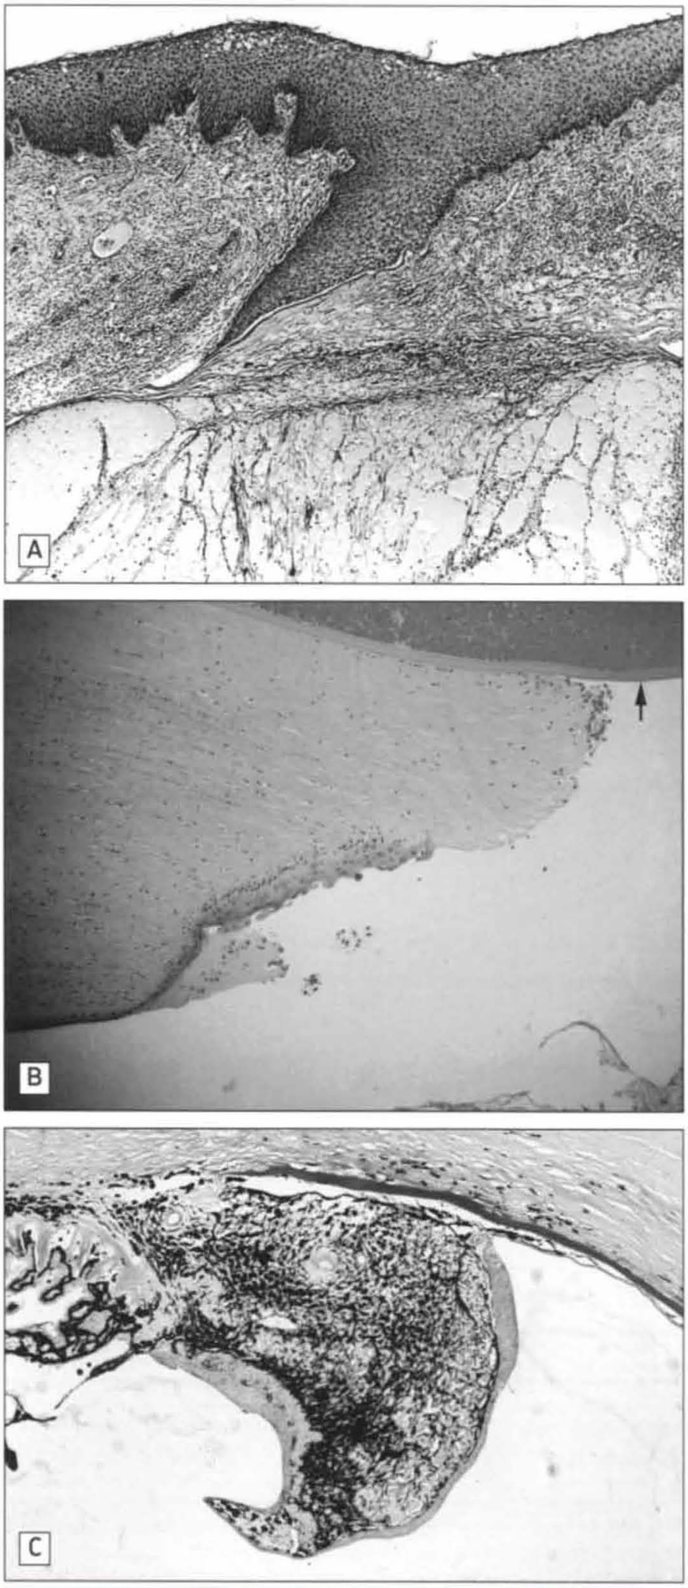

Figure 4.27 A. Corneal perforation in a steer. Defect filled by downgrowth of hyperplastic corneal epithelium. Adjacent stroma is vascularized and chronically inflamed. Edematous iris adheres to the innermost aspect of the lesion, creating focal anterior synechia. **B. Corneal epithelial downgrowth** along the gaping edge of an unsutured corneal laceration. Arrow points to Descemet's membrane that remains intact. **C. Corneal epithelial downgrowth** into the anterior chamber extends over the anterior and posterior surfaces of the iris.

original Descemet's membrane by a dense fibrous layer, called a *retrocorneal fibrous membrane*. Eventually, the corneal endothelium may regain continuity on the posterior surface of this membrane, secrete a new Descemet's membrane, and result in a cornea with two separate Descemet's membranes. Those perforations leading to iris prolapse will usually heal with permanent incorporation of the iris into the huge corneal scar, creating a permanent anterior synechia (Fig. 4.28).

Corneal dystrophy

Corneal dystrophies are bilateral, inherited (but not necessarily congenital) defects in structure or function of one or more corneal components. They are subclassified as epithelial, stromal, or endothelial. They are all uncommon, and almost all examples have been described in dogs. The list grows daily, with more than 30 different breeds affected. The least infrequent are the stromal dystrophies characterized by the deposition of lipids and/or minerals within an otherwise normal-appearing stroma. The deposition of mineral or lipid secondary to inflammatory disease or systemic metabolic abnormality should not be interpreted as corneal dystrophy.

Corneal endothelial dystrophy occurs in Boston Terriers, Chihuahuas, Dachshunds, and several other dog breeds, and causes slowly progressive bilateral corneal edema in mature dogs. The edema usually begins adjacent to the lateral limbus and may initially be unilateral and unaccompanied by other clinical signs. Later, epithelial fluid bullae may rupture to cause painful corneal ulcers and associated inflammation. Despite the persistent stromal edema, fibrosis and vascularization do not occur unless rupture of epithelial bullae initiates keratitis. *The primary lesion is spontaneous necrosis of corneal endothelium followed by hypertrophy, fibroblastic metaplasia, and sliding of viable endothelium.* A marked progressive decrease in overall endothelial cell density results, eventually, in what usually is severe bilateral corneal edema. The reason for the endothelial cell death is unknown. Focal irregularities in Descemet's membrane occur in areas of endothelial loss, presumably a result of new basement membrane production by adjacent reactive endothelium.

Posterior polymorphous dystrophy is characterized by multifocal random degeneration of corneal endothelial cells, accompanied by compensatory endothelial hypertrophy. Cellular loss causes exposure of Descemet's membrane, and adjacent deep stromal patchy edema.

A rare, juvenile-onset, genetically transmitted *endothelial dystrophy in Manx and domestic shorthair cats* is manifest as bilateral, progressive central epithelial and stromal edema. Fluid accumulates within superficial stroma and within the epithelium. Primary morphologic abnormalities are not described in the Manx, but in shorthairs there is irregularity and vacuolation of corneal endothelium.

Corneal stromal dystrophies include a wide range of breed-specific lipid and/or mineral deposits within the corneal stroma, with the exact age of onset, location, and clinical appearance being relatively specific in each breed. Specimens are rarely available for histologic assessment since the disease does not cause blindness and is not associated with any systemic abnormality. In most, the chemical nature of the deposit and character of the metabolic abnormality have not been determined.

Other corneal deposits

Deposition of mineral, lipid, or pigment within the cornea may occur secondary to chronic corneal injury or to systemic metabolic disease in any species.

Corneal hypermelanosis often accompanies *chronic corneal irritation in dogs* and less frequently in other species, particularly horses. The pigment is found in the basal layer of the corneal epithelium and in the superficial stroma. *It is the result of progressive ingrowth of new germinal cells that have retained pigment from the bulbar conjunctiva.* The clinical name, "*pigmentary keratitis*," is purely descriptive. The corneal epithelium is invariably hyperplastic and often has the other features of corneal cutaneous metaplasia, such as rete ridge formation, keratinization, and abnormally thick basement membrane. There is usually evidence of chronic stromal inflammation, including vascularization. Corneal stromal pigmentation without evidence of epithelial cutaneous metaplasia occurs infrequently, associated with previous iris prolapse that has contributed uveal melanin to the corneal stromal scar.

Other types of corneal pigmentation are rare. *Hemosiderin* will be found within corneal endothelial cells subsequent to anterior chamber hemorrhage or within stromal macrophages if there has been hemorrhage into the corneal stroma itself. Similar pigment may occur following implantation of corneal foreign bodies containing iron or other metals.

Diets high in cholesterol produce *diffuse corneal stromal lipidosis*, as well as focal lipid deposits in uveal epithelium and stroma. While hyperlipemia is not a documented prerequisite for most cases of corneal lipidosis in dogs (most of which are spontaneous dystrophies), *circumferential peripheral stromal lipidosis* is reported in dogs with hyperlipoproteinemia resulting from hypothyroidism and other causes.

Regardless of pathogenesis, the histologic lesion is similar. Cholesterol crystals and lipid vacuoles are found principally in anterior stroma, and are sometimes surrounded by lipid-laden macrophages and variable numbers of other leukocytes (Fig. 4.29). Vascularization is often present, but its pathogenesis is unknown. It appears that corneal vascularization can predispose to stromal lipidosis in animals with hyperlipemia, but it is also true that some animals with primary corneal lipidosis will develop secondary inflammation and vascularization.

Mineral deposition occurs primarily in the anterior stroma and the epithelial basement membrane. Predisposing corneal changes include desiccation, anesthesia, edema, or inflammation. *There are many methods for inducing deposition of calcium salts, but stromal edema seems to be the common denominator in almost all cases.* The edema may result from corneal epithelial desiccation (exposure keratitis), uveitis, corneal trauma, or chemical injury. Hypercalcemia from vitamin D toxicity or hyperparathyroidism exacerbates the mineralization and is essential to lesion development in some experimental models.

An unidentified corneal deposition is often seen in canine eyes suffering from multiple anomalies, particularly those involving uvea. Similar deposits are seen, with less regularity, in the horizontal midportion of the cornea of many normal puppies. Fine basophilic periodic acid-Schiff positive linear deposits are associated with the epithelial basement membrane or superficial stroma. There is some disarray of superficial stromal fibers but no inflammation. The nature and pathogenesis of the deposit are unknown, but most disappear after a few months.

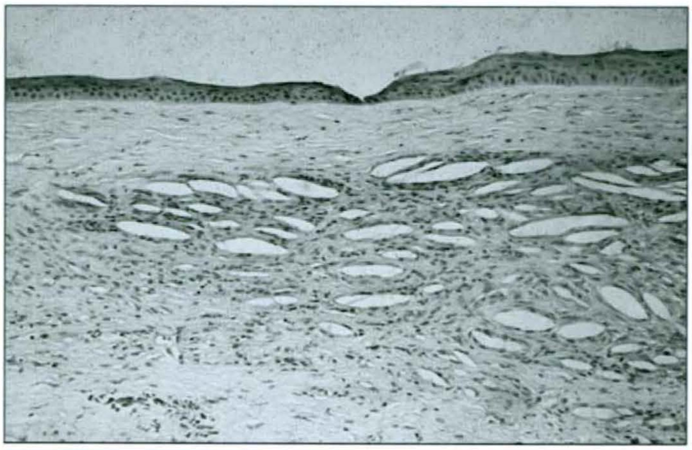

Figure 4.29 Lipid keratopathy. Clefts of cholesterol within the corneal stroma trigger mild nonseptic granulomatous inflammation.

Corneal degeneration

"Corneal degeneration" is a vague term sometimes used to describe those corneal lesions characterized by noninflammatory loss of epithelial or stromal viability. Diseases such as keratoconjunctivitis sicca and pannus keratopathy are sometimes considered primary degenerative lesions but their principal manifestation is inflammatory and they are discussed under keratitis.

The only degenerative, noninflammatory, acquired corneal lesions presented here are corneal sequestrum in cats and horses, and canine persistent erosion syndrome. It is quite possible that all three diseases have a similar pathogenesis, but for the moment they will be listed as three different diseases because of differences in clinical presentation.

Feline corneal sequestrum *is recognized clinically as a discrete orange-brown discoloration of the central cornea, affecting one or both eyes* (Fig. 4.30). Persian and Himalayan cats are more frequently affected than other breeds. Histologically, *the lesion is noninflammatory necrosis of stromal keratocytes, accompanied by pallor, hyalinization, and slight orange discoloration of the affected stroma.* The discoloration may be absent in very early cases. The overlying epithelium may be ulcerated or intact, but in those cases with an intact epithelium there is virtually always histologic evidence of previous ulceration. In older lesions, the periphery of the sequestrum may be marked by a zone of reactive mononuclear leukocytes and, perhaps, a few giant cells. The pigment is derived from porphyrins within the tear film, absorbed into the cornea as part of corneal edema that follows ulceration. *The sequestrum will eventually slough, and the defect heals by granulation* (although most lesions are treated by excision before that stage is reached).

The pathogenesis remains controversial. In flat-faced Persian and Himalayan cats, the pathogenesis probably involves corneal ulceration secondary to desiccation because of abnormal facial configuration. In

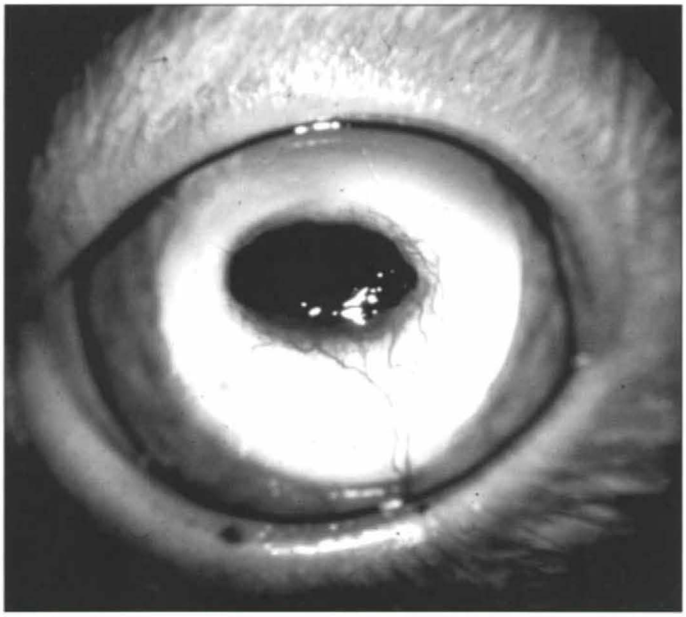

Figure 4.30 Feline corneal sequestrum.

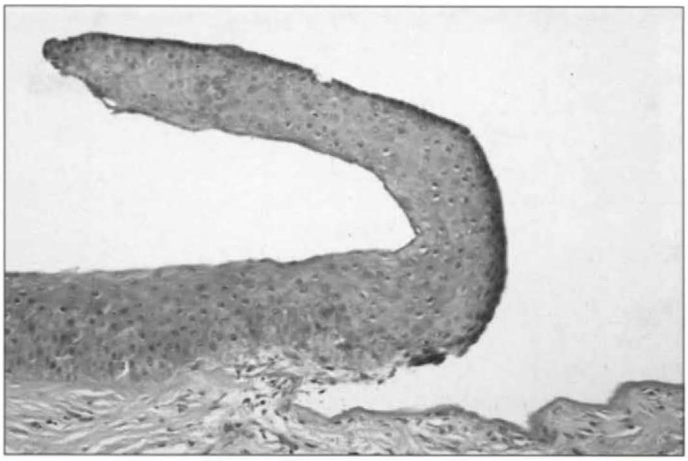

Figure 4.31 Canine persistent ulcer. Dysplastic, strongly regenerative epithelium is unable to adhere to the underlying superficial stroma.

non-Persian cats, there is a loose statistical association with herpesviral infection, and *it is reasonable to propose that corneal sequestrum is an uncommon sequel to any corneal ulceration in cats.* As will become clearer below, the brown discoloration is unique to cats and, for a long time, caused us to overlook the histologic similarity between the feline disease and similar histologic entities in horses and dogs. Not all feline cases acquire the characteristic brown pigmentation, and indeed some examples are virtually indistinguishable from canine and equine persistent ulcers described below.

Canine persistent (recurrent) ulcer syndrome was first described in Boxer dogs (hence the name "*Boxer ulcer*"). Although Boxers and related breeds may be predisposed, similar recurrent erosions are encountered in a wide variety of breeds. *The clinical syndrome is distinctive, characterized by a shallow central corneal erosion with scant edema and (at least initially) no vascularization.* The lesion refuses to heal, or repeatedly re-ulcerates, because of poor adhesion of the epithelium to the underlying stroma. The defect appears not to be in epithelial healing per se, since sliding and mitotic activity are normal in affected dogs. Keratectomy specimens reveal poorly adherent hyperplastic epithelium at the ulcer margins, usually with multiple clefts separating epithelium from stroma even in areas distant from the obvious ulcer (Fig. 4.31). The basal lamina is usually not visible with light microscopy, and the epithelium appears to be attempting to adhere to a thin zone of hypocellular, pale-staining stroma that could correctly be interpreted as a very shallow sequestrum qualitatively similar to what was described above in cats. *The observation of pyknotic and lytic keratocyte nuclei within this superficial zone suggests that the basic defect is degeneration of the superficial stroma,* so that epithelial hemidesmosomes and anchoring collagen fibrils attempting to reform after ulceration have no substrate in which to anchor. Very chronic cases usually acquire superficial stromal granulation tissue appropriate to any chronic ulceration, but its onset is much delayed in comparison to infectious or traumatic ulcers.

The lesion in **horses** is less frequent and less well characterized than in dogs or cats. It is histologically identical to what occurs in dogs, although it seems to be more often complicated and thus disguised by superimposed fungal infection (see Fig. 4.35B).

Keratitis

Corneal inflammation is called **keratitis** *and has traditionally been divided into epithelial, stromal (interstitial), and ulcerative keratitis.* It is probably time to abandon this arbitrary classification, at least when dealing with ocular histopathology. In realistic terms, almost all corneal inflammatory lesions reaching a pathologist are chronic and severe, and it is difficult to determine how they started. By the time we see them, almost all are ulcerated or show extensive stromal scarring below a healed ulcer. Regardless of cause, corneal inflammation initially follows the stereotyped sequence of edema and leukocyte immigration from tears and distant limbic venules. With severe lesions, corneal stromal vascularization, fibrosis and epithelial metaplasia with pigmentation may occur.

Keratitis usually results from physical, chemical, or microbial injury to the cornea, but the cornea may also be affected by extension of disease from elsewhere in the eye, adnexa, or conjunctiva. The stroma and endothelium may become involved in diseases of the uvea by extension via the aqueous or by direct extension from iris root or ciliary apparatus across the limbus.

Purely **epithelial keratitis** is rarely encountered in histologic preparations, either because the clinical lesion is transient and so mild that eyes are unavailable for histologic examination, or because the lesion progresses to ulceration (as in acute keratoconjunctivitis sicca).

Ulcerative keratitis includes a large group of lesions caused by physical and chemical trauma, desiccation, bacterial, fungal or viral infection, and rarely from primary degeneration of the corneal epithelium itself. *Regardless of cause, the loss of epithelium initiates a predictable series of corneal reactions caused by tear imbibition, local production of cytokines, and opportunistic microbial contamination of the wound.* Imbibition causes superficial stromal edema below the ulcer and is followed by immigration of neutrophils from the tear film and, later, from the limbus. The leukocytes, while somewhat protective against opportunistic pathogens, also add their collagenases, proteases, and stimulatory cytokines to the wound and thereby may contribute to its progression. Epithelial and stromal repair proceeds as already described for corneal wound healing, but the repair fails in those cases in which microbial contamination is well established or in which the cause of the initial ulceration has not been corrected. Common examples of the latter are found in dogs in which corneal trauma by misdirected cilia or facial hair, or desiccation due to lacrimal gland dysfunction, persists.

The usual role of bacteria and fungi in the pathogenesis of corneal ulceration is opportunistic. However, these opportunists contribute significantly to the perpetuation and worsening of the lesion. Proteases and collagenases of microbial, leukocytic, or corneal origin progressively liquefy corneal stroma, a process termed **keratomalacia** (Fig. 4.32). Ulcers contaminated by *Pseudomonas* and *Streptococcus* spp. are particularly prone to rapid liquefaction because of the potent collagenases and proteases produced by these organisms. *Pseudomonas* ulcers have been extensively investigated because of the devastating liquefaction of cornea that commonly accompanies this infection. The bacteria themselves produce numerous proteases and other toxins that may be important in the establishment of the early infection, but most of the characteristic stromal malacia results from the action of proteases originating from leukocytes, reactive corneal epithelium, or injured stroma. The stroma contains a variety of proenzymes (for collagenases, elastases, gelatinases, and other stromal lysins) that are cleaved by the *Pseudomonas* toxins to produce the active enzymes. Which toxins are produced, and in what quantities, is very strain dependent. The stepwise degradation of stroma is seen histologically as a featureless eosinophilic coagulum, which occurs with progressive septic ulcers regardless of the species of bacterium. Neutrophils may encircle the liquefying focus as a thick wall of live and fragmented cells. The resulting localized suppurative keratomalacia is called a ring *abscess* (Fig. 4.33), although that terminology is rarely used today. It is seen more commonly in cattle than any other species, perhaps because of the prevalence of untreated, contaminated corneal ulcers in that species and the prevalence of septic corneal perforation.

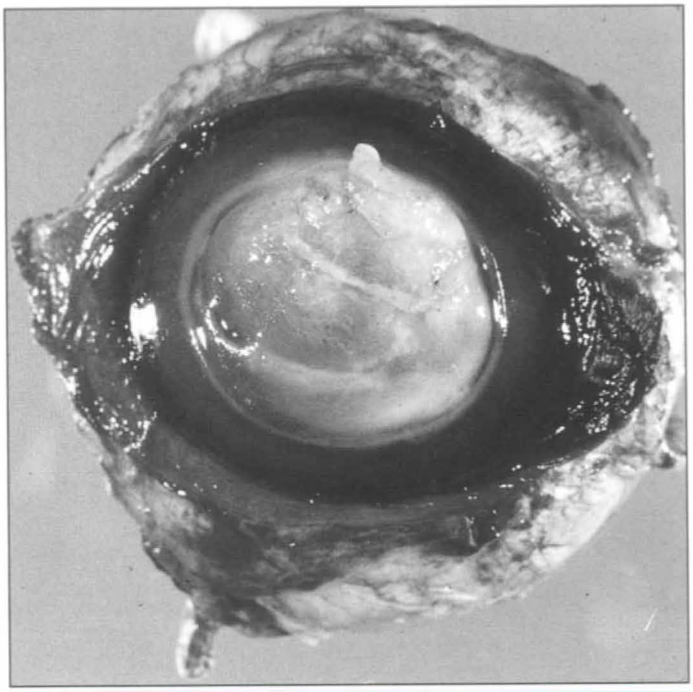

Figure 4.32 Keratomalacia in a horse with *Pseudomonas* keratitis.

The sequelae of ulcerative keratitis involve cornea, conjunctiva, and uvea. *The ulcer itself may heal with vascularization and scarring proportional to the severity of the initial lesion. It may persist as a stubborn but nonprogressive lesion, or it may progress to involve more of the stroma and epithelium.* Stromal liquefaction that reaches Descemet's membrane results in its forward bulging as a descemetocele. This membrane, while resistant to penetration of the microbial agents themselves, is apparently permeable to inflammatory mediators and microbial toxins that diffuse into the anterior chamber. These chemicals, combined with a vasoactive sensory neural reflex from irritated cornea, are responsible for the vasodilation and exudation in anterior uvea that are seen histologically in virtually all globes with deep ulcerative keratitis. Even in nonperforating keratitis, the anterior uveal inflammation may result in sufficient fibrin exudation so as to predispose to focal adhesions of iris to lens or (rarely) to cornea.

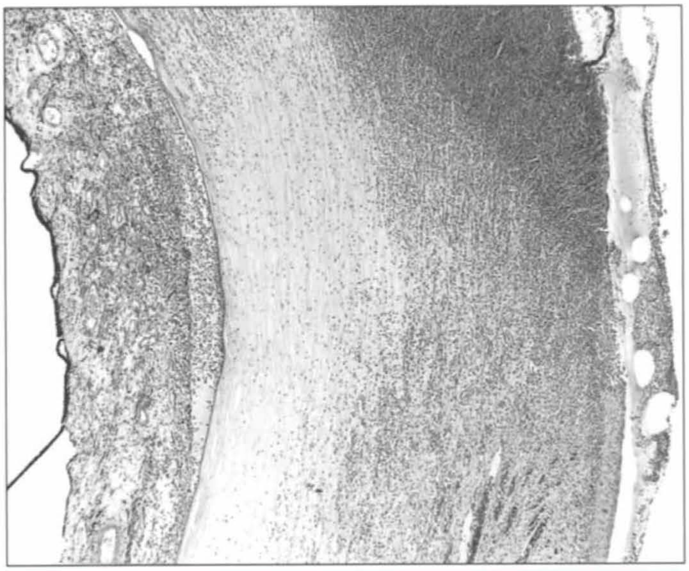

Figure 4.33 Severe suppurative keratomalacia accompanied by massive stromal edema, in a calf. The iris bows forward and almost obliterates the anterior chamber, a manifestation either of iris bombé or of nearby iris prolapse.

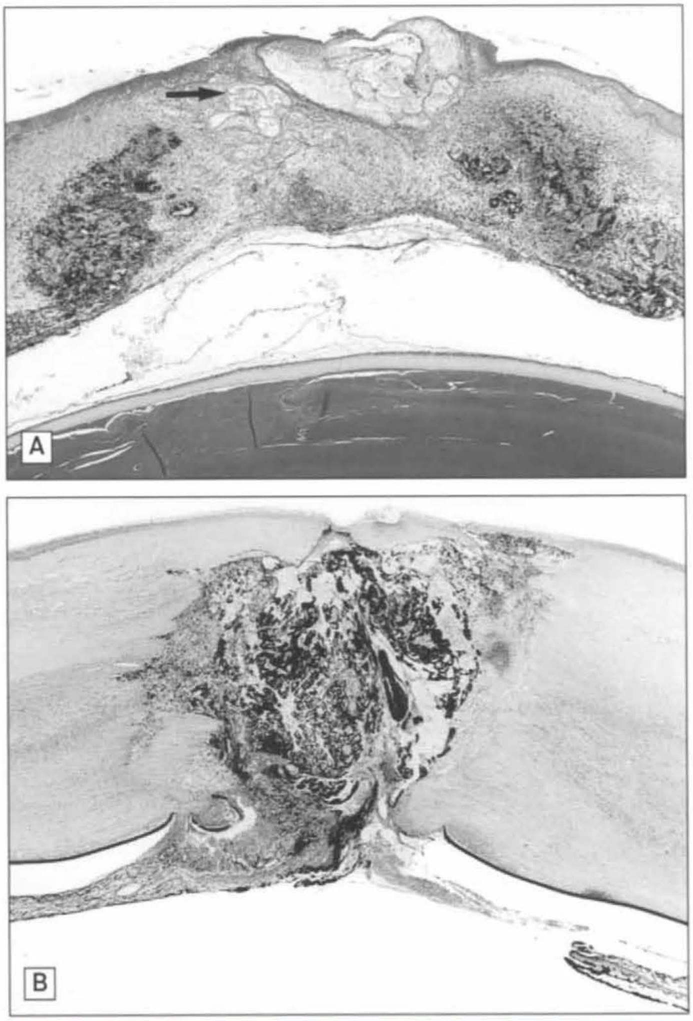

Figure 4.34 A. Healing corneal perforation. Corneal epithelium is attempting to heal across a fibrin mass plugging the defect. Iris is incorporated into the lesion and will form **anterior staphyloma**. Note coiled remnant of Descemet's membrane (arrow). **B.** Iris entrapped within the cornea following perforation of ulcer (**iris prolapse**).

In the case of corneal perforation, the iris flows forward to plug the defect (*iris prolapse*) and may subsequently become incorporated into the corneal scarring. This outcome is usually called **anterior staphyloma**, meaning a focal defect in the ocular fibrous tunic (i.e., cornea) that becomes lined by uvea (Fig. 4.34A, B). The distinction from anterior synechia is of little significance.

The conjunctiva is involved in almost all instances of keratitis, either as a victim of the same injury or as the nearest vascularized tissue to the diseased cornea. Hyperemia, cellular exudation, and lymphofollicular hyperplasia are common as the conjunctiva responds to the diffusion of inflammatory mediators of microbial, leukocytic, and tissue origin from the injured cornea.

There are some instances in which the lesions are found primarily within the stroma. Examples of bacterial or fungal keratitis in which the organisms were implanted into the stroma may cause chronic suppurative keratomalacia with negligible involvement of superficial stroma or epithelium. Alternatively, deep ulcerative septic keratitis may heal superficially, yet persist deep within the stroma. In either of these two situations, the deep lesion is referred to as *stromal abscess*.

Midstromal corneal vascular ingrowth from the limbus is a very common lesion in response to vascular endothelial growth factors elaborated in the course of chronic uveitis of virtually any cause. It appears to be a purely accidental lesion with no obvious purpose, but it does serve as a valuable and permanent histologic marker for previous or ongoing intraocular inflammatory disease. Its liability as a marker for subacute or chronic intraocular inflammation is probably not absolute, because similar midstromal vascularization can probably occur in response to growth factors liberated from detached retina or intraocular neoplasms (see Significance of uveitis).

Pannus keratitis

The only credible candidate for a *genuine stromal keratitis*, in which the primary target for the inflammatory disease is the stroma itself, is **pannus keratitis**. *This is an idiopathic disease seen most frequently in German Shepherds and phenotypically similar breeds.* Its prevalence and severity are directly correlated with altitude, suggesting that *sunlight exposure* is part of the pathogenesis. The clinical disease is distinctive. The early lesion is seen in dogs of either sex, usually in early middle age, as a vascularized opacity growing into the corneal stroma from the limbus. The ingrowth is bilateral although not always of simultaneous onset, and most frequently originates from the ventrolateral limbus. There is no ulceration, but pigmentation is often marked. The untreated lesion eventually infiltrates the entire cornea, converting the superficial stroma to an opaque membrane resembling granulation tissue. At one time, superficial keratectomy was the recommended therapy and so histologic specimens were quite often available. Today, most cases are treated with potent immunosuppressive therapy, and the need to perform a keratectomy to restore vision is rare indeed.

The histologic appearance varies with the duration of the lesion. *The initial lesion is superficial stromal infiltration of mononuclear cells, especially plasma cells.* Subsequently, there is progressive vascularization and fibroplasia in the superficial third of the stroma, accompanied by epithelial hyperplasia and pigmentation that may include the stroma. The deep stroma is never affected.

The pathogenesis of the condition is unknown, but an immune reaction to altered corneal epithelial antigens is hypothesized. Its response to continuous corticosteroid administration supports this hypothesis, as does it striking histologic similarity to discoid lupus and other lupoid dermatoses. Despite the similarity, immunofluorescence tests for intraepithelial or basement membrane immunoglobulin are negative. Infectious agents are not consistently isolated. A histologically similar lesion of the bulbar conjuctiva of third eyelid occurs in the same breed (so-called "*plasmoma*") and may reflect the same mysterious pathogenesis.

Keratoconjunctivitis sicca and desiccation keratitis

The response of the cornea to desiccation depends on the rapidity of onset and the severity of the desiccation. *It is seen as a consequence of inadequacy in the quantity or quality of the tear film* (usually called **keratoconjunctivitis sicca**). It also occurs as a consequence of exophthalmos, improper eyelid closure because of eyelid developmental anomaly, acquired eyelid disease, nerve injury to prevent blinking, profound CNS depression in which the blink reflex is lost, or conditions such as glaucoma or orbital mass that prevent proper eyelid closure because of abnormal ocular size or position. Under such circumstances, the corneal lesion is usually referred to as **desiccation keratitis**, although the effect upon the cornea is exactly the same as in acute keratoconjunctivitis sicca. In those cases in which the desiccation occurs only in a horizontal band not adequately covered by the eyelids for whatever reason, the lesion is sometimes referred to as *band keratopathy*.

If the desiccation is profound and occurs rapidly, the cornea has no time to adapt and the outcome is *acute ulceration*. It can be distinguished from other types of corneal ulceration histologically because *it is the only example of corneal ulceration that occurs in the absence of edema or neutrophilic infiltration* (because there is no tear film to provide either the water or the leukocytes). If the desiccation is only mild, or occurs over a long interval that allows corneal adaptation, the resulting lesion is *corneal cutaneous metaplasia*.

Desiccation keratitis (either acute or chronic) may follow destruction or denervation of lacrimal or accessory lacrimal gland by orbital inflammation, drugs, neoplasia, or trauma. Squamous metaplasia with resultant inadequacy of secretion may be seen with chronic deficiency of vitamin A. Specific lacrimal adenitis with subsequent atrophy is well recognized with coronavirus infection in rats and may be seen in the acute or chronic phases of canine distemper. Similar adenitis probably occurs with other viruses and in other species but such lesions are poorly documented. Transient keratoconjunctivitis sicca may accompany acute herpetic keratoconjunctivitis in cats.

Keratoconjunctivitis sicca, as a specific disease entity, is encountered more commonly in **dogs** than in any other species, with an overall prevalence in North America of about 1%. Most cases are chronic, progressive, and idiopathic. The reason for greater than expected prevalence in certain breeds (English Bulldog, Lhasa Apso, Shih Tzu, West Highland White Terrier, and others) is unknown. Because the disease is amenable to medical or surgical management, few specimens are available for histologic examination until the very chronic stages. At this time, the lacrimal gland is atrophic with interstitial lymphoid infiltration and fibrosis, but provides no clue as to the initial lesion. The ability of certain immune modulators, notably cyclosporine, to reverse the disease, points to some kind of immune-mediated phenomenon, perhaps autoimmunity.

The corneal changes vary with the severity and rapidity of onset of lacrimal deficiency. In acute disease with marked lacrimal deficiency, clinical signs of ulcerative keratitis may occur. The corneal epithelium is thinned, has numerous hydropically degenerate cells, and may suffer full-thickness ulceration. The accompanying stromal changes, including eventual vascularization and fibrosis, are those of ulcerative keratitis. More commonly in dogs, however, the desiccation is not absolute (at least initially) and the epithelial response is protective epidermalization without prior ulceration. Keratinization, marked hyperplasia with rete ridge formation, and pigmentation are commonly seen. Stromal inflammation and vascularization are usually superficial, resulting in a lesion very similar to pannus keratitis. Squamous metaplasia may also occur in the bulbar conjunctiva. The conjunctivitis that clinically is the earliest lesion of keratoconjunctivitis sicca is rarely available for histologic examination.

Herpetic keratitis of cats

Feline herpetic keratitis, caused by *Felid herpesvirus 1,* is seen either as the sole ocular lesion or in concert with conjunctivitis. Clinical signs associated with herpesviral infections in cats include conjunctivitis, keratitis, rhinotracheitis and, in neonates, systemic disease with encephalitis and necrosis in visceral organs. Acquired immunity alters the manifestations of the disease and results in different lesions predominating in different age groups. *Keratitis is commonest in adult cats* and seems to result from activation of latent infection during concurrent immunosuppressive disease or corticosteroid therapy. Concurrent mild respiratory disease may be present, but *in adults the disease is often purely corneal and may even be unilateral.* In contrast, *the infection in adolescent cats causes nonspecific bilateral erosive conjunctivitis without keratitis.* Intranuclear inclusions are numerous within cells prior to sloughing, and leukocytes are sparse until ulceration permits opportunistic contamination. Upper respiratory disease is almost always present.

The corneal lesions fall into two very different categories: *shallow transient erosions and ulcers* that represent the direct cytopathic effect of acute viral infection, and *more severe stromal keratitis* that is probably an immune response to viral antigen in persistent or recurring infections. The typical acute superficial corneal lesions are multifocal minute corneal erosions and ulcers that have a tendency to coalesce into branching dendritic ulcers. Early in the disease, typical herpesviral inclusions may be seen with histology, and herpesviral antigen can be demonstrated with immunofluorescence or other techniques. Severe or recurrent lesions in immunosuppressed cats may result in underlying stromal keratitis with lymphocytic infiltration, persistent edema, and vascularization.

There is much more written about the clinical features and clinical diagnosis of herpesviral keratitis than there it is about its pathology, simply because most cases are never subjected to histologic evaluation. By the time a sample of conjunctiva or cornea is taken for histologic assessment in cases that have been therapeutically resistant, histologic detection of inclusion bodies is futile and immunofluorescence is usually negative. Virus can usually be detected with PCR, but interpretation of that result is almost impossible because of the high prevalence of carriage in asymptomatic, healthy cats. For the same reason, attempts to link persistent herpesviral infection with feline corneal sequestrum or feline eosinophilic keratitis have been less than convincing.

Feline eosinophilic keratitis

Another uniquely feline ocular lesion is seen clinically as unilateral or bilateral proliferative, "fluffy" white stromal keratitis. There is no breed, age, or sex predilection, and no proven association with other ocular or systemic disease. Since the diagnosis is made by cytologic evaluation of superficial scrapings or (occasionally) by histologic examination of surgical keratectomy specimens, this disease is more likely to be seen by pathologists than most other corneal disorders. Scrapings of the surface of the lesion reveal numerous eosinophils and fewer mast cells and other mononuclear leukocytes. Eosinophils may be less conspicuous on histologic examination of keratectomy specimens, perhaps because most seem determined to emigrate through the epithelium and into the tear film rather than remain within the tissue. Instead, the stromal lesion is a *mixture of macrophages, plasma cells, fibroblasts and, unpredictably, mast cells and at least a few eosinophils.* The latter are least frequent in older lesions, either because of time alone or because older lesions are more likely to have received a lot of corticosteroid therapy. A characteristic lesion, not present in every case, is a *dense granular eosinophilic coagulum* along the surface of the keratectomy specimen. It seems to consist of free eosinophil granules. No bacterial or fungal agents have been seen. While there are histologic similarities to cutaneous eosinophilic ulcer and linear granuloma, no statistical association has been proven and the lack of understanding even of the cutaneous eosinophilic lesions makes such attempted comparisons of very limited value. While much speculation exists about the relationship between persistent herpesviral infection and eosinophilic keratitis, there is no proven etiologic link.

Mycotic keratitis

Mycotic keratitis *is a destructive, suppurative, ulcerative and deep stromal keratitis most commonly seen in horses,* but occasionally encountered in all domestic species. The offending fungus is usually a member of the normal conjunctival flora, and its role in the disease is always that of *opportunistic contaminant. Aspergillus* is the most frequent isolate, but cases caused by other common conjunctival fungi like *Alternaria, Penicillium,* and *Cladosporium* are not rare. *Most cases are probably iatrogenic,* occurring in animals in which a corneal ulcer, laceration, or penetrating wound had been treated with long-term antibiotics and/or *corticosteroids.* The latter is a particularly common villain in this context. Horses seem particularly prone to mycotic keratitis, perhaps related to the mold-laden, dusty environment in which many horses are housed; only rarely does the lesion occur in dogs or cats. Since virtually all stabled horses have fungi as part of their conjunctival flora, *seeing hyphae within the corneal stroma is required for the diagnosis.* Isolation from a corneal swab or shallow scraping is not adequate.

Because the disease is much more prevalent in horses than any other species, most of the description below is derived from equine cases. The histologic changes in other species, however, are very similar to what occurs in horses. There appears to be a difference in the typical lesion seen in temperate climates and what occurs in horses in very warm and humid environments. In the latter, there are cases in which the fungi are found throughout the cornea and are easily identified by even shallow scraping. That is not the case in those examples of the disease diagnosed in cooler climates, which I will consider the "typical" disease.

The typical early lesion is deep ulcerative keratitis with suppurative keratomalacia. Some chronic lesions are exclusively stromal because of successful epithelial and superficial stromal healing of the initial penetration (or perhaps because therapy eliminated the infection in the superficial stroma). For whatever reason, the typical equine eye enucleated for mycotic keratitis has an intense neutrophil-rich deep stromal keratitis with several characteristic features: neutrophils are karyorrhectic, inflammation is most intense immediately adjacent to Descemet's membrane, and frequently there is lysis of the normally resistant Descemet's membrane with spillage of the corneal inflammation into the anterior chamber. *Fungi are numerous within the malacia of the deep stroma and within Descemet's membrane itself,* but rarely if ever are seen within the anterior chamber (Fig. 4.35A). When they occur within the anterior chamber, they are always anchored to the nearby Descemet's membrane. Despite ample opportunity, there has never been a reported case of disseminated intraocular mycosis as a sequel to mycotic keratitis. Fungi are sparse or absent within the superficial half of the stroma, which explains why corneal scrapings or even keratectomy specimens may fail to reveal the agent. The reason for the apparent targeting of Descemet's membrane is not known, but the presence of the tropism even in untreated eyes suggests that it is a

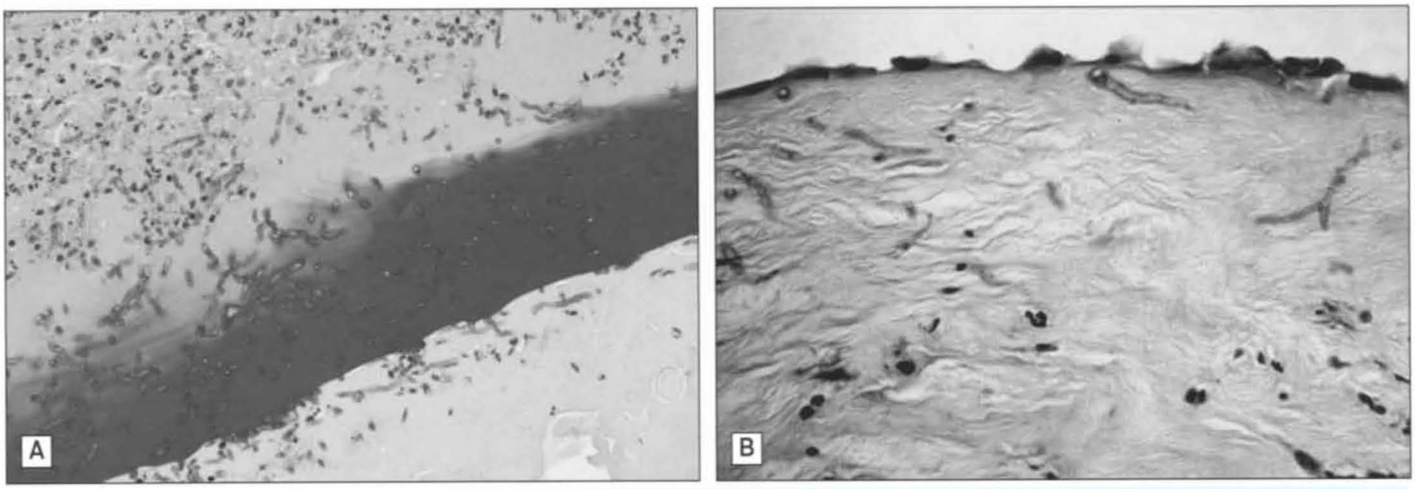

Figure 4.35 A. Equine mycotic keratitis. The fungi typically are found within and adjacent to Descemet's membrane, accompanied by karyorrhectic neutrophils and stromal malacia. **B. Opportunistic fungal contamination** of an equine superficial corneal sequestrum, but distinctly different syndrome from traditional mycotic keratitis. Note the absence of leukocytes.

genuine tropism and not just persistence of a previously generalized stromal infection in the site least likely to be reached by topical fungicides.

In horses in tropical and near-tropical climates (many reports, for example, come from Florida), the fungi are more diffusely distributed within the cornea and are thus more easily captured by routine cytology or culture swabs. While the distribution of the lesion within the cornea is also more diffuse, its fundamental lytic character remains the same.

In horses, cats, and dogs, we will occasionally see *corneal sequestra contaminated with fungal hyphae*; the fungi are easily found on scraping, leading to the mistaken impression that this is true mycotic keratitis (Fig. 4.35B). One could debate the issue, but it seems better to keep this as a separate syndrome quite different from the lesion described above.

Infectious bovine keratoconjunctivitis

Infectious bovine keratoconjunctivitis ("pinkeye") vies with squamous cell carcinoma as the most important disease of the bovine eye. It occurs worldwide, is most prevalent in summer due to the increase in fly vectors, and has a clinical expression that ranges from initial conjunctivitis and ulcerative keratitis to iris prolapse, glaucoma, and phthisis bulbi. The prevalence of severe sequelae reflects inadequate management of the disease rather than any special virulence of this agent as compared to other infectious causes of keratitis in other species.

The disease behaves as an infectious epizootic within a susceptible population, frequently affecting over 50% of the cattle at risk within 2 weeks of the initial clinical case. Shedding of virulent organisms by a carrier animal is thought to be the usual route of introduction into a previously unexposed group, although a role for various mechanical or biological vectors is also assumed.

Moraxella bovis has been confirmed as the most important causative agent, and the only one for which Koch's postulates have been fulfilled. Concurrent infection with other agents such as *Mycoplasma bovoculi, Mycoplasma conjunctivae, Acholeplasma laidlawii,* and bovine herpesvirus may contribute to lesion severity. Earlier skepticism about the virulence of *M. bovis,* based upon the unreliability of reproduction of the disease, isolation of the organism from apparently healthy cattle, and failure of isolation from some overtly affected cattle, has been overcome by detailed information on the pathogenesis of the disease. *It is now clear that virulence of M. bovis is associated with hemolytic, leukocytolytic, piliated strains that predominate only in the eyes of affected cattle.* Pathogenic isolates of *M. bovis* express a calcium-dependent transmembrane pore-forming cytotoxin. Nonpiliated, nonhemolytic strains predominate in healthy cattle and are probably part of the normal conjunctival flora. The use of immunofluorescence has demonstrated *M. bovis* in many of the naturally occurring cases for which the results of culture were negative. In naturally occurring outbreaks, the number of isolations of hemolytic *M. bovis* falls to almost zero as the outbreak wanes, but a few chronically affected carriers remain as the most important source of virulent bacteria for outbreaks of disease in the next summer.

In addition to variation in the virulence of different strains of *M. bovis*, sunlight, dust and, perhaps, concurrent infection with infectious bovine rhinotracheitis virus (*Bovine herpesvirus 1*) increase the severity of the disease. Calves are usually affected more severely than cattle over 2 years of age, although absolute resistance to infection seems fragile. The protective effect of serum antibody against the disease is controversial. Specific IgA is found in tears of infected calves, and there is substantial evidence that locally produced IgA is strongly protective.

Following experimental inoculation of virulent *M. bovis* onto the cornea, pilus-mediated adhesion and production of bacterial cytotoxin result in microscopic ulceration in as little as 12 hours. Initial adhesion is to older surface epithelium ("dark cells") and results in the development of microscopic pits in the cell surface. *Moraxella* is found within degenerate epithelial cells, but it is not known whether invasion is necessary for subsequent cellular destruction. *In field epizootics, the earliest lesion is bulbar conjunctival edema and hyperemia, followed in 24–48 hours by the appearance of a shallow central corneal ulcer.* The ulcer is a small (<0.5 cm) focus of epithelial necrosis that may appear as erosion, vesicle, or full-thickness epithelial loss. In untreated animals destined to develop the full clinical expression, the ulcer enlarges, deepens, and frequently attracts enough neutrophils to qualify as a *corneal abscess*. Stromal liquefaction ensues, probably as a result of neutrophil lysis, which is itself initiated by *Moraxella*-derived leukotoxins. By the end of the first week, there is extensive stromal edema and vascularization extending from the limbus. As with any severe ulcerative keratitis, the subsequent progression or regression of the lesion varies with each case as modifications by therapy, opportunistic bacterial and fungal contamination, trauma, inflammation, and immunity interact. Keratomalacia frequently leads to forward coning of the weakened cornea (*keratoconus*). In most instances, whether treated or not, the cornea heals by sloughing of necrotic tissue and filling of the defect by granulation tissue. Re-epithelialization may take up to a month, leaving a cornea that is slightly coned and variably scarred. The scarring often is scant and interferes little with vision in spite of the severity of the primary lesion.

Less satisfactory sequelae, while not common in relation to the overall disease prevalence, are still relatively common. Sterile anterior uveal inflammation may result in focal or generalized adherence of iris to cornea (anterior synechia) or lens (posterior synechia). Descemetocele may progress to corneal rupture, which in turn may lead to phthisis bulbi or resolve by sealing with prolapse of the iris. Synechia and staphyloma may lead to impairment of aqueous drainage and thus to glaucoma.

Infectious keratoconjunctivitis (contagious ophthalmia, pinkeye) of sheep and goats

Epizootics of conjunctivitis and keratitis in sheep and goats share many of the features of the bovine disease: summer prevalence, rapid spread, and exacerbation by dust, sunlight, and flies. Feedlot lambs seem particularly susceptible. Unlike bovine keratoconjunctivitis, the range of clinical signs and proposed causes suggests that there may in fact be several different diseases. Many agents including bacteria, mycoplasmas, chlamydiae and rickettsiae have been suggested as causes, but various mycoplasmas and *Chlamydophila psittaci* may be the most important agents. The lesions caused by *Mycoplasma mycoides* var. *capri* in goats and *Mycoplasma conjunctivae* var. *ovis* in sheep are similar but usually milder than those caused by *Moraxella bovis* in cattle. This is particularly true of goats in which deep corneal ulceration is uncommon.

Keratoconjunctivitis associated with *Chlamydophila psittaci* is usually predominantly conjunctivitis. Initial chemosis and reddening are followed by massive lymphofollicular hyperplasia in bulbar conjunctiva and nictitating membrane. Keratitis may occur but ulceration is seldom prominent. Animals with conjunctivitis may have concurrent polyarthritis from which chlamydiae can be isolated.

LENS

The lens is a flattened sphere of epithelial cells suspended in the pupillary aperture by a large number of transparent elastin-like fibers known as *lens zonules*. These originate from the lens capsule near the equator, and fuse with the nonpigmented ciliary epithelium along the lateral surfaces of the ciliary processes or in the valleys between adjacent ciliary processes. *The range of histologic reaction of lens to injury is very limited due to the simplicity of its structure and physiology, and its lack of vascularity.*

The lens is entirely epithelial. Outermost is a *thick, elastic capsule*, which is the basement membrane produced by the underlying germinal epithelial cells. The capsule is thickest at the anterior pole and becomes progressively thinner over the posterior half of the lens. The capsule in the neonate is thin, but it thickens progressively throughout life.

Below the capsule is a layer of simple cuboidal *lens epithelium* that, in all but fetal globes, is found below the capsule of only the anterior half of the lens. The apex of these cells faces inward toward the lens nucleus. At the equator, these germinal cells extend into the lens cortex as the *nuclear bow*, an arc of cells being progressively transformed from cuboidal germinal epithelium to the elongated spindle shape of the mature *lens fibers* (Fig. 4.36). The bulk of the lens is composed of onion-like layers of elongated epithelial cells anchored to each other by interlocking surface ridges, grooves, and ball-and-socket protuberances. These elongated fibers contain no nucleus and few cytoplasmic organelles, relying almost entirely on anaerobic glycolysis for energy. Since the lens cannot shed aging fibers as does skin or intestine, these cells are compacted into *the*

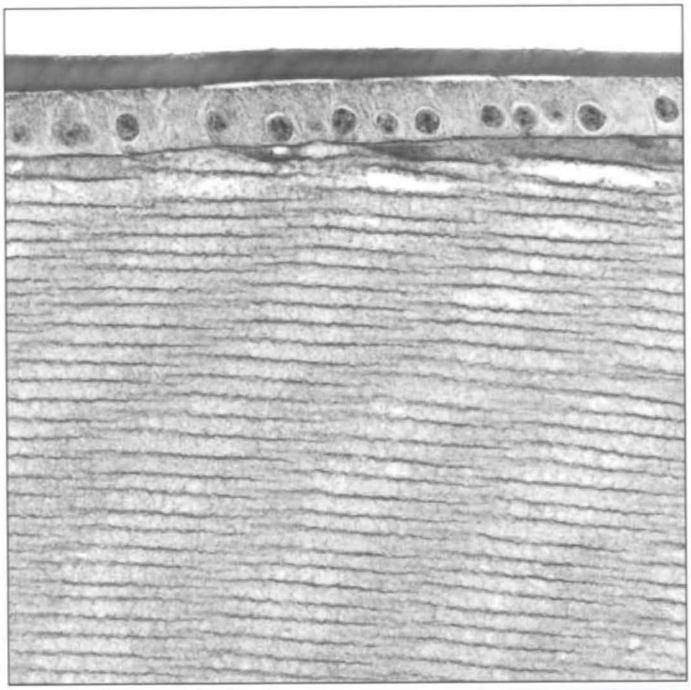

Figure 4.36 Normal canine lens with characteristic regularity of surface epithelium and lens fibers.

oldest central part of the lens, the nucleus. The continuous accumulation of these old desiccated fibers with altered crystalline protein results in the common but visually insignificant *aging change of nuclear sclerosis.*

Although in many ways similar to cornea in structure and function, the optical clarity of lens rests not with the regularity of its fibers but in its high percentage of cytoplasmic soluble crystalline protein and paucity of light-scattering nuclei or mitochondria. The lens is about 35% protein, the highest of any tissue, and over 90% is of the soluble crystalline variety. Insoluble high-molecular-weight protein (albuminoid) is found in the nucleus and cell membranes. Opacity of lens is associated, at least in some cases, with decreasing concentrations of crystalline and increasing albuminoid protein, the latter insoluble in water and optically opaque. *Many of the insults that result in degeneration of lens ultimately interfere with its nutrition.* Since it is avascular in the postnatal animal, *the lens relies entirely upon the aqueous for the delivery of nutrients and removal of metabolic wastes.* Glaucoma, ocular inflammation, metabolic disorders and various toxins share the common feature of altering the amount or quality of lenticular nutrition by altering the flow or composition of the aqueous humor.

Ectopia lentis

The only lenticular defects of importance in domestic animals are those affecting location, configuration, and clarity. Those affecting configuration are usually developmental defects and are discussed earlier. **Dislocations of the lens** may be congenital or acquired, and the latter include spontaneous dislocations and those secondary to trauma and glaucoma. *Apparently spontaneous dislocations* are encountered most frequently in middle-aged (3–8 years) terrier dogs in which an inherited predisposition to bilateral zonular rupture exists. The pathogenesis of the defect has been best studied in the Tibetan Terrier, in which the zonules develop in a dysplastic, reticulate fashion that precedes luxation by several years. *Traumatic dislocation* is usually via blunt trauma, notably automobile accidents. The dislocation may be partial (*subluxation*) or complete (*luxation*), and in the latter instance the free lens may damage corneal endothelium or vitreous causing edema and liquefaction, respectively. Such lenses may be surgically removed but seldom receive histologic examination. Anterior luxation frequently results in glaucoma, perhaps caused by anterior prolapse of the vitreous into the pupil. Lens luxation is inexplicably uncommon in cats. It is seen in middle-aged cats as unilateral and usually anterior luxation. One-third of cases occur in eyes with no other observed lesion, while the remainder occur in eyes with preexistent uveitis or glaucoma, or a history of trauma.

Cataract

Cataract is the most common and most important disorder of the lens. Cataract means lenticular opacity, and is usually prefixed by adjectives relating to location, maturity, extent, suspected cause, and ophthalmoscopic appearance. Of these adjectives, only those of location and, to some extent, maturity are useful in histologic description. *The simple structure of the lens results in a stereotyped reaction to injury that provides few clues to pathogenesis.* Unless permitted by invasion through a capsular tear, inflammation cannot occur within the avascular and totally epithelial lens.

The main challenge facing the pathologist looking at a histologic section of lens is whether any of the microscopic changes are genuine or not. The lens is difficult to section, and artifacts like fiber disruption and capsular tearing are almost unavoidable. *Histologic changes that distinguish genuine cataract from fixation or sectioning artifact are (in order of overall utility): detection of Morgagnian globules, bladder cells, lens epithelial hyperplasia, posterior migration of lens epithelium, and mineralization* (Fig. 4.37).

Morgagnian globules *are bright pink spherical globules of denatured lens protein.* They are distinguished from artifactual fragmentation of lens fibers because the latter form jagged rectangular fragments, not spheres (Fig. 4.38). With more advanced liquefactive change, fluid lakes appear between fibers, presumably the result of complete liquefaction of fibers. Some of the clefts are probably the result of osmotic fluid imbibition by the cataractous lens. The osmosis results from protein denaturation into more numerous, smaller peptides and from degeneration of the capsular epithelium in which resides the Na–K-dependent ATPase osmotic pump critical to normal lens hydration.

In advanced cataracts, the degenerate fibers may liquefy to the extent that their low-molecular-weight end products diffuse through the semipermeable capsule, resulting in the spontaneous clearing of the opaque lens typical of the *hypermature cataract.* Histologically, such lenses consist of a dense, eccentric residual nucleus in a lake of

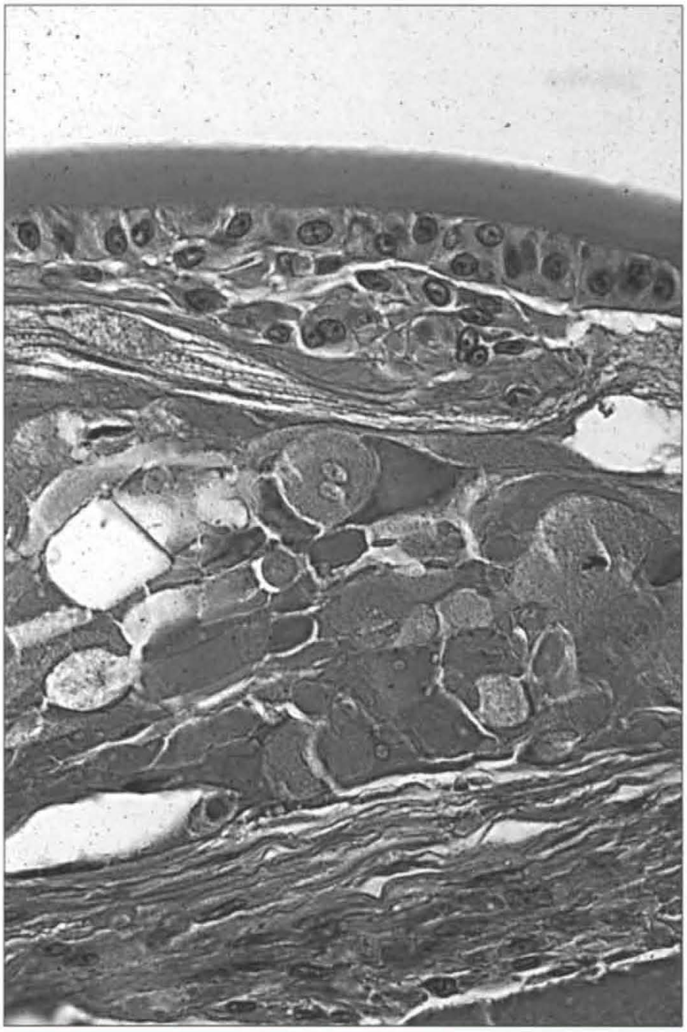

Figure 4.37 The general pathology of **cataract**: fiber liquefaction, reactive hyperplasia of capsular epithelium, and bladder cells.

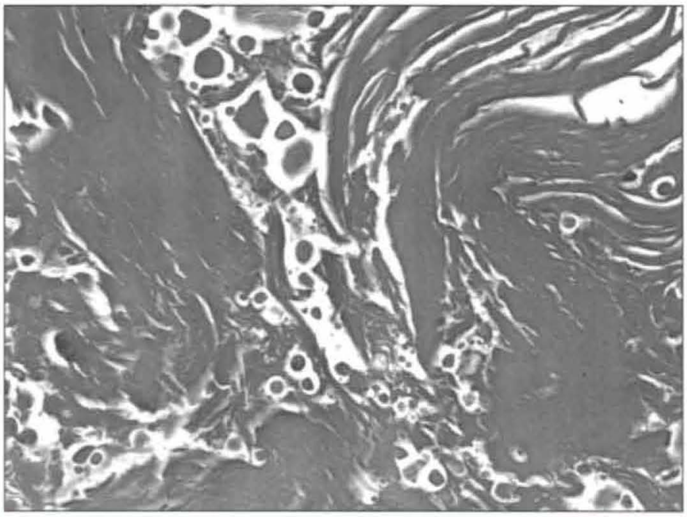

Figure 4.38 Spherical accumulations of denatured lens protein known as **Morgagnian globules**, probably the most reliable histologic criterion for distinguishing cataract from artifactual lens fragmentation.

proteinaceous fluid surrounded by a wrinkled capsule. The adjacent uvea will usually have a moderately severe lymphocytic-plasmacytic infiltration in response to unidentified inflammatory mediators present in that leaking lens fluid. The lesion/process is known as *phacolytic uveitis* (see below).

Bladder cells are claimed to reflect abortive efforts at new fiber formation by lens epithelium. Such efforts are apparently never successful, and the hydropic degeneration of such cells results in the formation of *large foamy nucleated cells called bladder cells* because of their bloated, fusiform shape.

Epithelial hyperplasia or **fibroblastic metaplasia** is the usual histologic counterpart of anterior subcapsular cataract, and is usually seen following focal trauma, or adherence of the iris or of persistent pupillary membranes to the anterior surface of the lens. *Initial epithelial degeneration or necrosis is followed by hyperplasia and sometimes by fibrous metaplasia.* The resultant *epithelial plaque* lies just under the anterior lens capsule. The innermost epithelial layer may remain basilar in type rather than fibroblastic. Each epithelial layer, even if metaplastic, secretes a new basement membrane that separates each layer from the adjacent layers. This characteristic feature is best seen with PAS stains. The end result is a focal plaque formed by multiple, sandwiched layers of flattened epithelium and basement membrane at the anterior pole of the lens. Remnants of adherent iris or pupillary membrane, including pigment, may complicate the histologic appearance.

Posterior migration of lens epithelium is a common change in chronic cataracts. Although it seems to occur more slowly than the changes of Morgagnian globule or bladder cell formation, it is equally reliable (when present) as a histologic indicator of cataract formation. The flattened cuboidal epithelial cells migrate from the equator to line the posterior capsule. Usually, they will also undergo stratification and sometimes fibroblast-like metaplasia. This re-establishment of the fetal morphology is seen most commonly with any chronic cataract in young animals, whose epithelial cells perhaps retain greater migratory ability. Adjacent cortical fibers are usually degenerate (Morgagnian globules, bladder cells, and clefts of granular proteinaceous fluid).

Deposition of calcium salts occurs quite frequently within cataracts of any type, and provides no clue as to pathogenesis.

The sequence of histologic change in cataract is the same regardless of cause, and thus diagnosis of cause can be made only in light of patient data or concurrent disease. In dogs, for example, familial cataracts may be congenital or of later onset. Specific examples may typically occur alone or with other ocular lesions, and occur at an age, in a location and with a progression sufficiently characteristic to allow presumptive diagnosis of a breed-specific syndrome. Cataract also occurs secondary to glaucoma, endophthalmitis, ocular trauma, and anterior segment anomalies, and observation of these latter defects permits presumptive diagnosis of the pathogenesis of the accompanying cataract.

Cataract may result from exposure of the lens to a wide variety of physical and chemical insults such as solar or other irradiation, cold, increased intraocular pressure, toxins, nutritional excesses and deficiencies, nearby inflammation, and direct trauma. The list of potential cataractogenic chemical toxins grows daily and includes food additives, chemotherapeutic agents, and by-products of ocular inflammation. The pathogenesis of the cataract is not determined for more than a few such insults, but a common denominator seems to be the ability to upset the precarious balance between substrate supply and enzymic activity within the almost exclusively anaerobic lens. This imbalance results in degeneration of fibers, accumulation of nonmetabolized substrate or production of abnormal metabolites. The latter two classes of products may be cytotoxic or osmotically active, thus drawing water into the critically dehydrated lens and causing opacity.

Most cataracts in people and animals are not identified as being caused by a single insult, but are assumed to represent the result of years of accumulated and perhaps synergistic cataractogenic activity of environmental, dietary, and inborn insults. *The majority of cataracts seen in veterinary practice fall into one of three categories: inherited, post-inflammatory, and idiopathic.* In reality, the large group of inherited cataracts in dogs is of unknown pathogenesis, although extrapolation from knowledge of similar cataracts in rodents and man suggests that inborn errors of lenticular metabolism are at fault. Postinflammatory cataracts result from injury to lenticular epithelium by adjacent inflammation, interference with aqueous production, composition and flow, and accumulation of toxic bacterial, leukocytic, and plasma by-products in the lenticular environment. Adherence of iris to lens (posterior synechia) inevitably causes a focal subcapsular cataract.

Other than these broad categories, there are a few naturally occurring examples of cataract about which there is some understanding.

Diabetic cataract develops in about 70% of spontaneously diabetic dogs, but is rare in diabetic cats. The opacity is bilateral and begins in the cortex at the equator. Progression to complete cortical opacity usually occurs within a few weeks. The pathogenesis of the cataract has traditionally been ascribed to the excessively high level of glucose within the aqueous. Glucose is normally the major energy source for lens fibers, with most of it used to fuel the Embden–Meyerhof pathway of anaerobic glycolysis. When the rate-limiting enzyme of this pathway, hexokinase, is saturated with glucose, the backup of glucose is shunted to alternative metabolic pathways. Chief among these is the *sorbitol pathway*, activated in the rabbit lens by glucose concentrations of >5 mmol/L (>90 mg/dL). In this pathway, the excess glucose is converted by an aldose reductase to the polyalcohol, sorbitol, which is then slowly reduced to a D-fructose, a ketohexose. Because this second reaction is much slower than the first, *sorbitol may accumulate to very high concentrations within the lens and osmotically attracts water even to the point of hydropic cell rupture.* Under experimental conditions at least, the early cataract may be reversed if aqueous sugar levels are reduced to normal, but the later cataract is irreversible.

However, osmotic events alone are not enough to explain all of the structural and metabolic changes in sugar-induced cataracts. The efficacy of antioxidants in ameliorating such cataracts, the nature of intralenticular biochemical alterations, and detection of increased intralenticular oxidants all point to some kind of oxidative damage as an additional promoter of cataract.

Galactose-induced cataracts probably have the same complex and incompletely understood pathogenesis as the diabetic cataract and are seen in orphaned kangaroos and wallabies raised on cows' milk, as well as in a host of experimental models. Since marsupial milk is much lower in lactose than bovine milk, the enzymically ill-equipped neonate develops osmotic diarrhea from undigested lactose and galactose in the intestine, and some excess galactose enters the aqueous humor. The lens, deficient in the enzymes needed to utilize the galactose by converting it to glucose–6-phosphate for anaerobic glycolysis, shunts the galactose via aldose reductase to its polyalcohol, *dulcitol*, which acts osmotically as does sorbitol to disrupt lens fibers.

Cataract reported in puppies and wolf cubs fed commercial milk replacer, or in kittens on feline milk replacer, has been attributed to *deficiency of arginine*, although in several case reports the specific dietary error was not identified. Cataract due to **dietary deficiency** of any of several sulfur-containing amino acids, zinc, or vitamin C occurs in farmed fish, and many models of nutritional cataract exist in various laboratory animals.

Various forms of **irradiation** cause cataract. The lens absorbs most of the ultraviolet and short-wavelength visible blue light that would otherwise damage the retina. At least in people, the chronic exposure to such irradiation is thought to be important in the pathogenesis of senile cataract. **Sunlight-induced cataract** has been described several times in farmed fish, but not yet for other domestic animals as a naturally occurring phenomenon. Absorption of ultraviolet or near-ultraviolet wavelengths by lens epithelium nucleic acids or lenticular aromatic amino acids results in photochemical generation of free radicals and peroxidative damage to numerous structural components of the lens.

A similar pathogenesis probably explains the development of cataract in animals irradiated as part of cancer therapy. In one study, 28% of dogs receiving **megavoltage X-radiation** for nasal carcinoma developed *diffuse cortical cataract* within 12 months of irradiation. In people, the risk of cataract is dose-related, and reaches virtual certainty with dosages of 800–1500 centigrays or rads, whereas rodents require at least twice that dosage. The dogs in the study cited above received between 3680 and 5000 centagrays. Antioxidants such as vitamin E or C, or hypoxia, are significantly protective against several models of light or other irradiation-induced cataract, providing further support for the common denominator of oxidative stress in the pathogenesis of such cataracts.

The aminoglycoside antibiotic and anthelmintic **hygromycin B** has been shown to induce *posterior cortical and subcapsular cataracts* in sows, but not boars, fed the drug continuously for 10–14 months. The effect is dose-dependent and perhaps even cumulative. Pigs fed the same therapeutic daily dose, but consuming the drug on an 8-week-on/8-week-off basis in accordance with the manufacturer's recommendations, do not develop cataracts. The pathogenesis of the cataract is unknown, but a partial inhibition of hygromycin-induced cataracts in vitro by addition of vitamin E suggests that peroxidative damage to lens fiber membranes may be important. *Deafness* in pigs, and also dogs, caused by hygromycin B is discussed with the Ear.

Traumatic lens rupture results in a spectrum of change much different from the changes of cataract described above. First, massive release of more or less native lens protein at the time of rupture may cause severe perilenticular nonsuppurative endophthalmitis about 10 days after the initial trauma (see **Lens-induced uveitis**). Second, the capsular rent permits leukocytes to enter the lens to speed the dissolution of lens fibers. Fibroblastic metaplasia of lens epithelium may result in cartilage or even bone within the lens. *Even after total destruction of the lens fibers, the durable capsule will be found somewhere in the anterior or posterior chamber as a curled eosinophilic mass*, often encapsulated in fibrous tissue probably derived from surviving lens epithelium or from injured ciliary epithelium. Such remnants distinguish lenticular rupture with subsequent dissolution from true developmental aphakia.

Cataract surgery is nothing more than planned traumatic lens rupture, and it is therefore not surprising that we sometimes encounter the same sequence of events as seen with accidental rupture. The main difference is that, with cataract surgery, the lens is already degenerate and the material that may be released following surgical incision of the capsule is not capable of inducing the same magnitude of inflammatory and proliferative reaction. Nonetheless, *complications of cataract surgery and prosthetic lens implantation are quite common in dogs*, the only species in which the surgery is performed on a regular basis. In most instances, the lens capsule remains within the globe and the degenerate lens material is removed by aspiration. The artificial lens is then implanted within the preexistent capsular "bag." Any lens epithelium left behind after removal of most of the cataractous lens forms the nidus for potential regrowth of lens fibers, usually as a combination of fibroblast-like cells and swollen bladder cells. This postoperative proliferation may use the implanted prosthetic lens (or, in its absence, the lens capsular bag) as the growth substrate, not only causing postoperative opacity but also posing the threat of causing pupillary occlusion. Some degree of postoperative epithelial/fibroblastic proliferation is normal in all such eyes, but the amount can be minimized by religious "vacuuming" of the inner surface of the lens capsule to remove all possible germinal epithelium.

Adhesion of pigmented or nonpigmented cellular material to the anterior lens capsule is a valuable histologic clue. *Pigmented epithelium adherent to the lens capsule is a reliable marker for previous posterior synechia*, even if this synechia has been reversed by surgical or pharmacologic intervention or has been accidentally broken during trimming of the globe. Similarly, fibrous or fibrovascular membranes along the anterior lens capsule most often are derived from previous posterior synechia (but they can represent complications of phacoclastic uveitis, pre-iridal fibrovascular membrane, or persistent pupillary membrane). They are significant causes for pupillary obstruction and secondary glaucoma.

UVEA

The uvea is the vascular tunic of the eye. It is derived from the primitive neural crest mesenchyme surrounding the primary optic cup (only the vascular endothelium is mesodermal). Its posterior differentiation into *choroid* is guided by the developing retinal pigment epithelium, but its differentiation anteriorly into *iris and ciliary body* is probably orchestrated mostly by lens. The presumptive anterior uveal mesenchyme accompanies the infolding of the neurectoderm at the anterior lip of the optic cup to form the stroma of the iris and ciliary processes. That portion of anterior periorbital mesenchyme not accompanying these neurectodermal ingrowths remains to form the ciliary muscle and trabecular meshwork. Posteriorly it forms the choroid and sclera. In all domestic mammals except the pig, the choroid undergoes further differentiation to produce the *tapetum lucidum* dorsal to the optic disk. Defects in development of the retinal pigment epithelium (including its cranial specialization as iridal and ciliary epithelium) inevitably result in defective induction or differentiation of the adjacent uvea.

The mature uvea includes iris, ciliary body, and choroid, the last divided into vascular portion and tapetum lucidum. The filtration angle is shared by iris, ciliary body, and sclera. Its diseases are discussed in the section Glaucoma.

The **iris** is the most anterior portion of the uveal tract. It is a muscular diaphragm separating anterior from posterior chamber, forming the pupil and resting against the anterior face of the lens. The bulk of the iris is stroma of mesenchymal origin, with melanocytes, fibroblasts, and endothelial cells its major constituents. There is neither epithelium nor basement membrane along its anterior face, but rather a single layer of tightly compacted fibrocytes and melanocytes. *The iris stroma is thus in free communication with the aqueous*, a fact of great importance when we consider the secretion or absorption of inflammatory mediators and growth factors in the anterior half of the globe.

The posterior surface of the iris is formed by the double layer of neurectoderm from the anterior infolding of the optic cup. The two layers are heavily pigmented and are apposed apex to apex, with the basal aspect of the posterior epithelium facing the posterior chamber, and separated from it by a basement membrane. The basilar portion of the anterior epithelium, in contrast, is differentiated to form the smooth muscle fibers of the *dilator muscle* of the iris. These fibers lie along the posterior aspect of the iris stroma immediately adjacent to the epithelium. The *constrictor muscle* is found deeper within iris stroma but only in the pupillary third to quarter of the iris. The iris epithelium is rather loosely adherent between layers and between adjacent cells of the same layer, so that *cystic separation* occurs quite commonly. Numerous spaces reminiscent of bile canaliculi lie between adjacent cells and communicate freely with the aqueous humor of the posterior chamber.

The **ciliary body** extends from the posterior iris root to the origin of the neurosensory retina. Like iris, it consists of an inner double layer of neuroepithelium and an outer mesenchymal stroma. The epithelial cells are oriented apex to apex and are separated from the posterior chamber and vitreous by a basal lamina. Only the outer epithelial layer is pigmented. The ciliary body is divided into an anterior *pars plicata* and a posterior *pars plana*, the latter blending with retina at the *ora ciliaris retinae*. The pars plicata consists of a circumferential ring of villus-like epithelial ingrowths supported by a fibrovascular core, called *ciliary processes*. External to the ciliary processes, the mesenchyme forms a ring of smooth muscle, the *ciliary muscle*, responsible for putting traction on the lens zonules and effecting the changes in lens shape necessary for visual accommodation in mammals (other vertebrates may use different and remarkably effective mechanisms). The muscle in domestic animals, particularly ungulates, is poorly developed and accommodation is thought to be minimal in these species. The lens zonules anchor in the basal lamina of the nonpigmented ciliary epithelium, particularly of the pars plana and within the crypts between ciliary processes. The precise location of this anchoring is highly variable among species.

The **choroid** is the posterior continuation of the stroma of the ciliary body. The posterior continuations of the inner and outer layers of ciliary epithelium are retina and retinal pigment epithelium respectively, with the transition made rather abruptly at the ora ciliaris retinae. *The choroid consists almost entirely of blood vessels and melanocytes*, except for the postnatal metaplasia to tapetum dorsal to the optic disk. The choroid is thinnest peripherally, thickest at the posterior pole, blends indistinctly with sclera externally and is separated from the retinal pigment epithelium internally by a complex basal lamina called *Bruch's membrane*.

Many portions of the uveal tract in carnivores continue to develop for at least several weeks after birth, and many of the uveal anomalies like goniodysgenesis or choroidal hypoplasia probably represent developmental errors in postnatal remodeling and maturation, rather than being truly "congenital."

The **general pathology of uvea** *includes anomalous or incomplete differentiation, degeneration, inflammation, and neoplasia.* Anomalies have been previously discussed, and uveal neoplasms are considered in the section on Ocular neoplasia.

Uveal degenerations, except as a sequel to uveitis, are poorly documented. *Idiopathic atrophy of the iris* is described in Shropshire sheep as a bilateral defect obvious by 1–2 years of age. About 25% of the iris is converted to full- or partial-thickness holes; those of partial thickness are spanned by a posterior bridge of iris epithelium. The eye is otherwise normal except for rudimentary corpora nigra. The pathogenesis of the apparently spontaneous atrophy is unknown. Similar atrophy is extremely common in *old dogs*, particularly those of smaller breeds (Poodles, Chihuahuas, Miniature Schnauzers). It is also seen in *old cats*, although much less frequently than in dogs. In both species, the pathogenesis is unknown and there are no published descriptions of the microscopic lesions.

Uveal cysts probably form as the result of fluid accumulation between the two layers of the posterior iris or ciliary epithelium. Such cyst formation is *common in old dogs* and less common in old cats. These cysts may be seen clinically as one or more translucent black cysts attached to the posterior iris or freely floating in the aqueous. Whether the cysts are truly degenerative, or represent residual lesions of fluid exudation from an undetected anterior uveitis, is unknown. A breed-specific syndrome of *iris cyst formation associated with the development of glaucoma* has been reported in Golden Retrievers and Irish Wolfhounds. In the Retrievers, there is concurrent lymphocytic anterior uveitis, although that uveitis is often barely perceptible when the globe is finally submitted for histologic examination. Whether the subtlety of the inflammation is genuine or just a result of aggressive anti-inflammatory therapy prior to enucleation is unknown. The exact relationship between the uveitis, the cyst formation, and the glaucoma has not been clarified.

Uveitis

Uveal inflammation is common and may result from ocular trauma, noxious chemicals, infectious agents, neoplasia, or immunologic events. In addition, corneal injury may cause hyperemia and increased permeability of anterior uveal vessels either by percolation of bacterial toxins or inflammatory mediators into the aqueous, or by stimulation of a vasoactive sensory reflex via the trigeminal nerve. The uvea may be the initial site of inflammation, as in localization of infectious agents, or may become involved as the nearest vascular tissue capable of responding to injury of the lens, cornea, or ocular chambers. Conversely, the uvea seldom undergoes inflammation without affecting adjacent ocular structures. The pathogenesis of uveitis can be arbitrarily divided into *three broad categories*: those examples associated with the hematogenous localization of infectious agents within the uveal tract, diseases resulting from the uveal response to infectious or noninfectious irritants within the ocular chambers, and "autoimmune" uveitis that results from a failure of immune tolerance or from immune mimicry by some infectious agent.

The vocabulary of uveitis

The vocabulary of uveitis and its sequelae is complex:

Anterior uveitis describes inflammation of iris and ciliary body.

Posterior uveitis involves ciliary body and choroid, with **panuveitis** occasionally used to designate diffuse uveitis.

Chorioretinitis describes inflammation of choroid and, usually less severely, overlying retina.

Endophthalmitis is inflammation of uvea, retina, and ocular cavities, with **panophthalmitis** reserved for inflammation that has spread to involve all ocular structures including sclera.

The usefulness of such terminology is doubtful when one considers the vascular unity of the uvea and its intimate association with other ocular tissues. Disagreement between clinical assessment of the extent of the uveitis and histologic evaluation is common: most cases diagnosed clinically as anterior uveitis would be designated as endophthalmitis by histologic assessment. *By convention, the choice of diagnostic classification is strongly influenced by clinical severity, with anterior uveitis the mildest and panophthalmitis the most severe lesion.*

The significance of uveitis

The major significance of uveitis is its effect on adjacent nonuveal tissues. Some effects result from the accumulation of acute exudates or chemical by-products of inflammation, but most result from the later organization of exudates and proliferative events of wound healing within ocular cavities (Fig. 4.39).

Corneal changes include edema and peripheral stromal hyperemia (*ciliary flush*). The edema results from corneal endothelial damage or from increased permeability of limbic blood vessels responding to inflammatory mediators released from the adjacent uvea. In the former instance, damage may be the direct result of the agent causing uveitis, as occurs in infectious canine hepatitis or feline infectious peritonitis. It may also occur as a result of an immune response to endothelial cells containing antigens of these infectious agents, to cross-reaction between microbial and corneal endothelial antigens (immune mimicry), or as a nonspecific response to the presence of the chemical by-products of inflammation within the anterior chamber. Similar by-products mediate the acute inflammatory response in the nearby limbic and conjunctival vasculature, leading to edema in the peripheral corneal stroma. Hyperemia of this limbic network also results in *the circumferential peripheral corneal stromal hyperemia, resembling*

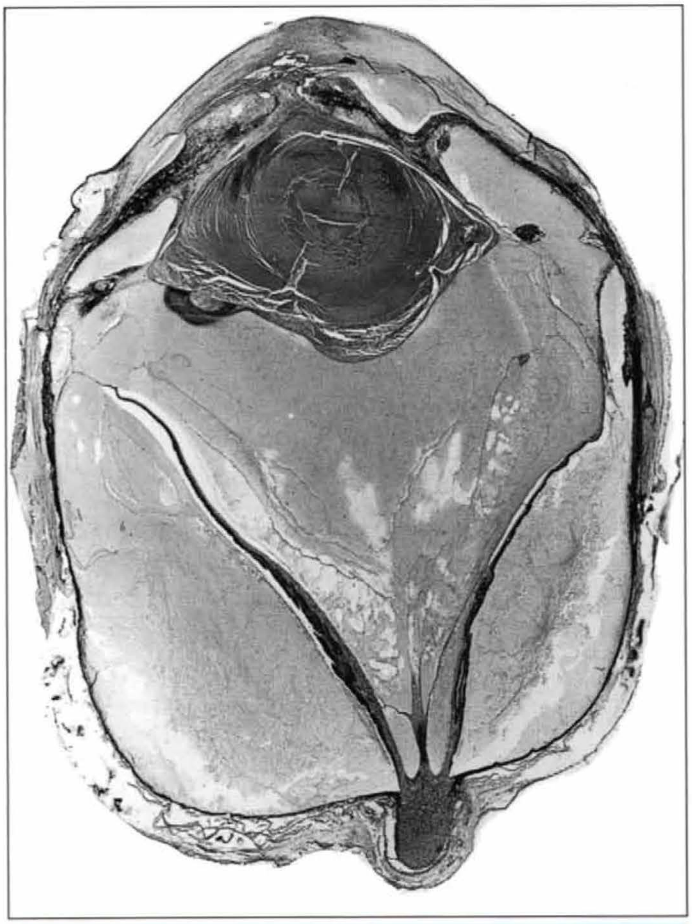

Figure 4.39 Endophthalmitis. Posterior synechia with pupillary block and iris bombé, serous effusion into the aqueous and vitreous humors, and complete serous retinal detachment. Note the healing corneal perforation and the ruptured anterior lens capsule, indicating that this particular example of endophthalmitis is secondary to lens rupture.

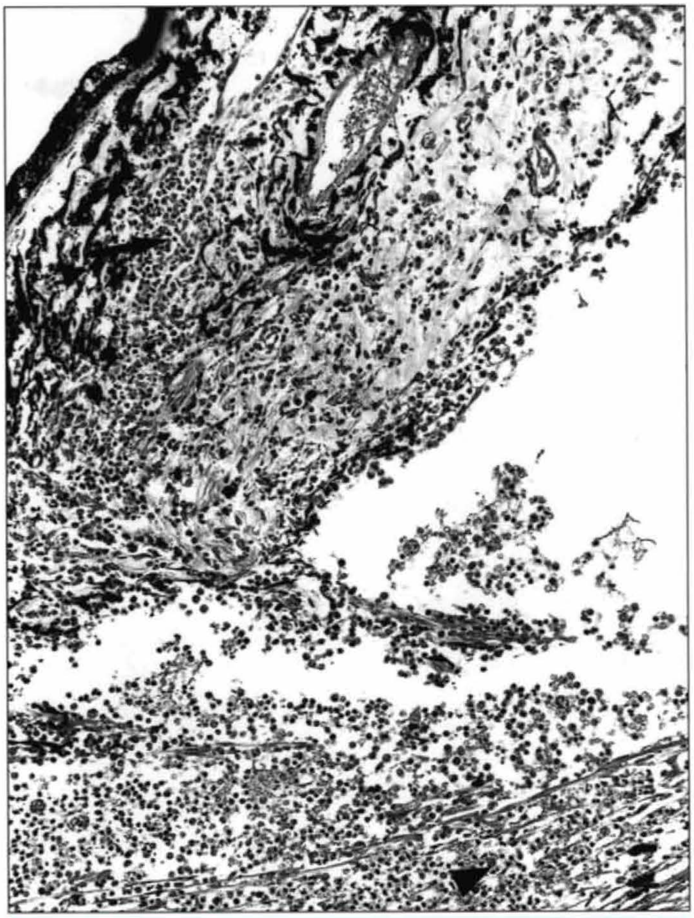

Figure 4.40 Anterior uveitis in a dog. Leukocytes are within the iris stroma and trabecular meshwork. Such exudates rarely if ever obstruct enough of the filtration angle to cause glaucoma. The arrow identifies the pectinate ligament, and the arrowhead is within the corneoscleral portion of the trabecular meshwork.

a brush border, which is a clinical hallmark of anterior uveitis. In eyes with chronic uveitis, corneal edema may also result from glaucoma or from anterior synechia. Persistent edema may lead to stromal fibrosis, vascularization, bullous keratopathy, and the risk of ulceration. *Limbic hyperemia may give way to corneal midstromal vascularization*. This last lesion is extremely common and is a reliable indicator of current or previous uveitis. It is presumed to be an "accidental" and apparently purposeless response to the percolation of angiogenic cytokines from the nearby uveal inflammation.

The accumulation of fibrin, leukocytes, and erythrocytes in the aqueous may result in plugging of the filtration angle and subsequent glaucoma. The infrequent observation of this sequel suggests either unusual potency of the fibrinolytic system within the aqueous, or the inability of exudates to plug more than the most ventral portion of the circumferential angle (Fig. 4.40). Much more common is the organization of inflammatory exudates upon the surface of iris or ciliary body. Adherence of iris to lens (**posterior synechia**) is more common than adherence to cornea (**anterior synechia**) because of the normally intimate association of the lens and iris. If the posterior synechia involves the circumference of the iris, the pupillary flow of aqueous is blocked, posterior chamber pressure rises, and the iris bows forward (**iris bombé**) and may actually adhere anteriorly to the cornea. Glaucoma results from pupillary block, peripheral anterior synechia, or both. In severe and prolonged anterior uveitis, there may be development of a **pre-iridal fibrovascular membrane** on the iris face (Fig. 4.41), which may span the pupil to cause pupillary block. Alternatively, this fibrovascular membrane may extend to cover the face of the pectinate ligament and cause neovascular glaucoma (Fig. 4.42). This membrane may contract on the face of the iris resulting in infolding of the pupillary border to adhere to the anterior (**ectropion uveae**) or posterior (**entropion uveae**) iris surface. Atrophy of iris may follow severe and necrotizing inflammation, and some examples can be distinguished from idiopathic and senile atrophy by the observation of residual lesions of the previous uveitis, such as lymphoid aggregates, focal synechiae, and uveal hyalinization.

The ciliary body suffers the same range of chronic lesions as does the iris. Deposition of PAS-positive hyaline material along the lumenal surface of the ciliary epithelium is particularly frequent in horses. It appears to be deposited in the cytoplasm of the nonpigmented epithelium, and may represent aberrant basement membrane. It is not fibrin; in many instances it has the staining properties of amyloid. Organization of exudate within the posterior chamber or vitreous results in *a retrolental fibrovascular membrane, called a* **cyclitic membrane**, which stretches around the ciliary body and across the back of the lens. Vitreous is almost always liquefied as a result of the severe uveitis, and continued contraction of fibrin in the posterior chamber

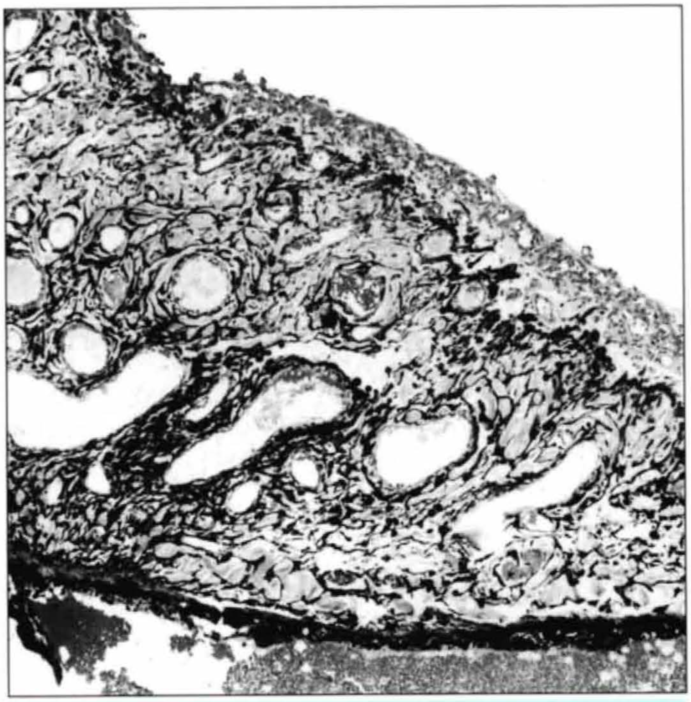

Figure 4.41 **Pre-iridal fibrovascular membrane**.

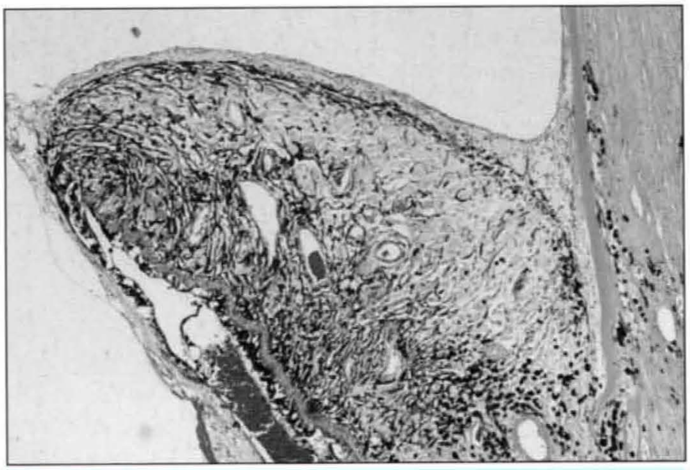

Figure 4.42 **Pre-iridal fibrovascular membrane** crossing the anterior face of the pectinate ligament, causing secondary glaucoma.

and vitreous causes a **tractional retinal separation**. Histologic examination of most cyclitic membranes reveals a fibrovascular retrolental membrane incorporating lens into its anterior face and a folded, degenerate retina in its posterior surface.

The residual lesions *of chronic choroiditis include focal lymphoid aggregates and scarring.* Tapetum usually remains unaffected. As choroiditis severe enough to evoke these lesions will almost invariably have involved retina and retinal pigment epithelium, the residual scar will involve these structures. *Chorioretinal scars are seen as focal fibrous chorioretinal adhesions* in place of normal retinal pigment epithelium. Because these scars prevent the involved retina from separating as part of processing artifact, they frequently appear as "spot welds" along an otherwise artifactually detached retina. Retinal pigment epithelium may be hypertrophic or hyperplastic, particularly if retina has been chronically separated by choroidal effusion. The fibroblast-like cells forming the scar may be derived from retinal Muller cells, choroidal fibroblasts, or metaplasia of retinal pigment epithelium, the last being the major source.

Cataract *is a common sequel to uveitis*, either as a result of uveal adhesions to lens surface, altered aqueous flow with lenticular malnutrition, exposure to injurious inflammatory by-products or increased aqueous pressure in postinflammatory glaucoma.

Phthisis bulbi *describes a hypotonic, shrunken, structurally disorganized eye that is the end stage of severe ophthalmitis*. Phthisis is seen most commonly as a sequel to severe prolonged suppurative septic ophthalmitis from corneal perforation. Cornea and sclera are thickened by fibrosis and leukocytic infiltration and ocular content is barely recognizable. Mineralization and even ossification may occur, but cartilage is absent (unlike congenitally dysplastic globes). *A shrunken, end-stage eye that contains ocular structures with at least recognizable orientation is properly termed* **atrophia bulbi**. The term is seldom used, but atrophia is much more common than true phthisis bulbi.

The classification of uveitis

There is no truly satisfactory method for classifying uveitis, or for organizing its presentation in a textbook in a manner suitable for all purposes. It does little good to organize classification based upon the innumerable specific diseases capable of causing uveitis, since that approach suffers from the "catch-22" that you need to know what the disease is before you can read about it! Classification based on pathogenesis suffers from the same problem. The clinical classification as anterior vs. posterior uveitis is essentially irrelevant when looking at histologic sections, because virtually all uveitis would be histologically classified as endophthalmitis. In the end, what seems most practical, at least for an audience of pathologists, is to initially classify uveitis on the basis of exudate type, with subdivision based upon histologic evidence of pathogenesis (lens-induced, traumatic, etc.) or etiology as appropriate.

Uveitis is thus classified as serous, suppurative, granulomatous, or lymphocytic-plasmacytic. The usefulness of such classification in predicting causes decreases as the lesion ages and as the events of host immune response blend with the initial inflammation. Furthermore, the reaction may differ among different compartments within the same globe. In general, the highly mobile neutrophils (if present) will be found mostly within the ocular chambers. The less mobile but longer-lived lymphocytes, plasma cells, or macrophages will usually predominate within the uveal tissue itself. As is true in other tissues such as joint and uterus, this may give rise to conflicting terminology depending upon whether the disease is being diagnosed by aspiration cytology of chamber fluid or histologic assessment of the solid tissue.

Acute serous uveitis involves the usual sequence of protein-rich fluid exudation, sometimes with fibrin, followed by emigration of neutrophils. In the iris, the protein-rich fluid readily percolates through the loose stroma to enter the anterior chamber as the clinically observed **aqueous flare**. The ciliary processes are usually distended by inflammatory stromal edema, perhaps a consequence of the initial inability of the serous exudate to pass through the tight intercellular junctions of the ciliary epithelium. Choroid exhibits the most convincing vascular engorgement as well as edema, with the latter frequently seeping through the retinal pigment epithelium to cause **serous retinal separation**. Since such mild uveitis is not likely to result in removal of the globe, observation of serous uveitis is usually restricted to globes enucleated for other reasons, such as severe ocular trauma, neoplasia, or corneal ulceration.

Suppurative uveitis *usually reflects a bacterial pathogenesis*, such as in the neonatal septicemias of calves, foals, and pigs. Neutrophils also predominate in acute mild neurogenic uveitis associated with corneal epithelial injury and in the acute phase of phacoclastic uveitis. In very mild uveitis, they are found marginated along the endothelium of iris and ciliary venules, in perivascular adventitia, adherent to ciliary processes, and in the filtration angle (see Fig. 4.40). Neutrophils rapidly degenerate within the aqueous to assume an unsegmented globular morphology. Clumps may adhere to the corneal endothelium as **keratic precipitates**, or settle ventrally within the anterior chamber as **hypopyon**. The hypopyon may, in histologic section, seem to be plugging the filtration angle, but only rarely would such exudate cause glaucoma, because only rarely would such exudate be able to occlude a significant part of the circumferential filtration angle. Fibrin exudation may accompany the suppurative inflammation, but fibrinolysis is very efficient within the anterior chamber, and glaucoma rarely results.

Granulomatous uveitis *is characterized by the conspicuous presence of epithelioid macrophages and, occasionally, giant cells.* As is true of granulomatous disease elsewhere, only rarely is the exudate purely granulomatous and most involve substantial participation by neutrophils. Ocular localization of some species of dimorphic fungi or of algae, helminths, or mycobacteria may cause granulomatous endophthalmitis, as may lens rupture and the Vogt–Koyanagi–Harada-like syndrome in dogs.

Lymphocytic-plasmacytic uveitis *is by far the most common histologic type of uveitis encountered in enucleated globes.* The leukocytes resident within the uveal tissue are dominated by lymphocytes and plasma cells, with or without the formation of actual lymphoid aggregates and nodules. It may occur simply as a chronic form of what was initially a suppurative uveitis, but is more frequently seen as the typical manifestation of immune-mediated uveitis, viral infection, phacolytic uveitis, or uveitis secondary to intraocular neoplasia. Inasmuch as the inflammation in most of these examples is probably of immunologic pathogenesis, *it is probably more accurate to consider all lymphocytic-plasmacytic uveitis as immune-mediated*, with the prefix "idiopathic" or the name of the inciting antigen. Dogs, cats, and horses are the species most frequently affected, and in these species the inciting agent is usually unknown.

Specific examples of uveitis/endophthalmitis follow.

Bacterial endophthalmitis

Bacteria may enter the eye hematogenously or via penetrating wounds. Those arriving hematogenously cause their initial lesion in ciliary body or, less frequently, in choroid. Those arising via penetration usually incite the initial reaction in anterior chamber, particularly if the penetration is via perforation of an ulcerated cornea. Most are suppurative, and their extent and severity vary with the size of inoculum, virulence of the agent, and host response and its duration.

The list of organisms capable of causing endophthalmitis is long. *It is probably true that any bacterium capable of bacteremia or septicemia can cause endophthalmitis.* Particularly prominent are the streptococci and coliforms in neonatal septicemia. The failure to detect ocular lesions in such animals is more often the result of the brief, fatal course of the disease than of specific ocular resistance. The ocular lesion may be very mild, better detected by opacification of the plasmoid aqueous in Bouin's or Zenker's fixative than by histologic examination. Histology may reveal only edema of ciliary processes with a few neutrophils along the capillary endothelium or enmeshed in filaments among ciliary processes. The well-known bovine *Histophilus somni* bacteremia, infectious thrombotic meningoencephalitis, is seen as focal rather than diffuse chorioretinitis.

Exceptions to the generalization that bacterial endophthalmitis is suppurative occur if infection is caused by bacteria which, in other tissues, incite lymphocytic or even granulomatous inflammation. *Ocular tuberculosis* is largely of historical interest. It occurred as part of generalized systemic disease and the typical tubercles were most numerous in the choroid. *Mycobacterium tuberculosis* var. *bovis* was the usual isolate except in cats where the human strain was common. In cats, ocular tuberculosis may also occur as keratoconjunctivitis without uveal involvement.

Brucella canis may cause chronic lymphocytic endophthalmitis that is probably immunologically mediated. Agglutinating titers for *B. canis* antigen in aqueous exceed those of serum, and the ocular lesions are similar to those of equine recurrent ophthalmitis.

Listeria monocytogenes often causes endophthalmitis in association with meningoencephalitis in ruminants (see Vol. 1, Nervous system). The condition is unilateral and the pathogenesis is obscure.

Uveitis caused by the rickettsias of *Rocky Mountain spotted fever* and *ehrlichiosis* are discussed under Retinitis.

Mycotic endophthalmitis

Fungi may affect the eye as causes of keratitis, orbital cellulitis, or endophthalmitis. Only rarely do the fungi causing keratitis or orbital infection penetrate the fibrous tunic to cause intraocular disease. However, hematogenous uveal localization is rather common in the course of systemic mycoses caused by *Cryptococcus neoformans* and *Blastomyces dermatitidis* and, less regularly, with *Coccidioides immitis* and *Histoplasma capsulatum*. In immunodeficient animals, one might expect occasionally to detect endophthalmitis as part of generalized disease caused by saprophytic fungi such as *Aspergillus* or *Candida*; these same agents will occasionally cause endophthalmitis in conjunction with penetrating plant foreign bodies. The frequency with which endophthalmitis accompanies systemic mycosis is unknown and probably varies with the specific agent, the species affected, and whether the disease is in an endemic area or is a sporadic occurrence. Hematogenous ocular mycosis is found almost exclusively in dogs, except for cryptococcosis, which is more common in cats. *Blastomyces* and *Cryptococcus* are more likely to invade the eye in the course of generalized infection than are *Coccidioides* or *Histoplasma*, and occurrence in nonendemic areas is strongly linked to prolonged systemic corticosteroid therapy. Involvement is bilateral but not necessarily equal. Blastomycosis, cryptococcosis, and coccidioidomycosis are discussed with the Respiratory system, and histoplasmosis with the Hematopoietic system.

Blastomycosis *is the most frequently reported cause of intraocular mycosis in dogs.* In is rare in cats. Between 20–26% of dogs with the systemic disease are blind or have grossly observed ocular lesions, suggesting that intraocular involvement would be recognized more often if histologic examinations were routinely done. The clinical ocular disease is severe diffuse uveitis, frequently with retinal separation.

The histologic appearance is of diffuse pyogranulomatous or granulomatous endophthalmitis with retinitis, exudative retinal separation and, commonly, granulomatous optic neuritis. Choroiditis is often more pronounced than is the anterior uveitis. The greatest accumulation of leukocytes often is in the subretinal space enlarged by exudative retinal detachment. The causative diagnosis depends upon the demonstration of the spherical-to-oval, thick-walled yeasts in vitreous aspirates or in the histologic section. They are usually most numerous in the subretinal exudate, but are rare in anterior chamber or in retina itself (Fig. 4.43). The organisms are free or within macrophages, are 5–20 μm in diameter, and show occasional *broad-based budding*. Extremes in sizes may result in yeasts from 2–30 μm diameter. The eye may, in addition, have the full spectrum of corneal, lenticular, and glaucomatous sequelae as expected of any severe uveitis. Panophthalmitis with orbital cellulitis is seen in about one-third of enucleated globes.

Cryptococcosis is similar to blastomycosis in that *the lesions are predominantly within retina, choroid, and optic nerve.* However, infection of the eye may arise either hematogenously or by extension from the brain via optic nerves, and lesions are often conspicuously lacking in cellular host reaction. *Large collections of poorly stained pleomorphic yeasts, surrounded by wide capsular halos, impart a typical "soap-bubble" appearance to the histologic lesions* (Fig. 4.44). The yeasts vary in size but most are 4–10 μm in diameter. Round, oval, and crescentic forms are seen. In some animals, however, a granulomatous reaction mimicking that of blastomycosis can be found. In such lesions the organisms typically are scarce.

The frequency with which ***Coccidioides immitis*** infects the eye appears to be low (~2%), despite the prevalence of generalized infection in endemic areas. The ocular lesion resembles blastomycosis in that *pyogranulomatous reaction occurs around fungal spherules.* The reaction is predominantly purulent around newly ruptured spherules, gradually becoming granulomatous as the released endospores mature. The lesion tends to be more destructive than other mycoses, usually

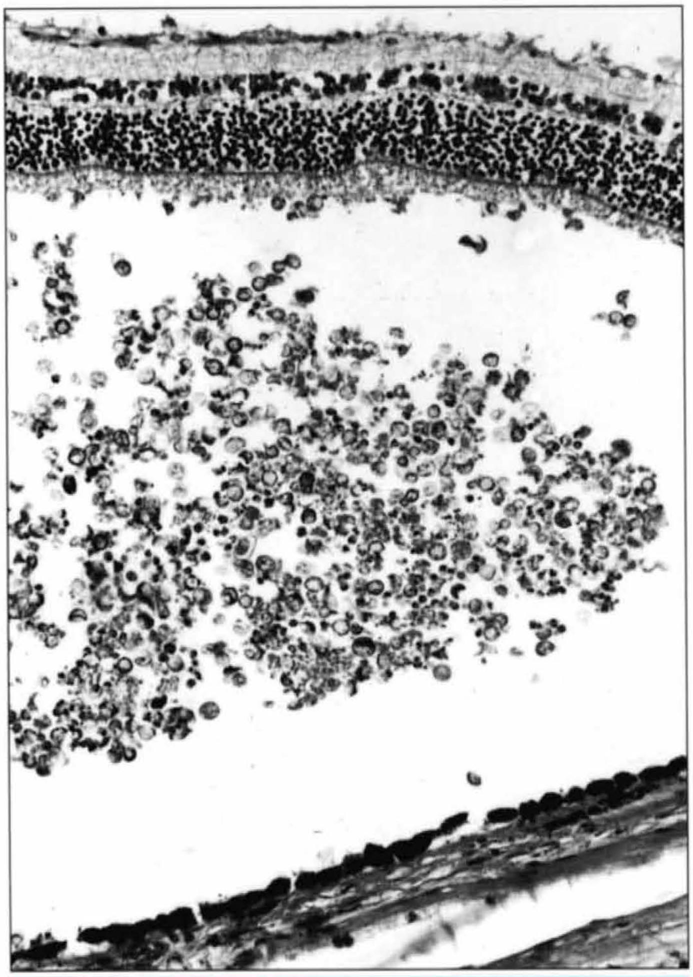

Figure 4.43 Subretinal exudate containing ***Blastomyces dermatitidis***, in a dog receiving long-term corticosteroid therapy.

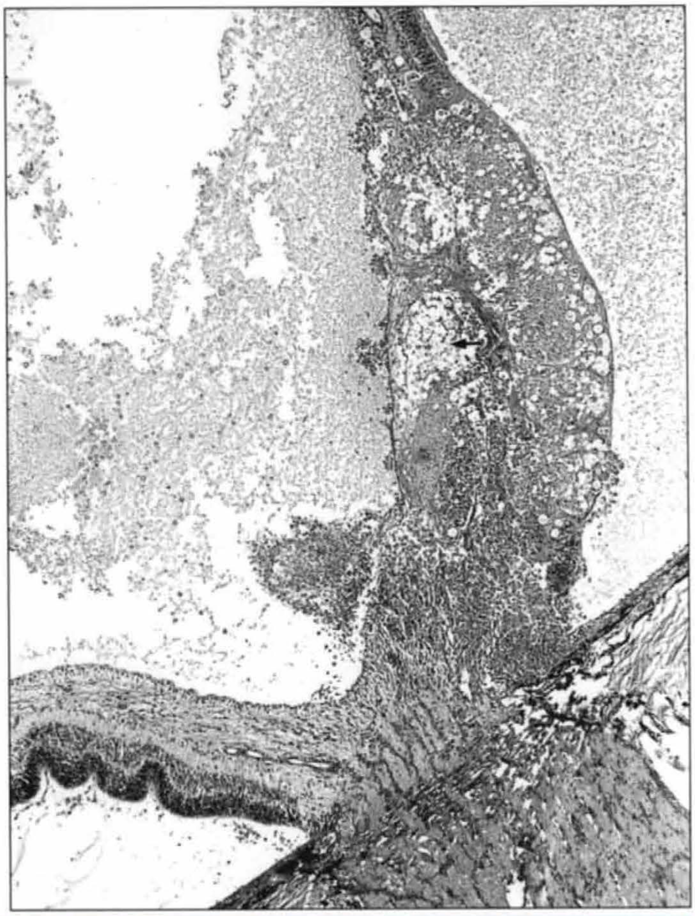

Figure 4.44 Retinal separation and focal necrotic retinitis in a cat with ***Cryptococcus*** infection. Note "soap-bubble" appearance (arrow) and minimal host reaction.

spreading to involve sclera and even episclera in a suppurative panophthalmitis.

Histoplasma capsulatum is a common cause of generalized mycosis in dogs but is rare in other domestic species. It has a predilection for lymphoid tissue and other tissues rich in phagocytes, such as lung and liver, and it is perhaps this preference that accounts for the paucity of ocular involvement in spontaneous disease. In dogs and cats, infiltrative choroiditis or panuveitis occurs and is dominated by plasma cells and by macrophages filled with the organisms. Retinal separation, plasmoid vitreous, and optic neuritis also develop. The reaction tends to target the choroid, and to be less destructive than either blastomycosis or coccidioidomycosis.

Prototheca are not fungi, but they are most easily confused with *Cryptococcus* and *Blastomyces*, and histologic lesions are certainly similar to those occurring in mycotic endophthalmitis. They are *colorless saprophytic algae* capable of causing enteric, cutaneous, mammary, or generalized granulomatous disease in a variety of mammalian species. Ocular lesions have been described only in dogs with the disseminated form of the disease. *The lesions are bilateral and may vary from lymphocytic-plasmacytic to granulomatous panuveitis with optic neuritis and exudative retinal separation.* The host response is usually quite mild. The lesions resemble ocular mycosis, particularly cryptococcosis, and are distinguished only by the observation of the pleomorphic algae. In histologic section, the algae are free or within phagocytes. The organisms are spherical to oval, from 2–20 μm in diameter with a refractile, PAS-positive, and argyrophilic cellulosic cell wall. Each cell consists of granular, weakly basophilic cytoplasm surrounding a central nucleus. *Prototheca* reproduces by asexual multiple fission, so that multiple daughter cells form within a single cell wall. One or two cycles of nuclear division without cytoplasmic cleavage may produce transient multinucleated cells before eventual cytoplasmic division results in up to eight daughter cells. Each daughter cell acquires a capsule, resulting in a parent cell criss-crossed by septations that represent the cell walls of maturing daughter cells. Rupture of the parent cell wall releases the unicellular autospores. Collapsed, crumpled, and seemingly empty cell walls are visible in histologic section. There is no budding as with *Blastomyces* and *Cryptococcus.*

Those canine isolates that were definitively identified were *P. zopfii*. An enteric route of entry is probable inasmuch as necrotic enteritis is a feature of the disease (see Vol. 2, Alimentary system). Immunodeficiency may be a prerequisite for dissemination of the organism. Lesions are found in many visceral organs, skin, and lymph nodes in most cases. The reaction is granulomatous but is usually minimal in comparison to the large number of organisms.

Protozoan endophthalmitis

While ocular lesions have been reported in infections caused by protozoa of the genera *Toxoplasma, Leishmania, Encephalitozoon, Besnoitia,* and *Trypanosoma,* only *Toxoplasma* specifically causes intraocular lesions, although many cases diagnosed as toxoplasmosis were probably caused by *Neospora*. Most of the others cause keratoconjunctivitis that occasionally extends to anterior or generalized uveitis in which the causal agent may be found. The exception is *Encephalitozoon* that may induce periarteritis within the uvea and retina as it does elsewhere.

Toxoplasmosis affecting the eye is, as elsewhere, much more frequently suspected than proven, and clinical diagnoses greatly outnumber those confirmed by histopathology. *The histologic lesion is usually in retina, uvea, or extraocular muscles, and varies from focal, acute coagulative necrosis to granulomatous or lymphocyte-rich inflammation.* The organisms are seen most easily as intracellular pseudocysts during acute disease or as true cysts during remission. The more noxious merozoites are found only with difficulty as 7–9 μm crescentic, basophilic bodies within phagocytes or free amid necrotic debris.

The histologic changes of ocular toxoplasmosis have received various interpretations and valid differences probably exist between species and between individuals of differing immune status. In man, the disseminated disease is usually congenital and the ocular lesion is multifocal necrotic retinitis in which free or encysted *Toxoplasma gondii* are found. There may be lymphocytes and plasma cells in adjacent choroid. In human adults, the ocular lesion is predominantly a lymphocytic-plasmacytic choroiditis, suggesting that the pathogenesis is related more to host immune response to the previously encountered, ubiquitous antigen than it is to local infection.

Lesions analogous to human congenital toxoplasmosis occur in *young cats* as multiple foci of retinal necrosis. Choroiditis may be present and is lymphocytic-plasmacytic, and anterior uveitis is seen in only 20–30% of such cases. *Much more common than this classical retinochoroiditis, however, is lymphocytic-plasmacytic anterior uveitis with serologic evidence of active Toxoplasma infection.* The role of toxoplasmosis in feline anterior uveitis is controversial (see Idiopathic lymphonodular uveitis of cats). Retrospective histologic studies list the majority of such cases as idiopathic and are presumed to be immune-mediated, with antigen or antigens unknown. In the several large published studies, there has not been a single case confirmed by observation of merozoites or cysts in the eye; even serologic evidence in these studies pointed to toxoplasmosis in only 1–2% of cases. In contrast, one study reported evidence of anterior uveal production of toxoplasma-specific antibody in 32 of 69 cats with anterior uveitis, and another report confirmed that anterior uveitis is indeed the most frequent manifestation of toxoplasmosis in cats, seen in 60% of cats with confirmed toxoplasmosis. Nonetheless, evidence remains less than conclusive about the role of *T. gondii* in the prevalent and enigmatic syndrome of anterior uveitis in this species. It may be that the local production of *Toxoplasma* antibody in cats with uveitis is merely the result of nonspecific recruitment of *Toxoplasma*-sensitized lymphocytes into the chronically inflamed uvea, and that lymphoid aggregates in such eyes are producing a whole range of antibody quite irrelevant to the original cause of the uveitis.

The situation in other species is not clear, but the prevalence of ocular lesions seems quite low. Lymphocytic cyclitis and multifocal necrotic retinitis are most frequently described and are usually seen together. *Multifocal choroiditis*, not necessarily adjacent to retinal lesions, is lymphocytic-plasmacytic in most species but granulomatous in sheep. A more common lesion is severe myonecrosis in extraocular muscles associated with free and encysted *Toxoplasma*. Toxoplasmosis is discussed in more detail in Vol. 2, Alimentary system.

Parasitic endophthalmitis

Many parasites are found incidentally in the eye, including: *Echinococcus* in primates and *Cysticercus* in swine, multifocal ischemic chorioretinitis and optic neuritis in elk caused by occlusive vasculitis due to microfilariae of *Elaeophora schneideri*, and uveitis associated with fortuitous localization of larvae of *Toxocara canis* or other ascarids, *Angiostrongylus* *vasorum*, *Dirofilaria immitis*, and *Onchocerca cervicalis*. In addition, adults of *Setaria* spp. are occasionally found within the eye of horses. The long threadlike worms are seen floating within the aqueous, and the uveitis that results seems to be the result of mechanical irritation. The only specific intraocular parasitism is seen with the lens fluke of fish (*Diplostomum spathaceum*), which, after penetrating the skin, seeks the lens with remarkable speed and specificity. The principal lesion is cataract induced by the intralenticular presence of hundreds of larvae awaiting ingestion by fish-eating birds for completion of their life cycle, but infected fish may have larvae arrested in many other ocular or extraocular locations.

Chronic mild anterior uveitis is reported to accompany ectopic localization of immature *Dirofilaria immitis* within aqueous and vitreous cavities of canine eyes. Studies of pathology are sparse, but endophthalmitis is reported in which anterior synechiae, subretinal exudate, and early cyclitic membrane may accompany the numerous vitreal and subretinal larval nematodes.

Ocular onchocerciasis affects people and horses. The *human* disease is endemic in Africa and Central America and is one of the most frequent causes of blindness in the world. The microfilariae of the causal agent, *Onchocerca volvulus*, are transmitted by *Simulium* spp. flies, and affect the skin, eyelids, and corneas of children and young adults. The microfilariae are found throughout the eye, but the lesion of greatest visual significance is diffuse sclerosing superficial stromal keratitis complicated by anterior uveitis with synechiae and eventual glaucoma.

Equine onchocerciasis has some similarities. The parasite, *O. cervicalis*, is of worldwide distribution and surveys from the USA document the prevalence of dermal infection in horses as varying from 48 to 96%. About one-half of the infected horses have microfilariae in conjunctiva or sclera. The microfilariae enter the eye only incidentally in the migration from the ligamentum nuchae to the subcutis. The ocular sites of greatest concentration are the peripheral cornea and the lamina propria of the bulbar conjunctiva near the limbus. The microfilariae in the cornea are associated with superficial stromal keratitis resembling the disease of man, albeit much milder. Some of the horses also have anterior uveitis typical of equine recurrent ophthalmitis, prompting theories that *Onchocerca* is one cause of this disease. The microfilariae can be recovered from the conjunctiva and eyelids of horses with uveitis, keratoconjunctivitis, and eyelid depigmentation, but are recovered with equal frequency from horses with no ocular disease and no microscopic reaction to the worms.

Ocular manifestations of **visceral larva migrans** in people are associated with larvae of *Toxocara canis* or, perhaps more frequently, of the raccoon roundworm *Baylisascaris procyonis*. The unilateral granulomatous fundic lesions are caused by a single wandering larva, and are relatively common in children but have rarely been described in nonhuman subjects despite the rather common occurrence of ascarid-induced granulomas in canine kidneys, lungs, or livers. The paucity of reports may not reflect the actual prevalence of disease in specific canine populations. One large survey of working sheepdogs in New Zealand recorded a 39% prevalence of lesions attributed to visceral larva migrans, contrasted to a 6% prevalence in similar dogs living in urban environments. *The active lesions were lymphocytic and granulomatous uveitis, nonsuppurative retinitis, and peripapillary nontapetal retinal necrosis.* Inactive lesions involved choreoretinal scars and multifocal chronic retinal separations in dogs older than 3 years. Larvae most compatible with *Toxocara canis* were seen in sections of some acutely affected eyes. The high prevalence in these dogs was tentatively ascribed to the feeding of uncooked frozen mutton that may have contained *T. canis* larvae as part of a dog–sheep–dog life cycle. A report of similar lesions in Border Collies in the US was associated with the feeding of raw pork.

Ocular disease may also result from the intraocular migration of *fly larvae*. This syndrome, termed *internal ophthalmomyiasis*, is discussed with diseases of conjunctiva.

Viral endophthalmitis

The fuzzy distinction between infectious uveitis/endophthalmitis and immune-mediated disease is most obvious when dealing with viral causes of endophthalmitis, even though it is probably also a major factor in mycotic and parasitic diseases. The distinction is therefore arbitrary, and *discussed below are those diseases that are probably best classified as immune-mediated endophthalmitis for which the antigen is identified as viral.*

Canine adenovirus

Canine adenovirus 1 (infectious canine hepatitis virus) is the best-documented cause of virally induced, immune-mediated uveitis in domestic animals. The systemic disease is discussed in Vol. 2, Liver and biliary system. During the acute viral stage of the disease, viral replication within endothelium and stromal phagocytes of the uvea results in a primary mild nonsuppurative uveitis that usually is clinically undetected. Inoculation of field virus into the anterior chamber of dogs and foxes may result in viral inclusion bodies within corneal endothelium and subsequent edema, but edema is not a feature of the active stage of naturally occurring disease. During the convalescent phase of the disease, or 6–7 days after vaccination with a modified live virus, a small percentage of dogs develops anterior uveitis, endothelial damage, and corneal edema ("*blue eye*") that is a manifestation of type III hypersensitivity to persistent viral antigen in which complement fixation attracts neutrophils. The proteases of neutrophils are responsible for the cell injury.

The histologic lesion is bilateral but not usually of equal intensity, thus clinically apparent disease may be unilateral. *Corneal edema results from diffuse hydropic degeneration of corneal endothelium and secondary stromal edema.* In a small percentage of affected dogs, the damage is so persistent as to cause interstitial keratitis and permanent fibrosis. Whether this sequel results from unusually persistent antigen, unusually severe endothelial damage or age-dependent variation in endothelial regenerative ability is unknown. *Intranuclear inclusion bodies* of adenovirus type may be seen in a few degenerate endothelial cells. There is accompanying anterior uveitis, with lymphocytes and plasma cells around vessels in iris and ciliary body, in the filtration angle and adherent to cornea as keratic precipitates. Choroidal involvement is mild or absent. Sequelae such as synechia or angle obstruction with debris are infrequent, occurring in less than 5% of affected eyes. In most dogs, whether recovering from natural or vaccine-induced infection, the ocular reaction subsides within 3–4 weeks.

Feline infectious peritonitis-associated uveitis

The coronavirus of feline infectious peritonitis causes diffuse uveitis that is probably immune-mediated (see Vol. 2, Alimentary system). The frequency of ocular lesions is unknown because the eyes are not regularly examined in cats with the disease. Estimates based upon clinical examination range from about 10% in an outbreak to 50% of unselected clinical cases. *Most cats that die of the disease have ocular involvement as detected by coagulation of aqueous with acidic fixatives (indicating increased aqueous protein).* The histologic evidence for inflammation in some eyes may be subtle indeed, and such eyes usually reach postmortem without clinically detected uveitis. Conversely, some cats develop severe uveitis attributed to this virus by clinical, serologic, or histologic evaluation, without concurrent evidence of the disease elsewhere.

The typical histologic lesion, as is the case elsewhere in the body, varies with time and location. Leukocytic infiltration is most extensive in ciliary body and adjacent limbic sclera, and is usually a rather even mixture of neutrophils, lymphocytes, plasma cells, and macrophages. In some eyes, the infiltrate is purely histiocytic. The inflammatory cell population often becomes more purely lymphoid in the choroid and more neutrophilic in the anterior chamber. Perivascular lymphocytic-plasmacytic aggregates are common in retrobulbar connective tissue and in the optic nerve sheath, and in the retina. In the retina, the accumulations are larger and are more likely to involve a true phlebitis than is the case with the subtle perivascular retinitis that is a frequent and nonspecific accompaniment to most forms of anterior uveitis. Sequelae to the uveitis are rarely seen, either because the cats are in the late stages of the disease when ocular lesions are examined or because euthanasia halts its progression. Retinal separation with serous subretinal exudate is occasionally observed. The presence of large globular accumulations of macrophages and neutrophils adherent to the corneal endothelium (*keratic precipitates*) is an important clinical hallmark of the disease, and is useful histologically as well. Neutrophilic endothelialitis with severe corneal edema may also occur.

Bovine malignant catarrhal fever-associated uveitis

The presence of severe uveitis is an important clue in the clinical differentiation of malignant catarrhal fever from other bovine systemic disorders, particularly from mucosal disease. The histologic lesions within the eye resemble those elsewhere in the body: arterial necrosis and perivascular and intramural lymphocytic accumulations. The presence of mitotic figures among the lymphoid cells is distinctive. The arteritis usually is most obvious in the iris, but may be seen affecting arterioles or venules in the retina, choroid, meninges of optic nerve, or even peripheral cornea. There is *marked corneal edema with a ring of peripheral corneal stromal vascularization*, clinically seen as a dark red circumferential brush border of straight vessels in the perilimbal cornea. Blood vessels in the conjunctiva and even in the newly vascularized cornea may be targets for the disease, so that the edema and hemorrhage of vessel injury are added to the nonspecific lesions of conjunctivitis and peripheral keratitis that accompany uveitis of any cause in all species.

Infiltration of lymphocytes among corneal endothelial cells is associated with patchy necrosis of that layer, which may also contribute to the corneal edema (Fig. 4.45). A layer of mononuclear leukocytes enmeshed in fibrin often is adherent to the aqueous face of the corneal endothelium.

Even the very early lesions are lymphocytic. In vessels, the first changes involve subendothelial and adventitial lymphocytic and lymphoblastic accumulation, with little necrosis. Despite longstanding speculation for an immune-complex pathogenesis for the vasculitis, proof is lacking. Deposition of immunoglobulin or complement is not a significant feature of the vascular lesion within the eye, and a T-cell-dependent, type IV immune pathogenesis has been suggested.

Immune-mediated uveitis

There is no clear distinction between immune-mediated uveitis and uveitis traditionally ascribed to a specific causative agent. Except for rapidly progressing bacterial uveitis following hematogenous localization or penetrating injury, *virtually all uveitis probably has an immune component superimposed on initial nonspecific inflammation.* Even traumatic uveitis probably permits unusually large amounts of endogenous ocular antigens to enter venous drainage and to reach the spleen and other lymphoid tissue. Types III and IV hypersensitivity have been induced in various laboratory animals using tissue-specific antigens of photoreceptor, uveal, lens, and corneal origin. *Lens-induced uveitis* and an *idiopathic uveitis associated with dermal depigmentation in dogs (the so-called Vogt–Koyanagi–Harada syndrome)* are naturally occurring examples of uveitis induced by endogenous ocular antigens. Recent

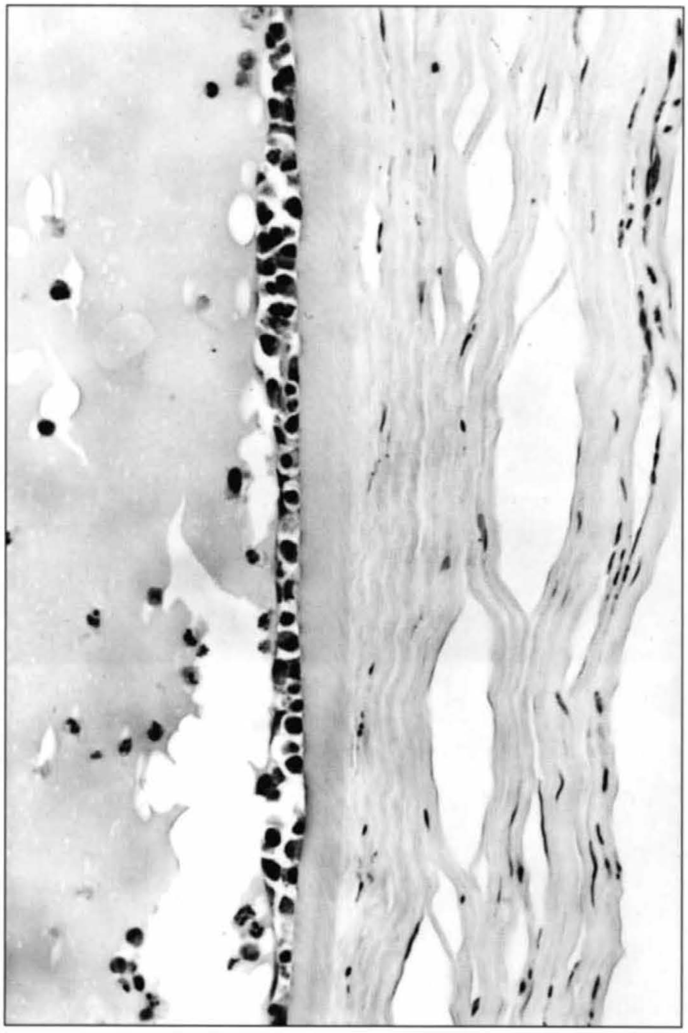

Figure 4.45 Lymphocytes, as part of a presumed **immune-mediated endothelialitis**, obscure the few remaining corneal endothelial cells in bovine malignant catarrhal fever.

demonstration of strong cross-reactivity between *leptospiral antigens* and equine corneal endothelium (immune mimicry) serves to further obscure the distinction between infectious and immune-mediated ocular disease.

Included in this section are those diseases that are exclusively or predominantly immune-mediated, and for which the triggering antigen has not been proven to be an infectious agent. *In general, all are characterized by chronic, lymphocytic-plasmacytic panuveitis, in which the infiltrating leukocytes form lymphoid aggregates and perivascular cuffs.* Clinically, they are either continuously progressive syndromes or subject to periodic irregular clinical exacerbations and remissions.

The normal eye contains almost no lymphoid tissue and, following initial antigenic challenge, must rely on diffusion of antigen to the spleen before effector lymphocytes return to enter the eye. The lymphocytes do so primarily as perivascular aggregates throughout the uvea.

Those examples of uveitis associated with penetrating injury or massive localization of infectious agents cause disruption of the blood–eye barrier. The globe thus responds to the inflammatory stimulus as would any other tissue, and those events will not be further described here.

Hematogenous localization (or experimental inoculation) of less damaging antigen within the ocular chambers that allows the blood–eye barrier to remain intact triggers a remarkable adaptation of the inflammatory and immune response known as anterior segment immune deviation, described below.

The eye was once thought to be an immunologically privileged site, with no resident lymphocytes, no antigen-processing macrophages or dendritic cells, and no lymphatic drainage. These peculiarities, plus the "*blood–eye barrier*" created by the tight intercellular junctions of iris endothelium, ciliary nonpigmented epithelium, and retinal pigment epithelium, fostered the mistaken belief that many intraocular antigens were sufficiently sequestered as to be seen as "non-self" in the event of their release into systemic circulation. The numerous diseases characterized by lymphocytic-plasmacytic uveitis in the absence of an identified infectious agent have thus been incautiously grouped as examples of "autoimmune" reaction to sequestered uveal, lenticular, or retinal antigens.

More recent studies have demonstrated that these supposedly unique and sequestered antigens are neither unique nor completely sequestered, and that antigens of any type introduced into the intraocular environment will trigger a robust immune response. Antigens identical to some of the lenticular or uveal antigens, for example, are found in nonsequestered tissues elsewhere in the body. Antigens inoculated into the anterior chamber induce a systemic humoral and T-cell response, clearly pointing to at least some leakiness in the blood–eye barrier. A variety of experiments have led to the discovery of a carefully regulated system of ocular immunity, termed **anterior chamber-associated immune deviation**. In this system, antigens introduced into the intraocular environment in a relatively controlled fashion are altered by contact with cytokines secreted by trabecular endothelial cells, corneal endothelium, and probably many other resident ocular tissues. The list of specific cytokines and how they alter antigen expression continues to unfold. The first cytokine proven to alter antigen reactivity was TGF-β2, but the list of chemical participants includes TNF-α, vasoactive intestinal peptide, and substance P. These altered antigens are then processed by macrophages and dendritic cells of bone marrow origin that are resident within the uvea. These antigen-presenting cells promote the development, after 5–6 days, of specifically sensitized suppressor T-cells within the spleen. These suppressor cells then return to the uvea where they act to suppress delayed-type hypersensitivity and the production of complement-fixing antibodies. The cells do not blunt the more discriminating noncomplement-fixing antibody production and cytotoxic lymphocytic activation that can destroy unwanted antigen without the messy bystander injury that would be so damaging to the globe.

Whatever their type, the splenic lymphocytes reach the eye about 1 week after experimental introduction of antigen into anterior chamber. Typically the lymphocytes are seen as perivascular aggregates in iris stroma, in the ciliary body and, less obviously, in the choroid and even the retina. In long-standing cases (which are most likely to receive histologic examination) the aggregates may be very large and resemble lymphoid follicles (Fig. 4.46). As in other tissues, amplification of the immune response results in recruitment of lymphocytes that are not necessarily specific for the inciting antigen. The polyclonal nature of these lymphocytes is probably important in the typically recurrent nature of uveitis in all species. Once established in the eye, these cells respond to a diverse range of circulating antigens that enter the eye through a blood–eye barrier disrupted by

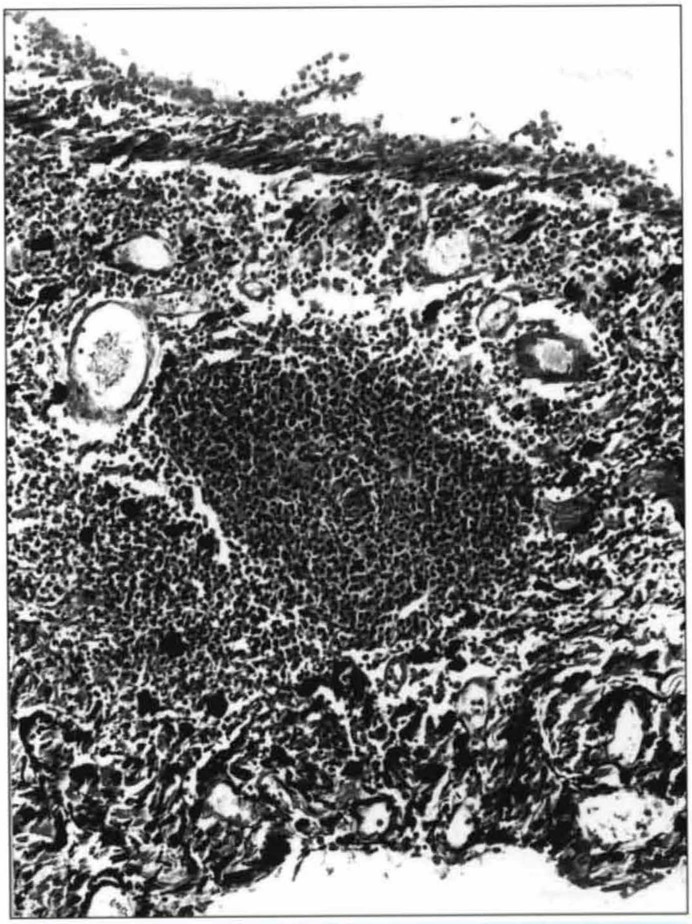

Figure 4.46 Equine recurrent uveitis. Lymphoid nodules in iris stroma.

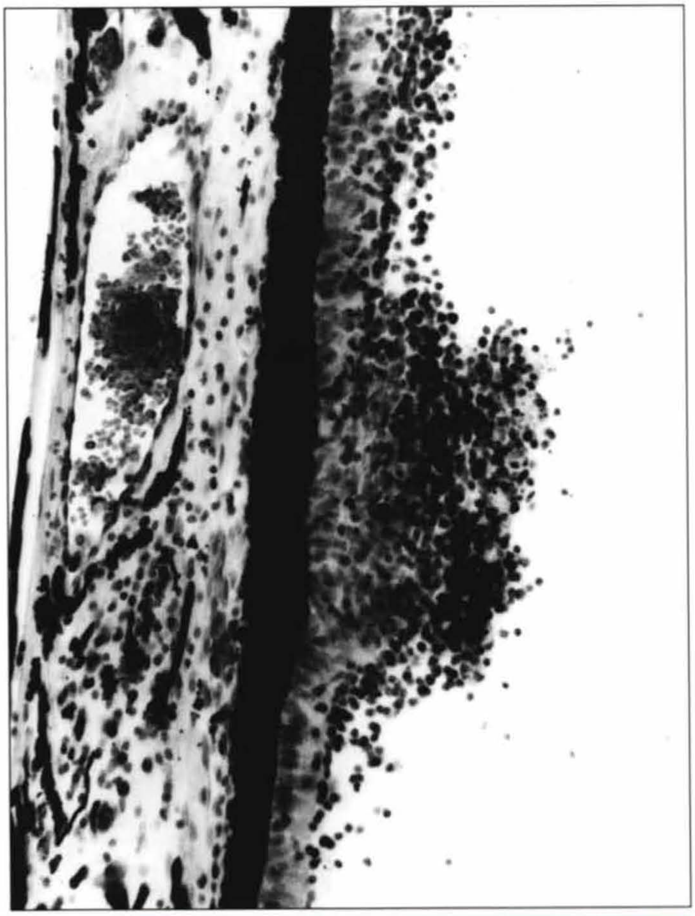

Figure 4.47 Choroiditis and inflammatory infiltrate of pars plana, in **equine recurrent uveitis**.

the previous bout of inflammation. *It is thus possible, or even probable, that chronic, recurrent uveitis results not from persistence of a single antigen, or repeated exposure to the same antigen, but is a stereotyped ocular response to activation of any one of its many acquired lymphoid populations by a variety of circulating antigens or native ocular antigens.*

Specific examples of immune-mediated endophthalmitis are discussed below, and include equine recurrent uveitis, idiopathic lymphonodular uveitis of cats, canine lymphocytic uveitis, canine uveodermatologic syndrome (Vogt–Koyanagi–Harada-like syndrome), and lens-induced uveitis.

Equine recurrent ophthalmitis (periodic ophthalmia)

This is a worldwide and important cause of blindness in horses and mules. The blindness results from repeated attacks of anterior uveitis occurring at unpredictable intervals and with increasing severity. With each attack, there is increasing involvement of the posterior uvea, retina and optic nerve, and increasingly frequent sequelae of cataract, lens luxation, synechiae, retinal separation, and interstitial keratitis. Despite the frequent observation of posterior synechiae, glaucoma is rarely reported. It is speculated that aqueous drainage in horses relies less on the trabecular meshwork and more on uveal resorption than is true of dogs or cats. The disease may initially be unilateral but eventually affects both eyes. Blindness is usually a late sequel, but may occur early in the disease if exudative choroiditis causes retinal separation.

Gross lesions of the acute disease are typical of anterior uveitis in any species: serous conjunctivitis, chemosis, circumcorneal ciliary hyperemia, corneal edema, and plasmoid aqueous and vitreous with fibrin and leukocytes in the aqueous. Clinically, such animals are often systemically ill as detected by fever, decreased appetite, and depression. Lacrimation and photophobia are usually marked. Subsequent attacks tend to become increasingly severe and resolution of the gross lesions between attacks is less complete. Such horses, during the quiescent period, may have one or more of: peripheral corneal vascularization with fibrosis and persistent edema; irregular thickening and pigmentation of iris; multiple posterior synechiae; patchy residual uveal pigment on lens capsule; and peripapillary retinal hyperreflectivity suggesting retinal scarring.

The microscopic lesions depend on the stage of the disease and represent a continuum from anterior uveitis to endophthalmitis with retinal scarring, or even phthisis bulbi. The earliest lesion is anterior uveal inflammation that is transiently neutrophilic but rapidly becomes predominantly lymphocytic. Ciliary processes are most obviously affected. Edema, fibrin, and leukocytes distend the stroma, and leukocytes and fibrin lie in the anterior chamber and in the filtration angle. Neutrophilic-to-lymphocytic pars planitis is fairly common (Fig. 4.47). In the eyes of horses with a history of several attacks of uveitis, the exudate in these acute flare-ups of the disease is almost purely lymphocytic-plasmacytic and is found about vessels of the choroid, retina, and optic nerve as well as the anterior uvea. Peripheral corneal

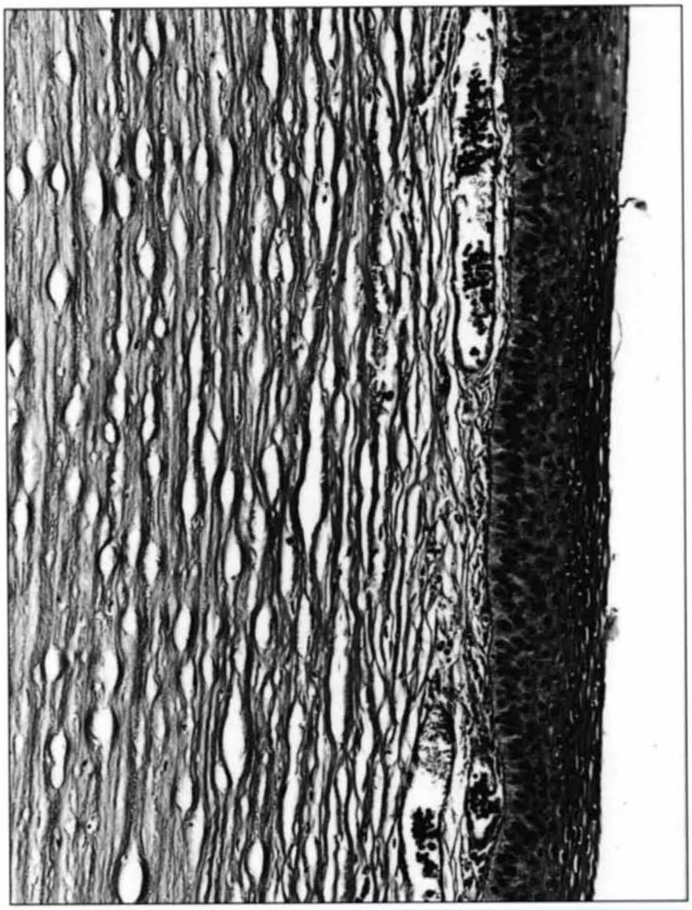

Figure 4.48 Peripheral corneal stromal vascularization and subtle fibrosis in a horse with **equine recurrent uveitis**.

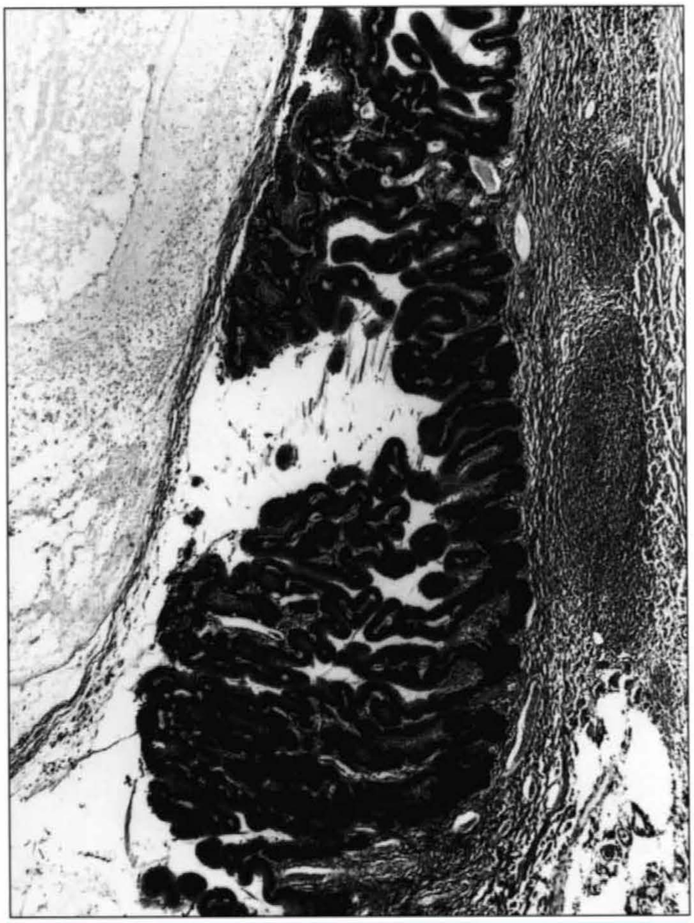

Figure 4.49 Equine recurrent uveitis. Lymphoid nodules may form anywhere in the anterior uvea. Here they coalesce within the stroma just below the ciliary processes.

vascularization, both from conjunctival and limbic ciliary vessels, becomes increasingly prominent and extends further toward the center of the cornea (Fig. 4.48). Edema accompanies the newly formed vessels. The chorioretinitis may be sufficiently exudative to cause multifocal retinal separation. As these severe uveal lesions regress during clinically quiescent periods, they leave behind characteristic residual changes. Relatively early in the disease there is the development of perivascular lymphoid aggregates in the iris and ciliary body that persist and may even form true lymphoid nodules (Fig. 4.49). The ciliary processes may remain thickened by fibrous organization of stromal edema, and a hyaline membrane often seems to cover the ciliary epithelium. This material, in fact, lies within the apical cytoplasm of the nonpigmented ciliary epithelium. In most respects, it resembles amyloid (Fig. 4.50). Small blood vessels persist along corneal stromal lamellae and there is subtle fibrous disorganization of the stroma, the result of previous edema. Peripapillary chorioretinal scarring is seen as focal retinal photoreceptor loss, jumbling of layers and gliosis. Adjacent retinal pigment epithelium may be hypertrophic or hyperplastic, and a focal cluster of lymphocytes in the nearby choroid is common.

Choroidal vessels are unusually thick-walled due to edema or fibrin, the latter probably analogous to the hyalinization described in several reports. Increased vascular permeability persists even in quiescent periods with loss of the blood–aqueous barrier demonstrated by fluorescein angiography. Whether or not this vascular alteration participates in the perpetuation of the uveitis is unknown, but it is known that such alterations predispose to localization of circulating immune complexes and subsequent type III hypersensitivity-induced inflammation.

Focal retinal detachments may reattach by fibrous organization of subretinal exudate or may progress to total separation with a barely recognizable retina adherent to the posterior lens capsule. Gliosis and lymphocytic aggregates may be found within proximal optic nerve. Scarring in optic disk and adjacent retina often is clinically obvious and may occur in horses with no other lesions of uveitis, leading to speculation that it is not really linked to, or at least not specific for, equine recurrent uveitis. Lesions of such sequelae as cataract, chronic conjunctivitis, and glaucoma are described elsewhere.

The *causes and pathogenesis* of recurrent equine ophthalmitis have not been intensively studied, in contrast to the abundance of opinion expressed in reviews or texts. *The almost universal opinion is that the disease is the result of hypersensitivity to exogenous antigen*. The most frequently cited antigens are *Leptospira* and dead microfilariae of *Onchocerca cervicalis*. The demonstration of antigenic cross-reaction between equine corneal endothelium and several common leptospiral serovars suggests that *accidental autoimmunity* may participate in some of the lesions. Cross-reaction with other ocular antigens has not been studied, but the repeated observation that lesion development follows the development of serum or aqueous antibody titers to *Leptospira* makes an immune pathogenesis very likely for this disease syndrome.

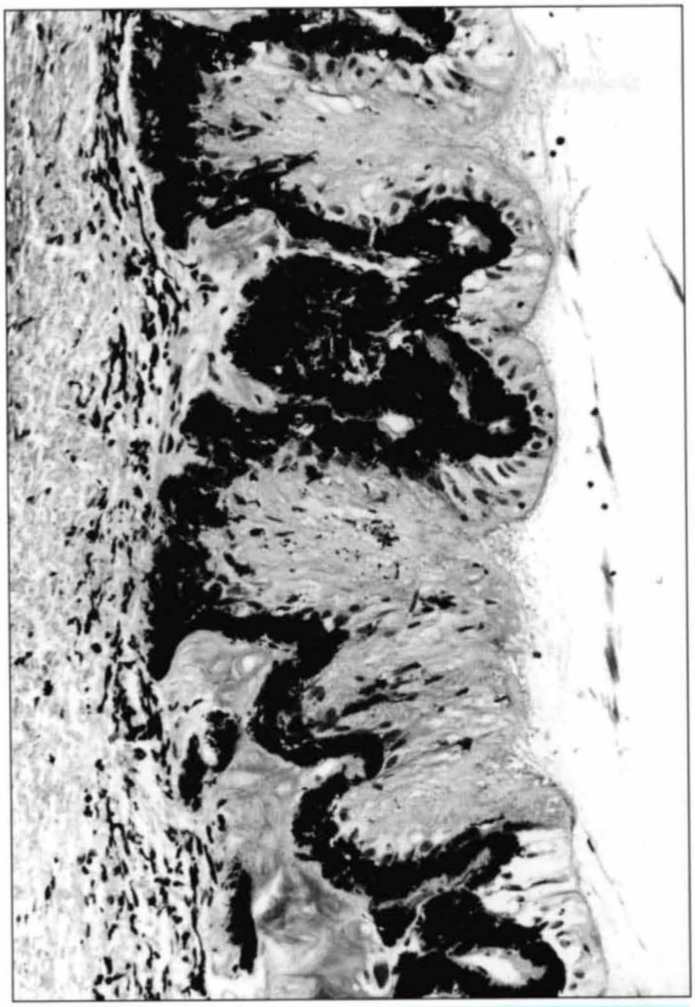

Figure 4.50 Deposition of amyloid-like material within the apical cytoplasm of the inner, nonpigmented ciliary epithelium, unique to **equine recurrent uveitis**.

There seems little doubt that *Leptospira,* particularly *L. pomona,* can initiate uveitis in horses and in man. In both species, the uveitis develops as a sequel to infection, delayed by weeks or years. The initial suspicion of this association was the observation, as early as 1948, that horses with uveitis frequently had very high serum and aqueous humour agglutination titers against *L. pomona.* This observation has since been repeatedly confirmed, and has been supported by the observation of uveitis in 22 of 36 eyes of Shetland ponies inoculated subcutaneously with small numbers of *L. pomona.* All ponies underwent subsequent leptospiremia but none developed ocular lesions until 50 weeks after inoculation. The lesions were typical of anterior uveitis, and six eyes progressed to phthisis bulbi after repeated bouts of uveitis. In 18 eyes, there were central retinal scars typical of the naturally occurring disease. *Although there seems little doubt that hypersensitivity to L. pomona can cause the syndrome of equine recurrent ophthalmitis, it is unlikely to be the only cause.* In a survey in Florida, only one of ten horses with uveitis had a positive microagglutination titer against *L. pomona.* Eight had cutaneous onchocerciasis but that was not significantly different from the overall 60% prevalence of that parasite in the sample population. Typical of the long-standing controversy about this disease is a 1990 survey of horses with uveitis in Virginia and Maryland, in which 52 of 80 affected horses had positive serum titers to one or more leptospiral serovars, and a statistically significant association between uveitis and positive titer was found for the serovars *pomona* and *autumnalis.*

Onchocerca cervicalis infection of the eye is considered briefly with helminthic uveitis. Reaction to dead microfilariae within uveal tissues is considered by some as an important cause of equine recurrent uveitis, although the high prevalence of this parasite in the horse population makes such claims difficult to support statistically. The enthusiasm for this pathogenesis may be generated, in part, by the importance of onchocerciasis as a leading cause of blinding keratitis in people.

Idiopathic lymphonodular uveitis of cats

This is by far the most frequent histologic pattern of the uveitis in cats, and vies with diffuse iris melanoma as the most common cause of glaucoma in this species. It is because of the glaucoma that these eyes are enucleated and thus become available for histologic evaluation. The mechanism by which the uveitis causes the glaucoma is unknown.

Perivascular accumulations of lymphocytes and plasma cells are seen throughout the uvea and, with less regularity, around small vessels in the retina. The iris tends to have the greatest accumulation, and the lymphocytic-plasmacytic perivascular aggregates may become so large as to be clinically visible. Formation of actual lymphoid follicles may occur in chronic and severe cases (Fig. 4.51). The nodules and follicles may also occur within the trabecular meshwork and and within the ciliary body, but choroidal involvement is usually quite subtle.

The syndrome is presumed to be immune-mediated, but the identity of the antigen or antigens is unknown. Its initial clinical presentation is usually unilateral, but the other globe is considered "at risk" for developing subsequent uveitis. There has been no study to document the actual risk. The pattern of serologic reactions in cats with this lymphonodular uveitis is no different than the general population, except perhaps to *Toxoplasma* (see Protozoan endophthalmitis, above). That debate continues, but it seems clear that the syndrome is not associated with the presence of histologically detectable infectious agent within the globe. Studies using immunohistochemistry and PCR to detect infectious agents have been similarly inconclusive.

Idiopathic lymphocytic uveitis in dogs

The histologic lesions are, in general, similar to those described above for cats and horses: *lymphocytic-plasmacytic panuveitis that tends to be more severe in the anterior uvea that in the choroid.* Some cases develop lymphoid nodules and even follicles within the anterior uveal stroma. The disease is bilateral but not necessarily of uniform severity. Unlike the situation in cats, it rarely is associated with glaucoma. The main differential diagnosis is phacolytic uveitis, and indeed in some cases the distinction is impossible.

Uveodermatologic syndrome in dogs (Vogt–Koyanagi–Harada syndrome)

Despite the exotic-sounding name, *this disease is relatively frequent in those areas in which the most susceptible breeds (Akitas, Siberian Huskies, Samoyeds) are popular. The clinical syndrome of facial dermal depigmentation and severe bilateral uveitis is distinctive,* although many dogs examined

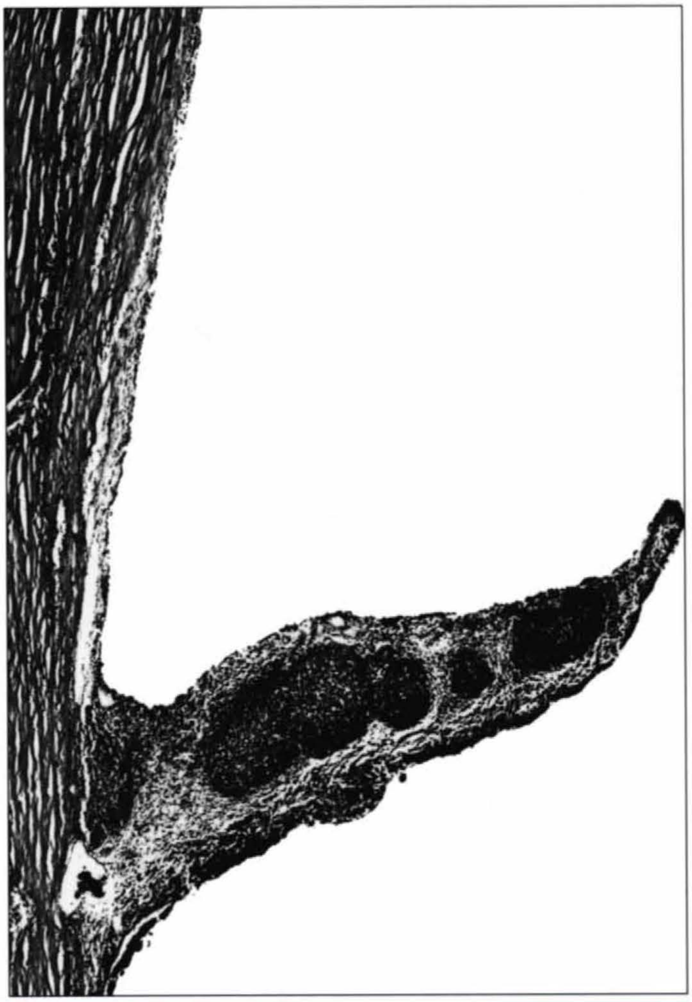

Figure 4.51 Lymphonodular iritis and secondary glaucoma in a cat. The iridocorneal angle has been dislocated far posterior to the termination of Descemet's membrane (angle recession).

for the uveitis are not noted to have skin lesions. The canine syndrome closely parallels the human disease, except for the encephalitis that is the least-frequent part of the human syndrome and has not been confirmed in dogs. The human disease is most prevalent in Orientals; the predilection in dogs for the Japanese Akita is a fascinating but unexplained parallel.

The histologic lesion is a destructive granulomatous endophthalmitis with abundant dispersal of melanin. The melanin-laden retinal pigment epithelium seems to be especially susceptible. Retinal detachment and destructive granulomatous inflammation are seen in advanced cases. The lesion is distinguished from the more prevalent systemic mycotic diseases by the predilection for pigmented tissues within the eye, lack of visceral involvement, and by the distinctive skin lesions if they are present (see Vol. 1, Skin and appendages).

The pathogenesis of the human disease is thought to involve cell-mediated immune reaction to uveal (or epidermal) melanin.

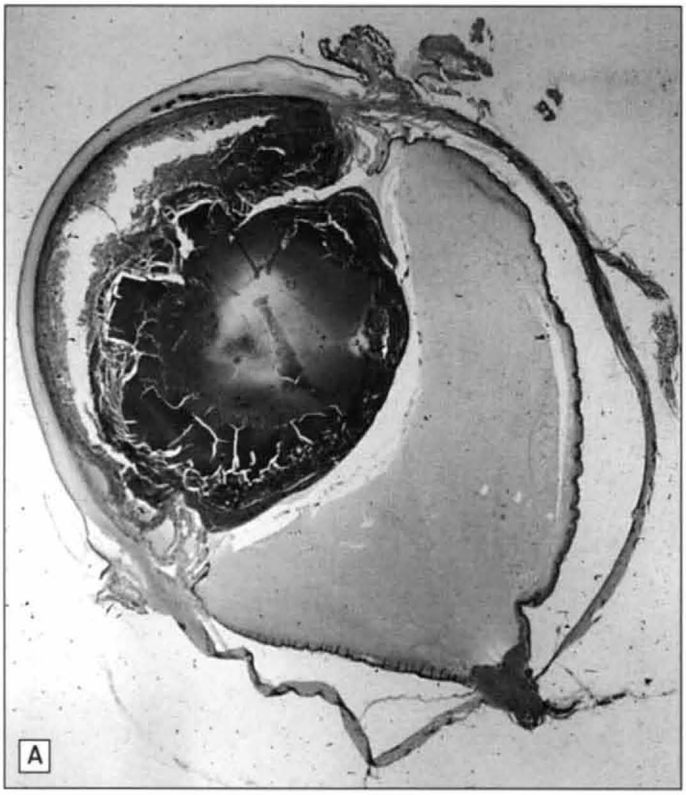
Lens-induced uveitis

Uveitis in response to leakage of lens material is seen in all species, but is most frequent by far in dogs. The term lens-induced uveitis encompasses two very different syndromes – phacolytic and phacoclastic uveitis – that differ markedly in clinical severity, in histopathology, and in pathogenesis.

Phacolytic uveitis is a *mild lymphocytic-plasmacytic anterior uveitis that occurs in response to the leakage of denatured lens protein through an intact lens capsule, which occurs regularly in the course of maturation of cataracts towards total fiber liquefaction.* The inflammation is readily controlled by routine therapy, so the pathologist is likely to encounter this lesion only as an incidental finding in eyes with hypermature cataracts that were enucleated for reasons unrelated to the uveitis. The lesion is identical to that described for idiopathic ("immune-mediated") uveitis, except it is always mild. Its pathogenesis is unknown. The lens leaks small denatured lens proteins that are not immunogenic but are, perhaps, direct inflammatory stimulants with lymphocytic chemotactic properties.

Phacoclastic uveitis *is, at least histologically, a more complicated disease that follows rupture of a normal lens in an unknown percentage of cases.* The rupture is usually from corneal penetration by a thorn, quill, bullet, or cat claw, and thus usually is of the anterior capsule. The clinical syndrome is distinctive: corneal perforation and mild traumatic uveitis that are successfully managed by conventional therapy, followed by the sudden reappearance of a severe, intractable uveitis 10–14 days after the initial injury. Poor response to medical therapy and the eventual development of glaucoma or phthisis bulbi prompt enucleation, such that *phacoclastic uveitis is one of the most prevalent ocular diseases to be submitted for histologic examination.*

The macroscopic changes in the bisected globe are diagnostic: the lens is flattened in its anteroposterior dimension and there frequently is a wedge of opacification extending from the anterior capsule towards the nucleus. Usually there is posterior synechia, iris



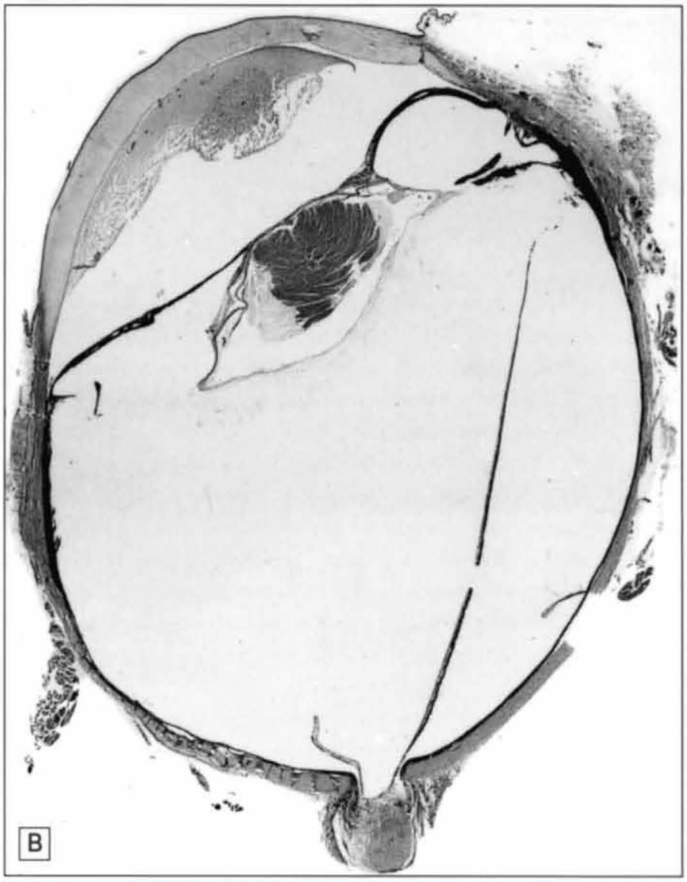


Figure 4.52 A. Acute phacoclastic uveitis following *Encephalitozoon*-induced lens capsule rupture in a rabbit. **B.** Posterior synechia, iris bombé, and glaucomatous cupping of optic disk following **traumatic corneal and lenticular perforation**. The anterior-posterior flattening of the liquified lens is typical.

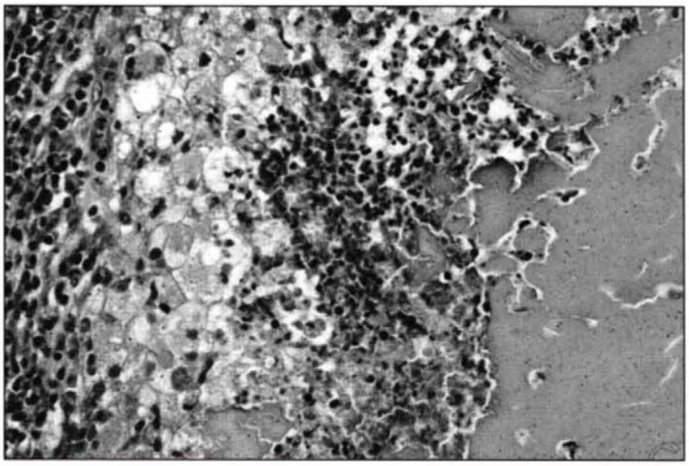

Figure 4.53 Acute phacoclastic uveitis. Laminations of neutrophils, macrophages, and then lymphocytes surround fragments of ruptured lens (arrow).

bombé, and the various other lesions as seen in any severe uveitis (Fig. 4.52A, B).

The histologic lesions vary considerably depending on duration and, probably, on the amount of lens protein that escaped through the rupture site. There are often complex lesions that result from a combination of the direct effects of trauma, immunologic reaction to massive release of lens protein, reparative proliferation of metaplastic lens and/or iridociliary epithelium, and possible contributions by corneal wound healing, sepsis, and glaucoma. It is worth mentioning that some, and perhaps most, of these globes have at least some participation by bacterial infection that occurs concurrently with the original penetrating injury. How much that infection contributes to the histopathology described below remains unknown. Most samples reaching a pathologist are from animals that have been treated extensively with antibiotics, but it is still possible that previous septic inflammation was the significant contributor to the persisting histologic changes.

The simplest and presumably earliest lesion of phacoclastic uveitis occurs at the site of capsular perforation. The edges of the capsule are retracted and coiled outward, and a wedge of neutrophils and liquified lens material extends from the perforation towards the nucleus. The inflammation outside of the lens is usually distinctly perilenticular and involves a mixture of neutrophils and macrophages in the anterior and posterior chambers, and a lymphocyte-dominated reaction within the uveal stroma (Fig. 4.53).

Older lesions (which predominate in most enucleated globes) are dominated by perilenticular proliferative changes of wound repair. There is proliferation and fibroblastic metaplasia of lens epithelium adjacent to the perforation, which escapes from the lens to ramify over the lens surface and frequently incorporates the lens, ciliary processes, and iris leaves into a large fibrous mass that obstructs aqueous outflow. Metaplasia of ciliary epithelium or recruitment of fibroblasts from uveal stroma may contribute to the proliferation (Fig. 4.54). Many such specimens contain little evidence of inflammation other than fibroplasia, probably because of very extensive anti-inflammatory therapy that is, in hindsight, useless against the proliferative events that doom the eye to glaucoma or phthisis.

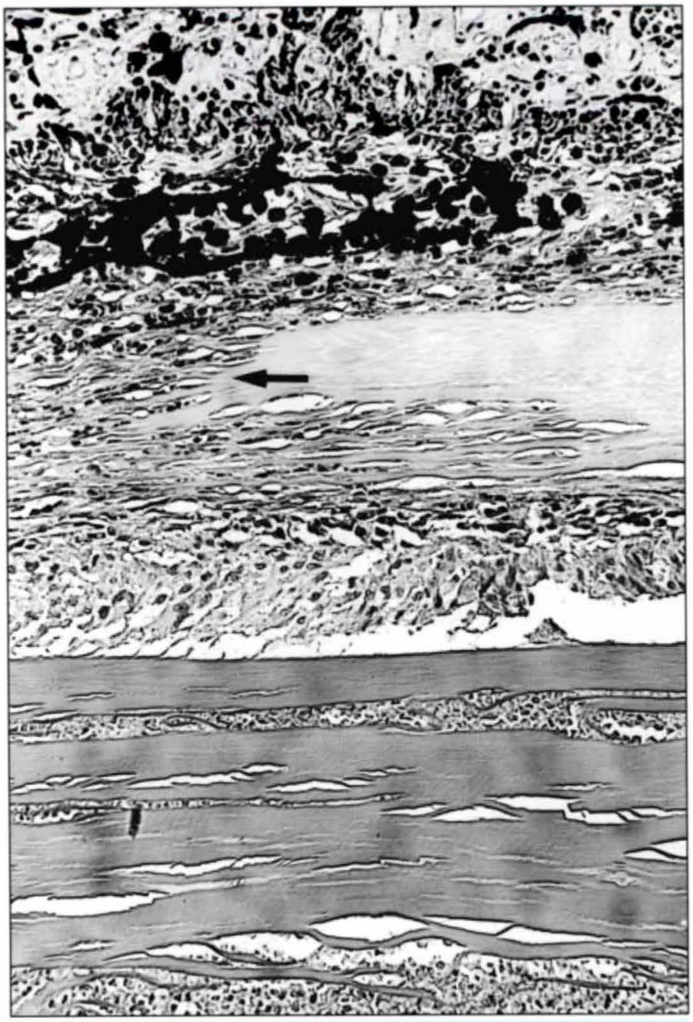

Figure 4.54 Chronic phacoclastic uveitis. Severed ends of anterior lens capsule (arrow) are fimbriated. Typical fibrous proliferation fuses cataractous lens to the (pigmented) iris.

Phacoclastic uveitis is an important complication of cataract surgery in which fragments of lens cortex or epithelium may be left in the eye. These initiate the same inflammatory and proliferative reaction as described above, and the complications are as refractory to conventional anti-inflammatory therapy as is the naturally occurring disease.

The immune pathogenesis of phacoclastic uveitis has been extensively studied, but with no universally accepted conclusion. The current theory is that the release of massive amounts of lens protein antigen overwhelms the splenic T-cell tolerance to small amounts of lens antigen. Recruitment of lens-sensitized lymphocytes into the perilenticular uvea then initiates both the pyogranulomatous perilenticular inflammation and the proliferative events of healing that, unfortunately, doom the eye. This pathogenesis, if true, explains the typical delay between injury and reaction, and why rapid surgical removal of the lens is preventive. It may also explain the unpredictability of phacoclastic uveitis, especially following small perforations in puppies, which seem often to heal uneventfully. Even in adult dogs the disease in unpredictable, so owners' questions about the risk of phacoclastic uveitis as the justification for surgical removal of a perforated lens cannot be answered with certainty. One study found lens removal shortly after perforation prevented serious complications in six of seven dogs thus treated, whereas five of six dogs treated with aggressive medical therapy lost the eye to complications of uveitis.

Two interesting variations on what is basically a canine scheme are seen in rabbits and cats. *Rabbits* suffer what appears to be spontaneous lens capsule rupture of a previously normal lens. The response is well-contained perilenticular granulomatous inflammation very similar to human phacoanaphylactic uveitis. The rupture is associated with the intralenticular presence of *Encephalitiozoon*, and it is assumed that the organisms penetrate and thus weaken the posterior lens capsule. *Cats* occasionally develop lesions similar to those in dogs, but also develop a unique feline primary intraocular pleomorphic sarcoma that may arise from metaplastic lens epithelium or from other transformed epithelial elements in the reparative reaction (see Feline post-traumatic sarcoma).

Glaucoma

Glaucoma is a pathophysiologic state characterized by a prolonged increase in intraocular pressure. While such increases of pressure may theoretically result from increased production or *decreased removal of aqueous*, only the latter is known to occur. The lesions in glaucomatous eyes include those related to the pathogenesis of the glaucoma and those resulting from the glaucoma itself. *Glaucoma occurs commonly in dogs*, less commonly in cats and horses, and rarely in other species. The medical and surgical control of glaucoma remains problematic despite extensive experimentation with many different therapeutic modalities. Because most affected eyes eventually require enucleation or evisceration, *glaucoma is one of the most frequent ocular conditions submitted for histologic evaluation.*

The lesion predisposing to glaucoma may be the result of *antecedent ocular disease*, particularly intraocular neoplasia and anterior uveal inflammation with posterior or anterior synechiae. Such cases are termed **secondary glaucoma. Primary glaucoma** describes those cases without evidence of prior ocular disease and, in practical terms, is *synonymous with malformation of the filtration angle.* Primary glaucoma is seen almost exclusively in dogs, and vies with neoplasia as the most frequent cause of glaucoma in dogs.

Because the pathogenesis of glaucoma so frequently involves developmental or acquired distortion of the filtration angle, a description of that structure is appropriate here.

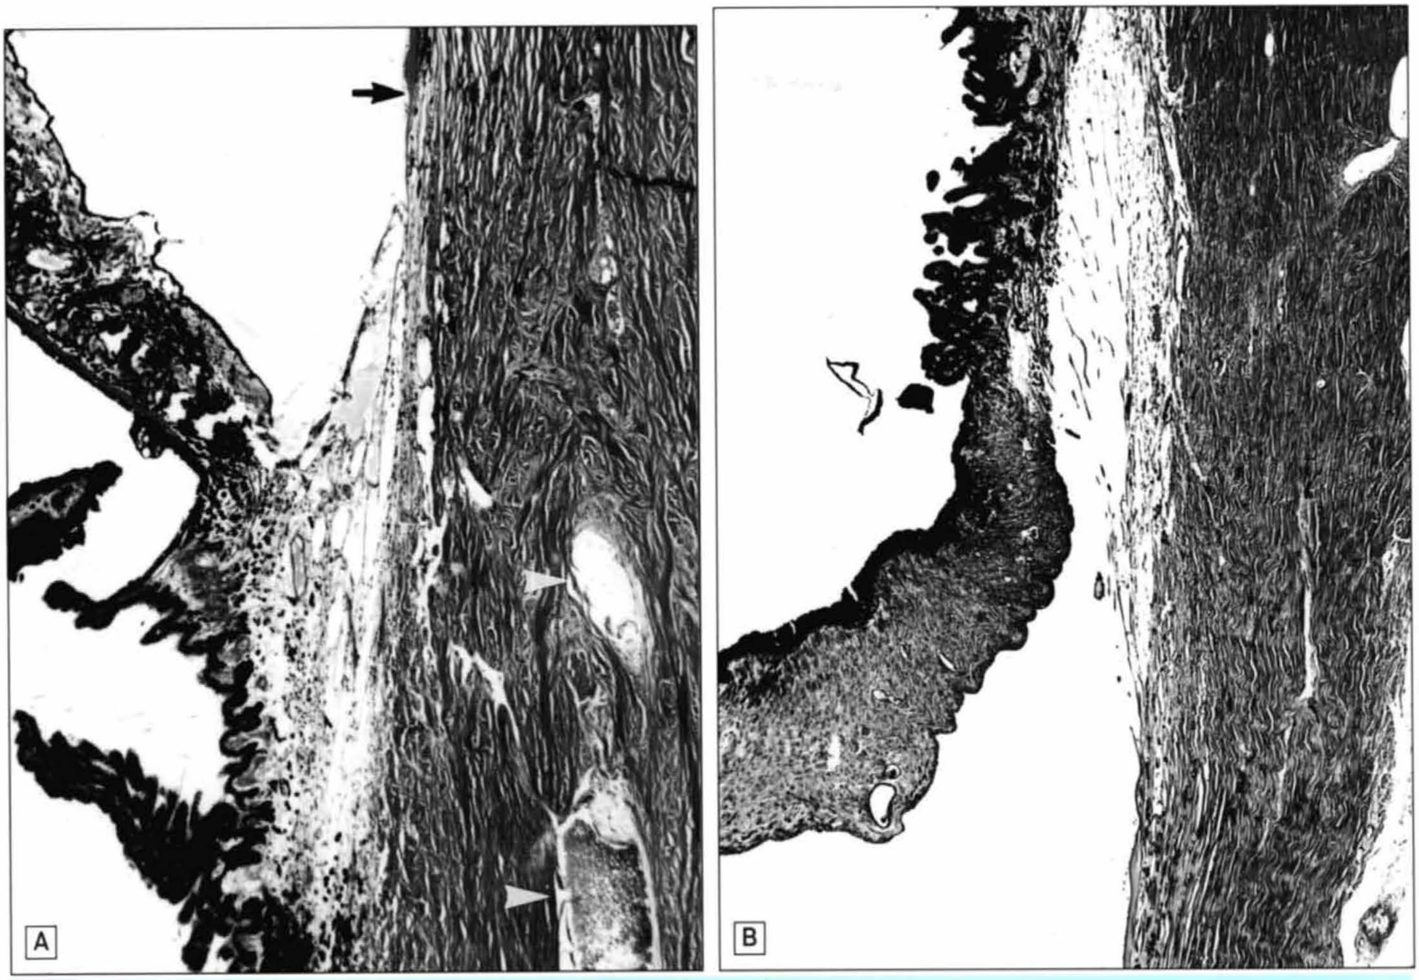

Figure 4.55 A. Normal canine filtration angle showing fenestrated pectinate ligament inserting at the termination of Descemet's membrane (arrow). Large vessels (arrowheads) are part of scleral venous plexus. **B. Normal feline filtration angle**.

The **filtration apparatus** is a series of mesenchymal sieves that occupies the iridocorneal angle, and extends circumferentially around the globe. These sieves appear to form by rarefaction of the same mesenchyme that forms iris stroma, and its rarefaction continues (at least in carnivores) for several weeks after birth. This area of perforated mesenchyme is the **ciliary cleft**, bordered externally by sclera, posteriorly by the muscles of the ciliary body, and internally by the iris stroma. Its anterior border, at least in dogs, extends for about a millimeter into the deep peripheral corneal stroma just external to Descemet's membrane. Its border with the anterior chamber is marked by the **pectinate ligament,** which is visible clinically as a series of cobweb-like branching cords (carnivores) or a fenestrated sheet (ungulates) stretching from the termination of Descemet's membrane to the anterior portion of the iris root. They consist of collagenous cords covered by a very thin endothelium, with a thin intervening layer of basement membrane-like material. The endothelium is continuous with the corneal endothelium, and the collagenous core is continuous with corneal stroma.

Aqueous humor percolating through the pectinate ligament into the ciliary cleft must then pass through mesenchymal sieves consisting of collagenous cords covered by phagocytic and pinocytotic endothelium, called the **trabecular meshwork**. The large, open network of cords occupying most of the ciliary cleft is the uveal trabecular meshwork, while anterior and external to it is a more compressed network called the corneoscleral trabecular meshwork. Ordinarily, aqueous humor produced by the ciliary processes passes through the pupil, through the pectinate ligament, and then through the uveal and corneoscleral trabecular meshworks en route to the *scleral venous plexus* that will return the aqueous to the systemic circulation. Improper development or acquired obstruction of any part of this drainage pathway may result in glaucoma, but one must remember that *the ciliary cleft extends 360° around the iridocorneal angle. Blockage of most of it is required for the development of glaucoma*, and this assessment is virtually impossible with two-dimensional histologic examination. It is quite common to encounter dog eyes with maldeveloped filtration angles in both the dorsal and ventral portions contained in a routine sagittal histologic section, yet with no evidence of glaucoma. Examination of the circumference of the angle with a dissecting microscope or scanning electron microscope in such cases often reveals the maldevelopment to be segmental and thus not a cause for glaucoma.

Differences exist among species in the finer details of angle structure and in the degree to which alternative routes of aqueous outflow are utilized (Fig. 4.55A, B). The horse, for example, has very thick pectinate fibers, and an inconspicuous corneoscleral trabecular meshwork and scleral venous plexus. As implied by these histologic features, *the horse employs alternative routes of aqueous outflow* (into iris stroma and especially posteriorly through ciliary muscle and into choroid) that are much more important than similar routes in dogs or cats. In contrast, the *cat* has extremely delicate pectinate fibers, a very large, open ciliary cleft, a conspicuous scleral venous plexus, and minimal (about 3% of aqueous outflow) reliance on alternative outflow pathways. In dogs, alternative drainage routes account for 15–25% of all outflow. The existence of these alternative routes may explain the absence of glaucoma in some eyes (especially in horses) in which the angle changes would ordinarily have resulted in glaucoma, and may even explain the presence of glaucoma in eyes with apparently normal angles but lesions affecting portions of these other potential drainage routes.

Lesions causing glaucoma

Primary glaucoma is most frequently encountered in dogs. Although theoretically primary glaucoma may have no visible angle lesion (which is frequently the case in people), *in dogs there is almost always a readily detected maldevelopment.* The one exception is primary open-angle glaucoma in Beagle dogs in which there is no visible antecedent lesion. The broad term **goniodysgenesis** encompasses all developmental defects of the filtration angle, of which two types account for most canine cases. *The most prevalent is continuation of mature iris stroma across the trabecular meshwork to insert into the termination of Descemet's membrane.* Some consider this an example of dysplasia of pectinate ligament, and the term **imperforate pectinate ligament** is widely used. The band usually is much thicker than pectinate ligament and lacks the appropriate perforation to allow the drainage of aqueous humor. The trabecular meshwork posterior/exterior to this broad mesenchymal band often seems normal, although that is quite variable (Fig. 4.56A). It is seen as a *breed-related and thus presumably inherited defect* in Bouvier des Flandres, Basset Hounds, American Cocker Spaniels, Dandie Dinmont Terriers, Siberian Huskies, Samoyeds, Chows, and numerous other breeds. The defect, and the resultant glaucoma, is occasionally seen in mixed-breed dogs. The dysplasia is usually bilateral but not necessarily of equal extent, thus the glaucoma is often present initially only in one eye. The prevalence of iridopectinate dysplasia is much higher than the prevalence of glaucoma, and even in dogs with very extensive dysplasia that should seemingly eliminate almost all aqueous drainage, the onset of glaucoma is not until several years of age. It is not unusual to have cases in which clinically detected glaucoma was delayed until 8–10 years of age. Age-related changes in outflow resistance within the alternative routes of aqueous outflow have been postulated as the explanation, as have changes to the angle configuration related to age-related forward movement of the lens. These remain as theories.

Importantly, there appears to be little direct correlation between the severity of the goniodysgenesis and the actual risk of developing glaucoma, its age of onset, or its severity. The extent to which this is true seems to vary by breed, and perhaps the best generalization is that dogs with structurally (i.e., as evaluated by gonioscopy) normal filter angles have no increased risk of glaucoma, while those that have at least some developmental abnormality are at increased risk. *Continuing to breed dogs with abnormal angles increases the prevalence of glaucoma within that line.* It may be that the goniodysgenesis that is visible clinically and histologically is not the direct cause for the glaucoma, but a marker for some other defect in trabecular development that is the real cause of the glaucoma.

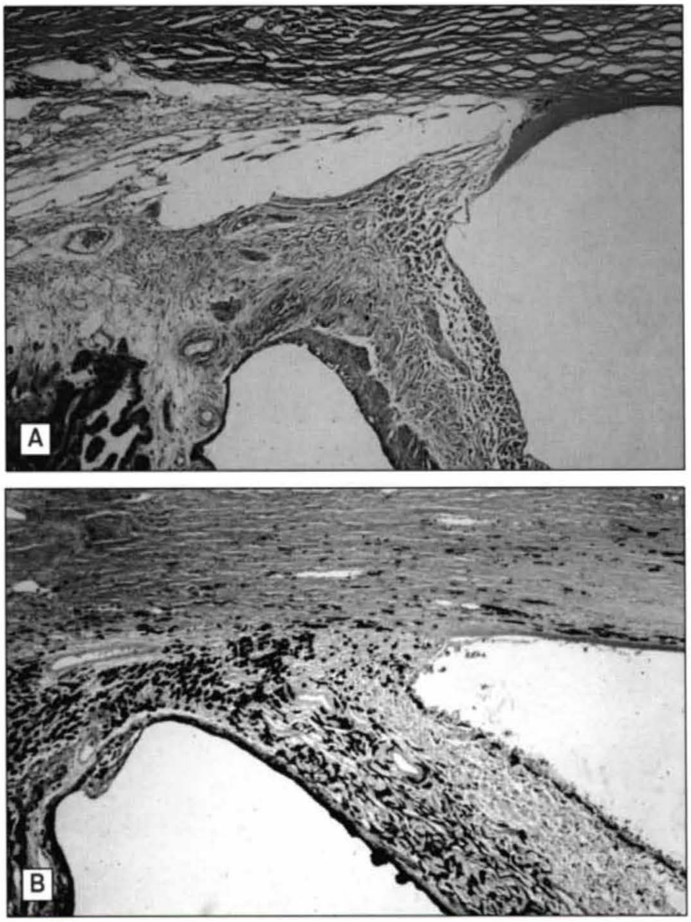

Figure 4.56 A. Goniodysgenesis, with a continuous band of iris-like mesenchyme in place of the normal, perforated pectinate ligament. **B. Trabecular hypoplasia**. This rare, profound arrest in mesenchymal development causes truly congenital glaucoma.

The second major type of goniodysgenesis is seen as a more fundamental arrest in the maturation of the trabecular meshwork such that the ciliary cleft is filled with tissue resembling primitive anterior uveal mesenchyme (Fig. 4.56B). This may occur in conjunction with iris hypoplasia or anterior chamber cleavage syndromes, but it may exist as an isolated defect termed **trabecular hypoplasia**. It has no known familial predilections. Such animals usually have truly congenital glaucoma, in contrast to the adult onset that characterizes the more common breed-associated glaucomas. It is important to note that the remodeling of the trabecular meshwork in dogs and cats continues for several weeks after birth, so that one should avoid overinterpreting apparent angle solidification in very young carnivores.

Secondary glaucoma *occurs most commonly as the result of posterior synechiae as a sequel to anterior uveitis.* The pupillary margin of the iris normally floats along the surface of the lens. Any fibrinous effusion that increases the stickiness of the iris creates a substantial risk of iridocorneal adhesions and resulting pupillary block. Continued production of aqueous humor in the presence of pupillary obstruction results in characteristic forward bowing of the iris known as *iris bombé* (Fig. 4.57). In this condition, the glaucoma is caused not

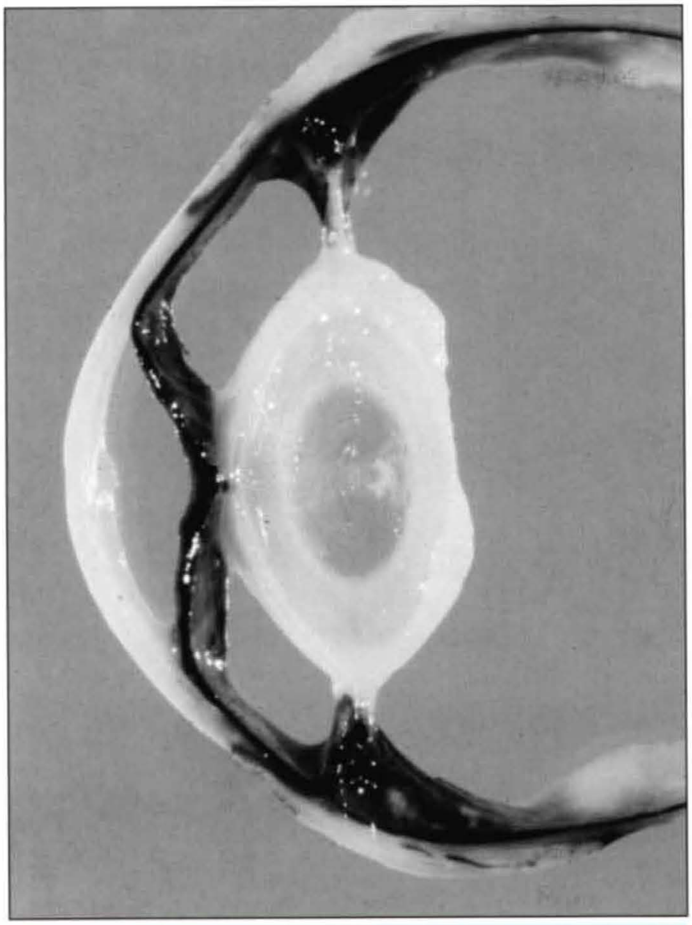

Figure 4.57 Iris bombé, reflecting a combination of posterior synechia, pupillary block, and eventual peripheral anterior synechia.

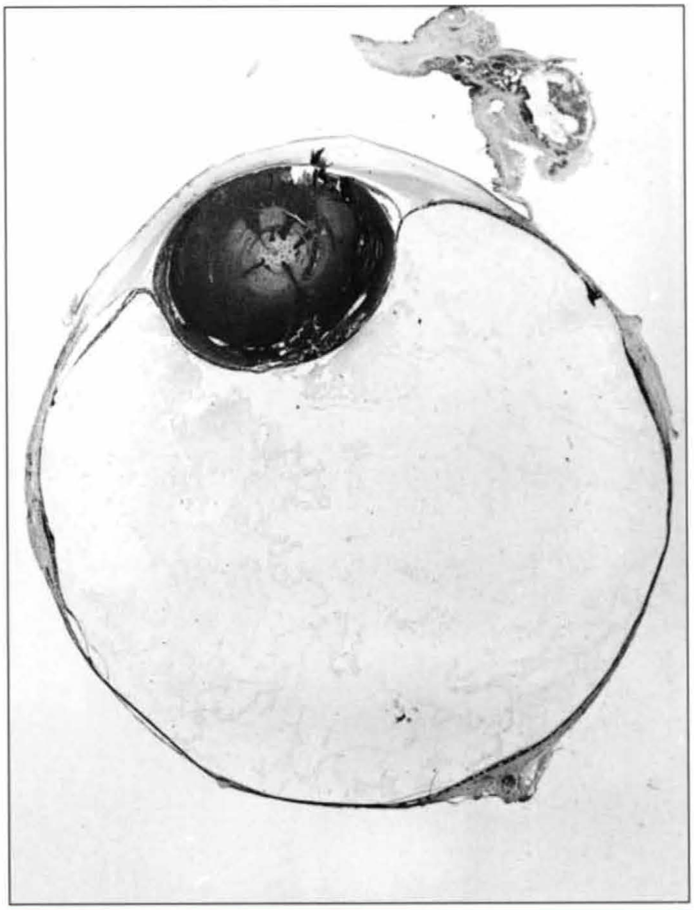

Figure 4.58 Glaucoma caused by swelling of cataractous lens (intumescent cataract) and resultant functional anterior synechia, in a dog. Note thin sclera typical of buphthalmos secondary to glaucoma.

only by pupillary obstruction but by peripheral anterior synechia as the forward bulging of the iris effectively seals the iridocorneal angle. Anterior synechia occurring independently of iris bombé is an occasional cause of secondary glaucoma. Because the iris does not normally contact the cornea, anterior synechia unrelated to iris bombé is frequent only as a consequence of corneal perforation, in which case the iris flows forward as an iris prolapse to seal the defect and may then adhere diffusely to the corneal endothelium (see Fig. 4.34).

Other frequent causes of secondary glaucoma include occlusion of the trabecular meshwork or pupil by pre-iridal fibrovascular membrane or by neoplasia. Posterior migration by corneal endothelium to cover the anterior face of the pectinate ligament and iris is seen quite frequently and may represent an important mechanism for the development of secondary glaucoma, even though the cause for the endothelial migration is usually not obvious. It may be particularly important as a trigger for the still unexplained delayed onset of glaucoma in adult dogs with lifelong goniodysgenesis.

Lens luxation may precipitate glaucoma by allowing vitreous to occlude the pupil, by stimulating anterior uveitis, or by trapping iris against cornea. Rarely, lens swelling with cataract (intumescent cataract) seems to occlude the pupil (Fig. 4.58). In small terrier dogs with an inherited tendency to luxation, there is an unusually high prevalence of glaucoma. Removal of lens prior to the onset of glaucoma prevents the expected glaucoma, seemingly establishing the causal role of the luxation. Posterior synechiae may also occlude the pupil (particularly as part of phacoclastic uveitis), but posterior synechiae usually cause glaucoma via iris bombé and thus a circumferential peripheral anterior synechia.

There are substantial species differences in the prevalence of the mechanisms by which glaucoma may occur. In *dogs*, goniodysgenesis, posterior synechiae with iris bombé, pre-iridal fibrovascular membrane, anterior uveal melanoma, and anterior lens luxation are the leading causes, in approximately that order of prevalence. In *cats*, diffuse iris melanoma and chronic idiopathic lymphonodular uveitis are the only prevalent causes of glaucoma, with posterior synechiae being inexplicably rare. In *horses*, the presence of pre-iridal fibrovascular membranes across the pectinate face is the most frequent cause, although the stimulus for the membrane development is unknown in most reported cases. Many horses with glaucoma have a clinical history of previous uveitis, but histologic assessment of the glaucomatous globe usually reveals very little evidence of that inflammation and no obvious connection between the inflammation and the development of glaucoma. In those horses with glaucoma in which the membrane had not apparently crossed the pectinate ligament, glaucoma may have been caused by obstruction of alternative uveal routes of aqueous outflow, which are more important in horses than in dogs or cats.

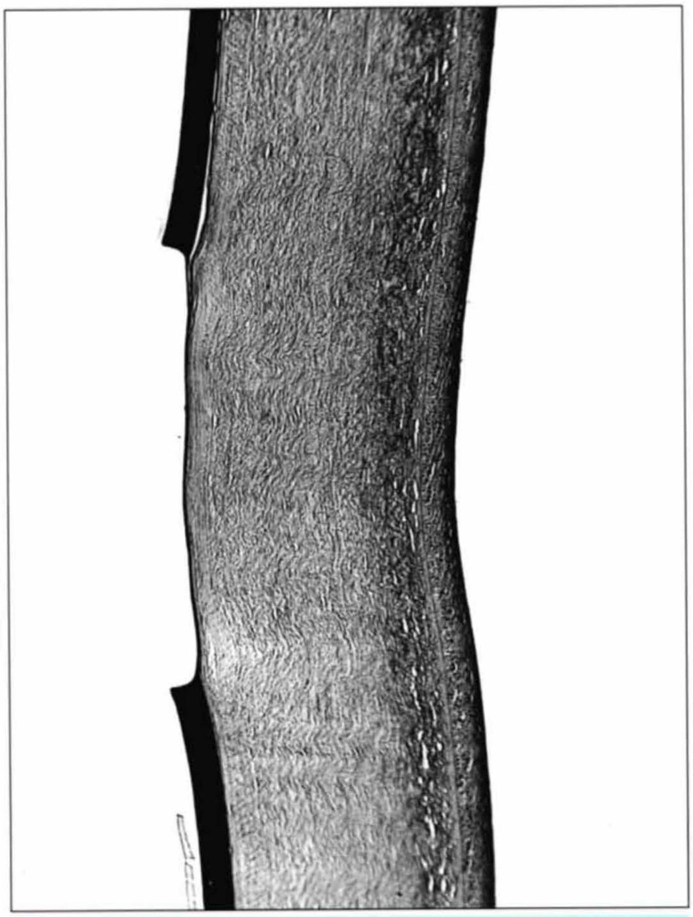

Figure 4.59 Focal break in Descemet's membrane (**corneal stria**) commonly seen in horses and dogs with glaucoma.

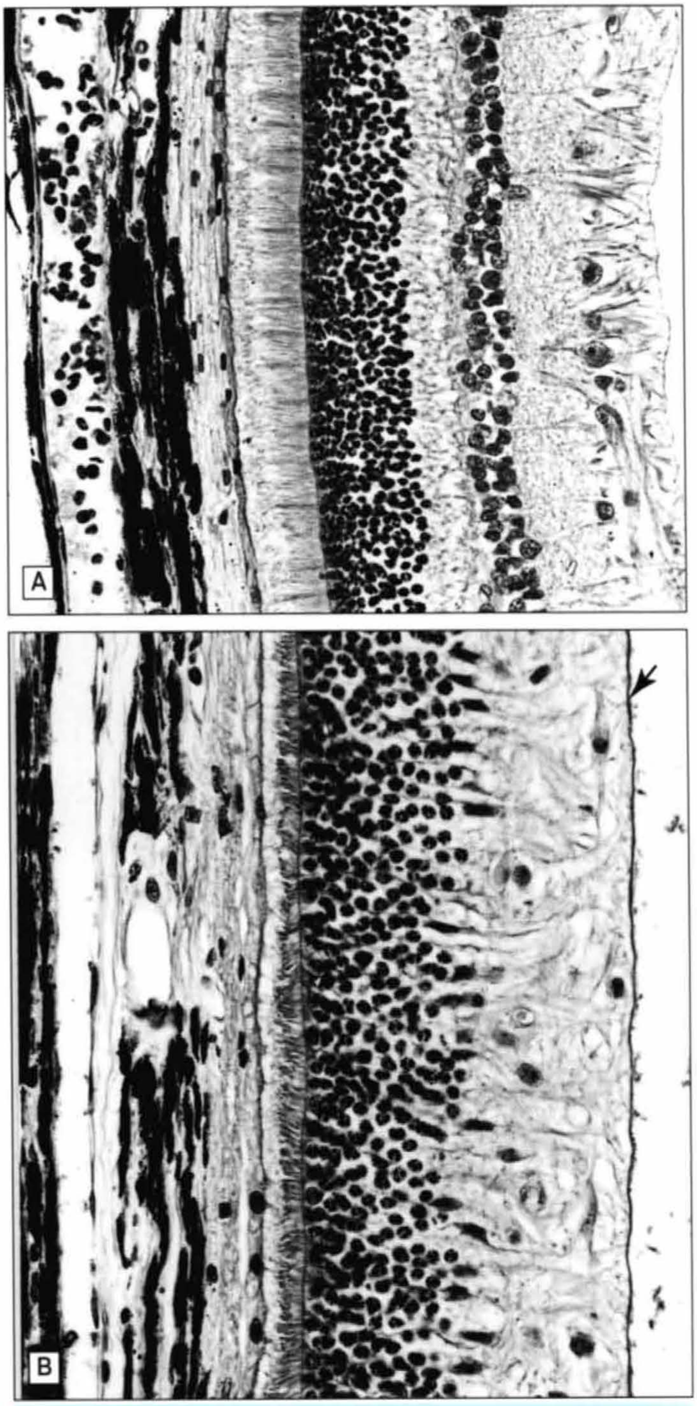

Figure 4.60 A. Normal canine retina overlying tapetum lucidum. **B. Early glaucomatous retinopathy** in a dog. Ganglion cells are absent. Remnant of inner nuclear layer remains. Inner limiting membrane is abnormally prominent (arrow) over atrophic nerve fiber layer.

Lesions resulting from glaucoma

Lesions that develop as a result of glaucoma vary with the duration and severity of the glaucoma and the distensibility of the globe, and affect virtually all parts of the globe. *Enlargement of the globe* (**buphthalmos** or **megaloglobus**) occurs most readily in young animals or in those species with thin scleras such as cats and laboratory animals. In the cornea, increased aqueous pressure injures the corneal endothelium, resulting in *diffuse edema and eventual fibrosis and vascularization.* If buphthalmos occurs, corneal stretching results in rents in Descemet's membrane, visible clinically as **corneal striae** (Fig. 4.59). These are relatively most frequent in horses and least prevalent in cats with glaucoma. Failure of lids to cover the enlarged globe permits *corneal desiccation and eventual ulceration* with all its sequels. If the ocular enlargement has developed only slowly, the cornea may have time to undergo adaptive keratinization and even cutaneous metaplasia. *Cataract is usual*, presumably the result of stagnation of aqueous humor and subsequent lens malnutrition. Iris and ciliary body undergo bland atrophy, most obvious as thinning and flattening of ciliary processes. Collapse of the ciliary cleft and trabecular meshwork itself is frequent and makes evaluation of these structures for possible goniodysgenesis very difficult. *Migration of corneal endothelium across the face of the pectinate ligament and on to the surface of the iris is commonly seen,* but we do not know whether it is part of the pathogenesis of glaucoma, or just a result of that glaucoma.

The retinal lesions are characteristic. Atrophy begins in nerve fiber and ganglion cell layers, making glaucoma the only naturally occurring cause of inner retinal atrophy other than the rare instances of traumatic or neoplastic disruption of optic nerve (Fig. 4.60A, B). *Loss of nerve fibers unmasks the normally inconspicuous Muller fibers*, a lesion that may be more easily seen and more confidently interpreted than the loss of the nerve fibers or ganglion cells themselves (Fig. 4.61). This is

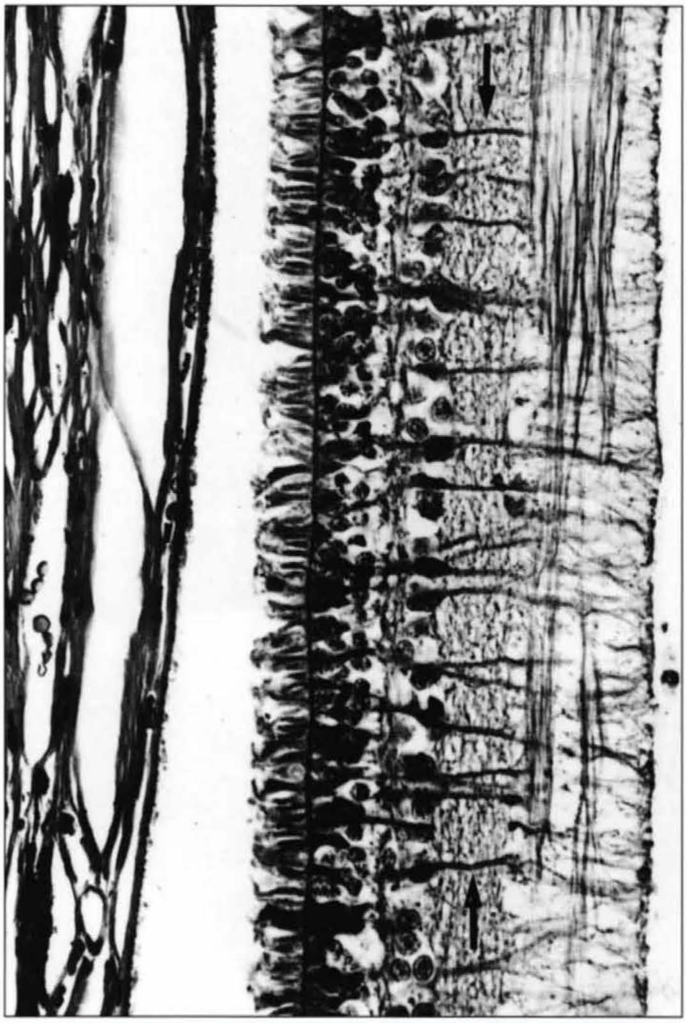

Figure 4.61 Glaucomatous retinal atrophy. Ganglion cells are absent, inner nuclear layer is sparse, and Muller fibers (arrows) unduly obvious due to loss of nerve fiber layer.

particularly true in cats, in which the ganglion cells persist with considerable tenacity under circumstances that would, in dogs, have progressed to a very obvious atrophy. With increasing duration or severity, the inner nuclear layer and its axons and dendrites also atrophy, resulting in thinning of the inner nuclear layer and the blending of this layer with the outer nuclear layer as the plexiform layers (the axons and dendrites of the nuclear layer cells) rarify.

In dogs with high-pressure glaucoma, there is sometimes *full-thickness retinal atrophy* that includes even damage to the RPE. Although the cause is unknown, it may be that the very high pressure causes collapse of choriocapillaris, resulting in ischemic damage to those tissues supplied by this delicate but essential capillary layer. This appears to be a uniquely canine susceptibility, in that the glaucomatous retina of other species rarely if ever shows full-thickness atrophy.

In all species, the dorsal half of the retina is less severely affected than ventral retina. The basis for this sparing remains speculative, but it may be related to the anatomy of the lamina cribrosa and the ease with which increased intraocular pressure compresses axons as they exit through that scleral sieve.

The pathogenesis of the selective ganglion cell loss in glaucoma remains controversial, and there is probably more than one mechanism. The loss may be the result of in situ apoptosis triggered by exposure to elevated retinal and vitreal levels of excitatory amino acids (especially glutamate), a response to pressure-associated ischemic injury, or a result of loss of axoplasmic flow secondary to pressure-induced injury to the optic nerve as it traverses the lamina cribrosa. It is clear that the ganglion cell injury is not directly correlated with the magnitude of the increase in intraocular pressure.

Excavation ("cupping") of the optic disk *is a pathognomonic lesion when present*, but its absence does not rule out the diagnosis. It occurs by at least three mechanisms, any (or all) of which may explain the cupping in an individual eye. Particularly in animals with a thin sclera and lamina cribrosa, the elevation of pressure may cause rapid posterior bowing of the lamina, resulting in visible cupping without apparent nerve atrophy. This is frequently seen in cats and rabbits, but not in ungulates with their thick, rigid lamina. In all species, cupping also occurs by axonal loss from the optic nerve. The pathogenesis for that axonal degeneration is either direct compression of axons or ischemic injury. It has been suggested that the posterior bowing of the lamina cribrosa contributes to the axonal injury by mechanical pinching of axons or blood vessels as they pass through the distorted lamina (Fig. 4.62A, B). This cupping is distinguished from coloboma by the absence of dysplastic neurectoderm lining the defect and by the presence of inner retinal atrophy.

RETINA

When involution of the primary optic vesicle brings into apposition the anterior and posterior poles, the anterior (innermost) neurectodermal layer undergoes mitotic replication and subsequent specialization to form the *nine layers of the neurosensory retina.* The outermost neurectoderm remains as a relatively unspecialized simple cuboidal layer, the *retinal pigment epithelium.* Although it is traditionally considered the tenth retinal layer, its structure, function, and reaction to injury are unlike those of neurosensory retina and it is best discussed separately. *In this discussion, retina refers only to the neurosensory retina.*

In the fixed, bisected globe, the retina is seen as a thin, opaque membrane lining the posterior half of the globe between vitreous and choroid. It joins the darkly pigmented pars plana of the ciliary body at an abrupt transitional point called the *ora ciliaris retinae.* In all but the best-preserved specimens, the retina is separated artifactually from the retinal pigment epithelium and adjacent choroid, remaining adherent only at the ora ciliaris and at the optic disk.

Histologically, the neurosensory retina begins abruptly at the ora ciliaris as a multilayered continuation of the inner layer of the ciliary epithelium. In dogs and sometimes in horses, the layers here are poorly defined and photoreceptors sparse. The peripheral retina is only about half the thickness (100 μm) and has half the photoreceptor density (250 000/mm^2) of the central retina, with fewer nuclear and plexiform elements and a thin innermost nerve fiber layer.

The retina consists of three structural components: neurons, glia, and vasculature. The neurons are the functional elements and transmit the photoactivated electrical impulse from photoreceptor process to occipital cortex. *The photoreceptor is the raison d'etre of the entire globe.* It is a sensory, apical cytoplasmic process of the neurons forming the outer nuclear layer. These processes, called **rods or cones** based upon their shape and ultrastructural composition, extend from the outer nuclear layer toward the choroid. They are enveloped by a glycosaminoglycan interphotoreceptor matrix, and interdigitate with apical processes of the retinal pigment epithelium, but no actual adhesions exist between the two layers. Within the outer segment of the photoreceptors are stacks of collapsed, disk-like spheres that contain the photoactive chemicals. The disks within rod outer segments are constantly produced basally and shed apically at the rate of 80–100 disks per day, with an outer segment turnover time of 6 days in dogs. Effete disk debris is engulfed and degraded by the retinal pigment epithelium. Such turnover has not been demonstrated in the outer segment of cones which have stacks of lamellae formed by infoldings of the plasma membrane. In addition, cones appear to be of many different types within a single retina. It is probably the ratio of different cones sensitive to different wavelengths of light that permits the visual cortex to discriminate color. *In general, fish,* *amphibia, reptiles, and birds have excellent color discrimination. Ungulates can distinguish yellows, blues, and, variably, green and red. Carnivores have very limited color perception, as far as can be determined.*

Other retinal layers are best described in terms of function. The photoelectric stimulus originating in the photoreceptor outer segment is transmitted through the outer nuclear layer and along the axons of the photoreceptor nuclei to the bipolar and horizontal neurons of the *inner nuclear layer*. The accumulation of outer nuclear layer axons and inner nuclear layer dendrites forms the *outer synaptic or plexiform layer*. The inner nuclear layer contains the nuclei of the bipolar, horizontal, amacrine, and glial (Muller) cells. The bipolar cells receive impulses from the photoreceptors and relay them to ganglion cells. The bipolar cells also stimulate the horizontal cells, which transmit the impulse horizontally to excite adjacent bipolar cells. Amacrine cells counterbalance the bipolar cells in that their stimulation releases an inhibitor of ganglion cell excitation. The glial cells are primarily structural support cells, whose processes traverse the retina to form the retinal scaffold and their anterior and posterior terminations fuse to form the inner and outer limiting membranes. The axons of the bipolar and amacrine cells, dendrites of ganglion and horizontal cells, and glial processes form the thick *inner synaptic or plexiform layer*. The *ganglion cell layer* is the thinnest and innermost of the neuronal layers. Large, granular neurons form a single and often sparse layer, supplemented by a few astrocytes, which become bilayered in the area centralis to accommodate the marked increase in photoreceptor density. *The density of ganglion cells predicts, in a general way, visual acuity.* They are most closely packed in animals requiring fine visual discrimination (most birds, predatory fish, many reptiles). In contrast, they are sparse in ungulates who do not feed by sight but who flee at anything that moves. Their axons form the *nerve fiber layer* that gradually increases in thickness towards the optic disk. In most animals, the fibers are not myelinated until they reach the optic disk. The nerve fiber layer is separated from the vitreous by an *internal limiting membrane* formed by the terminations of the Muller fibers and a true basal lamina.

The organization of the **retinal vasculature** is an important variable in ophthalmoscopic examination, both because vascular abnormalities are frequent signposts of disease and because normal species variation can erroneously be diagnosed as disease. Carnivores, ruminants, and swine have large venules and smaller arterioles radiating from the optic disk to the peripheral retina. The horse has about 60 thin, short vessels extending from the disk for about 5 mm into surrounding retina. In dogs and cats, the major vessels lie within the deep half of the nerve fiber layer and the ganglion cell layer. In ruminants and pigs, the vessels are very superficial and bulge into the vitreous, covered only by a thin layer of nerve fibers and basal lamina. The retinal vessels form an end-artery circulation that supplies the inner layers of the retina. The photoreceptors and outer nuclear layers are avascular and receive nutrients primarily by diffusion from choroid. Such dependence cannot be absolute (except in horses) because degeneration of these outer layers is surprisingly slow (weeks to months) following retinal separation. In contrast, occlusion of a retinal vessel results in focal infarction of the inner retina within less than 1 hour.

The blood vessels also participate in the *blood–eye barrier* similar to that already described for the uvea. The tight endothelial junctions and junctions between adjacent retinal pigment epithelial cells conspire to create a retina that is immunologically isolated from nonocular tissues in a manner similar to that described for the uvea. Like the uvea, such a barrier is likely not absolute and the various retinal antigens are likely to be neither totally sequestered nor absolutely unique to the retina. Saline extracts of retina yield the retinal S antigen, and the interphotoreceptor retinoid-binding protein is another antigen that may be important in the initiation or perpetuation of degenerative (see Retinal degeneration) or inflammatory retinopathies.

The **retinal pigment epithelium** extends from the ora ciliaris to the optic disk as the posterior continuation of the outer layer of ciliary epithelium. It forms a simple cuboidal epithelial layer that is separated from the choroid by a complex basal lamina, *Bruch's membrane*. The apical border interdigitates with the photoreceptors, with an average of about 30 photoreceptors contacting a single pigment epithelial cell, but forms no junctional complexes. The inclusion of the adjective "pigmented" is something of a misnomer in domestic species except the pig, inasmuch as the epithelium overlying the tapetum contains no cytoplasmic pigment granules. This seemingly insignificant layer plays a major role in embryologic induction of the eye as previously described, and also plays a crucial role in the nurturing of the photoreceptors throughout life. The pigment epithelium engulfs and degrades obsolete rod and cone outer segments, absorbs light to protect photoreceptors, synthesizes and degrades part of the glycosaminoglycan matrix enveloping photoreceptor outer segments, and participates in the vitamin A–rhodopsin cycle. Which of these functions are most essential for photoreceptor health is still unclear.

The **ocular fundus** *is a clinical term describing those ophthalmoscopically visible portions of the posterior globe excluding vitreous.* The fundus is commonly divided into dorsal tapetal and ventral nontapetal fundus, with the optic disk usually at the junction of the two. The retina, although almost transparent, does absorb some incident and reflected light to dull somewhat the fundus reflection ophthalmoscopically. Areas of retinal atrophy absorb less light and are seen as areas of increased tapetal reflectivity. Pre- or subretinal exudates, conversely, increase light absorption and are seen as focal fundic opacities. Developmental or acquired absence of tapetum allows black choroidal pigment to be seen. More severe choroidal lesions may be seen as red choroidal vasculature or even pink sclera obscured by variable amounts of residual pigment. Particularly in dogs, cats, and horses, selective breeding has made hypoplastic variations in amount and pigmentation of choroid and tapetum normal for particular breed or color varieties.

The **general pathology of retina** is often said to resemble that of brain. While this is undoubtedly true inasmuch as retina is merely an extension of the brain, the prevalence of such lesions as malacia, nonsuppurative perivascular cuffing, and proliferative microgliosis within the retina is very low compared to the brain. While no actual data are published, *most animals with encephalitis do not, in fact, have concurrent retinitis. Retinal inflammation is most often the result of spread from choroid or across the vitreous from anterior uvea.* Degenerations are much more common than inflammations and are not usually accompanied by inflammatory reaction. The mature mammalian retina has no capacity for regeneration of entire neural cells, although photoreceptor outer segments and glia may be replaced if destroyed in the course of degenerative or inflammatory disease. Even the fetal retina has poor regenerative capacity as evidenced by the prevalence of retinal dysplasia following prenatal or neonatal retinal injury. Retinal repair is by proliferation of inner layer astrocytes that eventually form a dense glial scar. Occasionally the astrocytes proliferate along the vitreal face of the retina, forming a preretinal fibroglial membrane. Similar subretinal membranes are seen with chronic detachments and originate from retinal pigment epithelium or Muller cells. The retinal pigment epithelium retains mitotic ability. When injured, these cells respond with hypertrophy, hyperplasia, and fibrous metaplasia. The presence of pigment in the neuroretina is frequent in instances of retinal atrophy, most probably derived from migration of retinal pigment epithelial cells into the adjacent retina.

Autolytic changes are visible within retina within 30 minutes of death, and within a few hours are of sufficient magnitude to interfere with the diagnosis of retinal degenerations. The earliest histologic change is pyknosis of a few nuclei in outer and inner nuclear layers, and loss of uniform density of the photoreceptor layer. Progressive dissolution of the photoreceptor outer segments results in retinal separation. Nuclear layer pyknosis and ganglion cell chromatolysis are widespread within 4–6 hours. *By 12 hours, retinal separation is complete and the extensively folded retina, with autolytic photoreceptors, may mimic genuine retinal separation.* The extensive pyknosis within both nuclear layers distinguishes the two, being absent in antemortem separation (see below for other criteria). By 18 hours after death, the retina is represented by a barely separable bilayer of pyknotic nuclei suspended in a pale, eosinophilic foamy matrix representing fragmented nerve fiber and plexiform layers.

Overview of retinal histopathology

The large amount of information about the causation and clinical features of the various retinal diseases is intimidating and serves to obscure the *fundamental simplicity of retinal histopathology*. The vast majority of retinal lesions fall into three categories: *inflammatory disease* as part of endophthalmitis, *photoreceptor degeneration* from inherited metabolic disease, detachment, or toxicity, and *inner retinal atrophy* (particularly ganglion cells) as a result of glaucoma. The angst over retinal histopathology can be further reduced by recognizing that many diseases of different pathogenesis share the same histologic appearance. For example, there are dozens of inherited photoreceptor diseases of dogs, yet they all look histologically identical. Most are even ultrastructurally identical. Furthermore, photoreceptor degeneration resulting from inherited retinopathy looks histologically identical to atrophy resulting from excessive exposure to light, from chemical toxicity, and even from retinal separation.

Retinal separation

The retina is firmly attached in the globe only at the ora ciliaris and at the optic disk. *When the retina separates, it does so by cleaving photoreceptors from their interdigitations with the retinal pigment epithelium.* Separation may occur as the result of accumulation of inflammatory exudates, transudates, tumor cells, or helminths between pigment

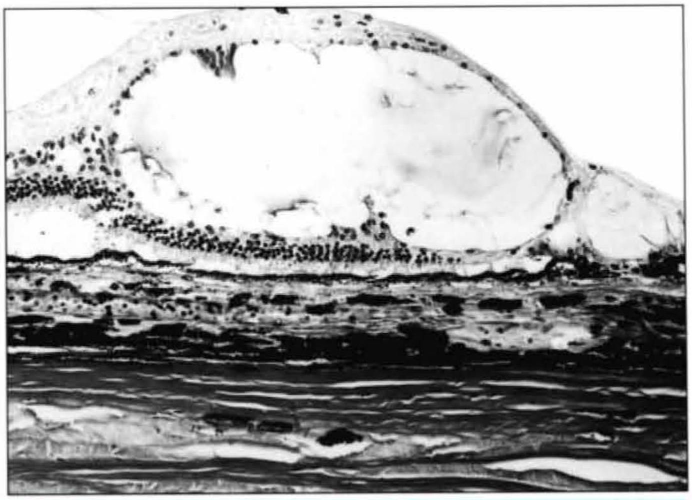

Figure 4.63 Peripheral microcystoid retinal degeneration in a dog. Such change is very common and of no apparent functional significance.

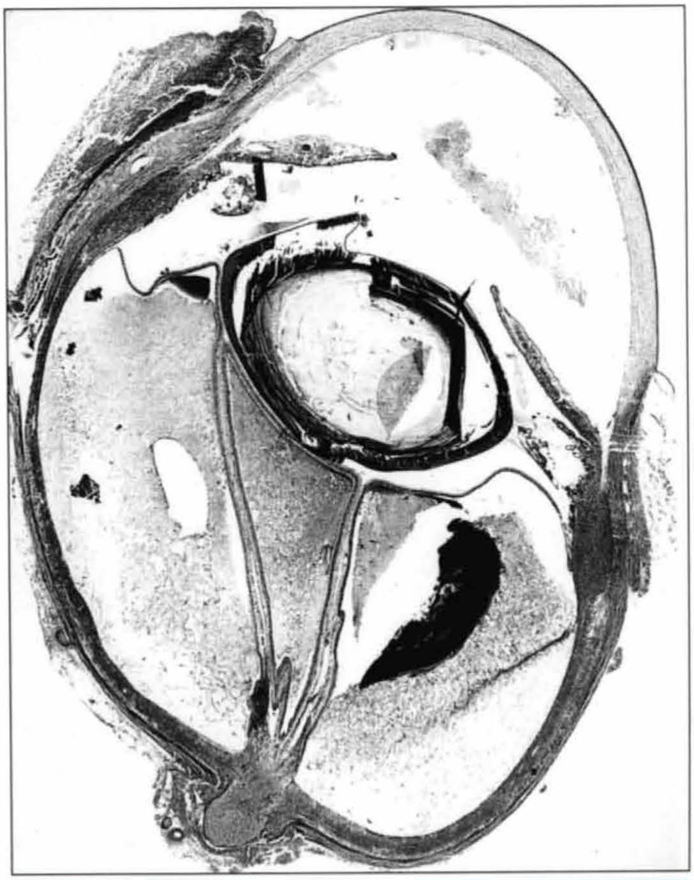

Figure 4.64 Complete retinal exudative separation in a dog with metastatic choroidal melanoma.

epithelium and photoreceptors, by contraction of a cyclitic membrane, or by the subretinal leakage of liquefied vitreous through retinal tears. Such tears may result from orbital trauma or from progression of peripheral cystic retinal degeneration. The latter is relatively common in man but not in domestic animals despite the frequent occurrence of microcystoid retinal degeneration in the peripheral retina of dogs (Fig. 4.63) and, less often, of horses.

The diagnosis of retinal separation in fixed specimens is complicated by the ease with which retinal separation can be induced by delayed fixation or improper handling of globes. *The credibility of the diagnosis is greatly enhanced by the presence of subretinal exudates or cyclitic membranes* (Fig. 4.64), *but in their absence the diagnosis rests upon the observation of photoreceptor outer segment degeneration, hypertrophy and hyperplasia of pigmented epithelium, and the development of marked edema in inner nuclear, ganglion cell and inner plexiform layers* (Fig. 4.65A, B). *Hypertrophy of the retinal pigment epithelium* is the most rapid change, occurring within a few hours of separation. The edematous changes are visible with the light microscope as early as 3 days following experimentally induced separation in owl monkeys. Coalescence of the edema creates a virtual cleavage of inner from outer retina, called **retinoschisis**. The cleavage is spanned by the radial Muller fibers, which seem the only anchor holding retina together. *Photoreceptor degeneration* is slower to appear under the light microscope, with loss of outer segments (probably the most subtle change that can be unequivocally diagnosed with routine light microscopy) visible by about 14 days after experimental saline-induced "exudative" retinal detachment. It is probably much faster than that when the exudate is full of noxious by-products of cell necrosis and inflammation, but no precise figure is available. Inner segments and the cell bodies of the outer nuclear layer are almost unaffected and may remain so for months, suggesting that their maintenance is not so intimately linked to the pigment epithelium as is the case with the outer segments. This temporal hierarchy of change permits reasonably accurate aging of retinal separations, sometimes a necessary or at least interesting assessment in eyes enucleated after numerous clinical examinations or manipulation. The outer retinal lesions are apparently not ischemic inasmuch as there is very little necrosis and no similarity to the lesion induced by retinal artery occlusion. Perhaps the outer layers can survive by diffusion of oxygen and nutrients from the subretinal fluid or from vascularized inner layers, and indeed the speed of photoreceptor atrophy varies with the height of the separation. An exception is seen in horses, inasmuch as the horse retina depends almost entirely on choroidal diffusion for oxygenation. Separation in this species results in rapid, full-thickness retinal infarction. A very

frequent lesion in horses is focal, linear, or multifocal chorioretinal glial scarring with pigment migration and fibrous metaplasia of pigment epithelium, a lesion that is probably a healed infarct following traumatic separation or thromboembolic disease.

Retinal degeneration

Retinal degeneration, more commonly called **retinal atrophy**, *may result from senile change, nutritional deficiency, metabolic disorder, or injury caused by infectious, chemical, or physical agents.* With the exception of the previously described glaucomatous retinal atrophy, virtually all are initially degenerations of photoreceptor outer segments or of retinal pigment epithelium, and many retinal atrophies of different pathogenesis have similar histologic appearance. The similarities become even stronger as the lesions progress to the severity usually encountered in enucleated eyes from clinically affected animals. Nonetheless, it is useful to review the subject and to discuss the differences between some of the best-studied examples of naturally occurring retinal atrophies. Most frequent are the inherited retinopathies of dogs grouped under the name, *progressive retinal atrophy*. Less common are retinal degenerations caused by deficiencies of taurine, vitamin E or vitamin A, by excessive visible light, or by several toxic or metabolic diseases.

Inherited retinal atrophies in dogs

Progressive retinal atrophy describes, admittedly with some inaccuracies, *a large group of bilateral retinal diseases in dogs*. They share the clinical features of being bilateral, progressing to blindness and being unassociated with inflammatory or other ocular disease. More than 100 breeds have been identified as affected, although there is little published information as to the prevalence within various breeds. Almost all of the ones thus far studied are inherited as an *autosomal recessive trait*. Some are juvenile-onset degenerations that result from a congenital biochemical defect and are thus properly termed *photoreceptor dysplasias*. Photoreceptors never reach proper ultrastructural or physiologic maturity, and affected dogs may be blind by a year or two of age. Irish Setters, Collies, Norwegian Elkhounds, and Miniature Schnauzers are the best-studied breeds that are affected, each with slightly different clinical expression and biochemical abnormality. Some initially affect only rods, but most affect both rods and cones. Alaskan Malamute dogs have what seems to be a purely cone dysplasia, leaving dogs visually impaired in daylight but with good night (i.e., rod-dependent) vision.

A quite separate group of diseases are currently considered to be *true degenerations* in that photoreceptor development seems normal. It may be, however, that even these inherited atrophies will be shown to have a developmental biochemical defect. *The trend to date has been to reclassify more and more degenerations as biochemical dysplasias*, a consequence of the use of more sensitive investigative techniques.

All of these different diseases may have significant differences in pathogenesis, but by the time the eyes are removed from impaired or totally blind dogs, the histologic and ultrastructural lesions are similar. *At this stage, the old name of progressive retinal atrophy continues to be used as a catchall.* The light microscopic lesion is degeneration of photoreceptors beginning dorsolateral to the optic disk. Over months or years, the photoreceptor loss extends and there is secondary atrophy of nuclear and plexiform layers of retina (Fig. 4.66). Eventually, in dogs permitted to live long enough, the retina remains as a poorly cellular glial scar. Despite the many similarities in clinical and histologic features, the importance of these retinopathies in the study of retinal disease in general warrants some more detailed explanation of the best-described variants.

Retinal atrophy in Irish Setters is described as *rod–cone dysplasia type 1* (rcd1), inherited as a simple autosomal recessive trait. Dogs homozygous for the defect have arrested differentiation of the rod external segments. Cones are less affected. The defect is detected ultrastructurally as early as 16 days after birth, at which time the

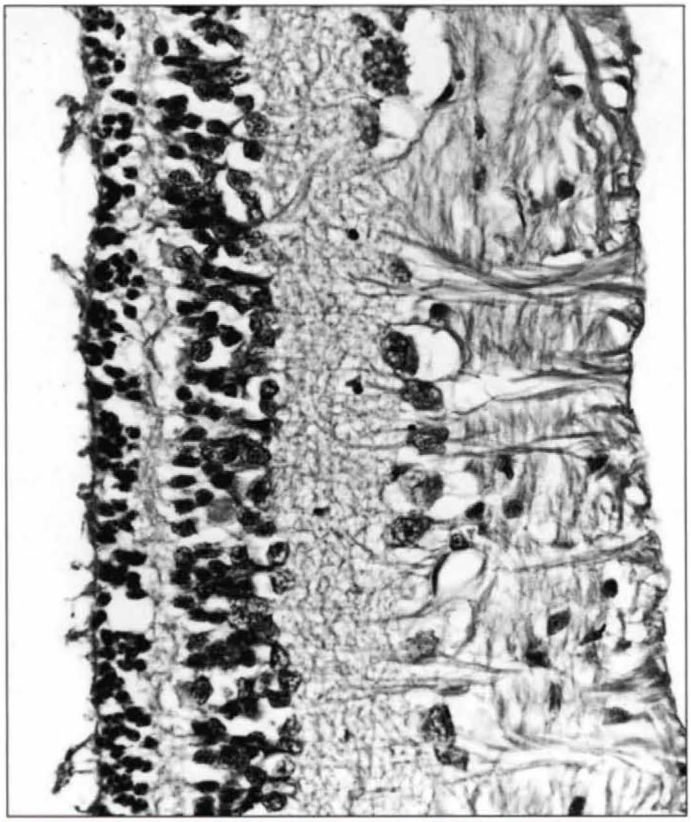

Figure 4.66 Progressive retinal atrophy in an English Cocker Spaniel. Diffuse atrophy of photoreceptors and outer nuclear layer.

outer rod segments should be developing adjacent to the pigment epithelium. Arrested development is followed by degeneration of inner rod segments, so that there is *diffuse loss of all rod photoreceptors by 12 weeks of age.* This is followed by loss of cones and of outer nuclear layer. The central retina is affected earlier and more severely than is peripheral retina. By the time the dog is about 1 year of age, there is diffuse atrophy of the outer nuclear layer, and the inner nuclear layer is in direct contact with the pigment epithelium. The inner retinal layers are unaffected. Dogs show visual deficits in dim light as early as 6 weeks of age and are usually blind by 1 year. *The biochemical defect is a marked deficiency of the phosphodiesterase responsible for the continuous hydrolysis of cyclic guanine monophosphate within outer segments.* While the function of the enzyme in this site is not fully understood, the resultant excess of cGMP is toxic to photoreceptors in vitro, and is known to cause arrested development or degeneration of rod outer segments in vivo. In the Irish Setter, the substrate levels are about ten times higher in affected than in control dogs, and the elevation precedes morphologic change in the photoreceptors. There are other biochemical retinal abnormalities (in rhodopsin and in membrane lipids), but it is not known whether they are primary abnormalities or merely effects of the cGMP phosphodiesterase deficiency. *The basic defect in rcd1 in Irish Setters is a nonsense mutation in the cGMP phosphodiesterase beta-subunit gene (PDE6B).* Also in the Irish Setter breed, there is a late-onset, progressive retinal atrophy that is likely hereditary, and that is distinct from rcd1.

Rough Collies have a *virtually identical photoreceptor dysplasia*, also inherited as an autosomal recessive trait. The progression of the lesion is slightly slower than in Irish Setters, but the biochemical defects are virtually identical. It appears that the defect results from a mutation of different genes than are involved with the Irish Setter dysplasia. In neither instance is it clear how photoreceptor death leads to death of all the outer nuclear layer neurons.

Retinal atrophy in Norwegian Elkhounds *is a historical disease, now eliminated*, that resembled the Collie and Irish Setter diseases in most clinical respects, but the biochemical defect was never identified. It was apparently not related to elevated cGMP. Onset of visual deficits in dim light was early; progression to blindness was only slightly less rapid than that in Setters. Ultrastructurally and biochemically, however, the two diseases were distinct. In Elkhounds, the primary lesion was restricted to rods. The rods were not arrested in their development but developed imperfectly. Light microscopic lesions appeared at about 6 months of age and progressed to complete photoreceptor loss by 1–2 years.

A *second type of rod–cone dysplasia* exists in this breed, with rapid progression to blindness by 12–18 months of age. Photoreceptor growth is erratic and apparently uncoordinated, but there is also dysplasia of rod and cone axonal synaptic junctions in the outer plexiform layer, which results in greatly reduced transmission of impulses from the photoreceptors. Ultrastructural changes are present in both the rod and cone outer segments as early as a few weeks after birth, but progression to complete retinal degeneration takes many years.

Cone degeneration (dysplasia) in Alaskan Malamute dogs *is a progressive and highly selective cone dysplasia*, inherited as a simple recessive trait. Although now rare because of elimination by selective breeding, it remains an interesting example of specific cone dysfunction. Affected dogs are noticed to have poor vision in bright light as early as 8 weeks of age. Night vision is, and remains, clinically normal, as does the ophthalmoscopic appearance of affected eyes. The ultrastructural lesion is disorganization and loss of cones, with rods normal. Adult dogs have no cone outer segments, and atrophic inner segments, but no change in rods or outer nuclear layer.

Rod–cone degeneration in Miniature Poodles *is classified as a true degeneration in that photoreceptor differentiation seems to be normal until 6–9 weeks of age.* After this time, and progressing at an unpredictable rate, there is disk disorganization and plasma membrane fragmentation in rod outer segments, visible as early as 15 weeks of age in the retina adjacent to the optic nerve. Peripheral retina is unaffected at this early stage, but by several years of age, the entire retina is affected. Cones are affected in a similar but milder fashion later in the disease course. The reason for the fragmentation is unknown, but it is known that affected dogs have abnormally slow outer segment turnover (about 40% of normal) prior to any observed structural change. Affected Poodles have evidence for a decreased rate of incorporation of docosahexanoic acid, the major long-chain structural membrane fatty acid, into rod outer segments. It may be that the decreased disk turnover permits older membranes to unduly persist and to be peroxidatively damaged in situ. The histologic lesion is identical to that of Irish Setters or Norwegian Elkhounds. Cataracts are present in many Poodles with retinal atrophy. Because of wide variation in disease progression, dogs may not be noticed to have dim-light deficiencies until middle, or even old, age.

An *almost identical disease* occurs in English and American Cocker Spaniels, Labrador Retrievers and Portuguese Waterdogs, resulting from a *mutation at the same genetic locus.* The diseases differ from breed to breed in the age of clinical onset and geographic distribution within the retina as seen ophthalmoscopically. The list of breeds reported to have some type of progressive retinal dysplasia/degeneration grows daily, and it is hard to determine how many of these represent a purely local phenomenon related to one or two specific lines of dogs, and which ones are truly global problems.

Central progressive retinal atrophy of dogs (pigmented epithelial dystrophy) denotes *a peculiar lesion in retinal pigment epithelium of dogs that apparently results from defective intracellular phagocytosis of shed photoreceptor outer segments.* Normal pigment epithelium engulfs and enzymatically degrades this material, resulting in a gradual buildup of intracellular lipopigments throughout life. In dogs with this pigment epithelial dystrophy, membrane peroxidation is excessive, and lipopigments accumulate to excess. Associated with the pigmentary accumulation, the epithelial cells hypertrophy. Photoreceptor outer segments adjacent to hypertrophic pigment epithelium degenerate. As the lesion progresses, hypertrophy and hyperplasia of epithelium give rise to dysplastic pigmented cell clumps. Within such clusters there may be an eosinophilic, hyaline, periodic acid-Schiff positive concretion resembling drusen. This material, rather frequent in ophthalmic specimens from people with a variety of degenerative retinal or choroidal diseases, is a concretion of excess basal lamina produced by the pigment epithelium. The eventual histologic lesion in affected dogs is a *monolayer of hypertrophic, lipochrome-rich pigment epithelial cells with multifocal hyperplastic clumps.* Retina has atrophy of photoreceptors and outer nuclear layer, and some irregular gliosis. Pigment-laden cells may invade the retina.

The disease is sporadic and of unpredictable clinical progression. The prevalence is, for example, much higher in Great Britain than in

North America, where it is rare. Retrieving and herding dogs are most frequently affected, with particularly high prevalence in Briards. The prevalence seems to vary dramatically from region to region, and over time. The ophthalmoscopic lesion of irregular black mottling begins near the optic disk and may progress to generalized pigment mottling interspersed with the increased reflectivity of atrophic retina. The mode of transmission is autosomal recessive in those breeds for which it is known. An interesting speculation, based upon morphologic similarities, is that the disease represents a defect in vitamin E metabolism within pigment epithelium. In Briards, the disease has been termed congenital stationary (i.e., nonprogressive) night blindness, although in many cases the disease does undergo slow clinical progression so the designation as "stationary" may not be appropriate. The *genetic defect (deletion of RPE65)* allows injurious accumulation of phospholipid esters of photoreceptor origin within the RPE, which eventually can be seen histologically as accumulation of lipid vacuoles.

Sudden acquired retinal degeneration is *an enigmatic, rapidly progressing photoreceptor degeneration that is histologically identical to the inherited progressive retinal atrophies. Blindness occurs very rapidly (over a period of a few days to a few weeks). Affected dogs are adult or even elderly, and the disease can affect any breed or crossbreed.* The fundoscopic lesion is bilaterally symmetrical and diffuse across the retina, but histologic studies of the early lesions are very few. The cause is unknown, but the presence of the retinal disease is linked to systemic signs of polyuria, polydipsia, and elevated serum cholesterol and alkaline phosphatase. Some, but not even the majority, of the affected dogs have adrenal cortical hyperfunction. How this malfunction causes the irreversible retinopathy, if indeed it does, is unknown. One small study demonstrated circulating, complement-fixing antibody to retinal S-antigen and interphotoreceptor retinoid-binding protein, raising the possibility that the disease is a cytotoxic autoimmune phenomenon.

Photoreceptor degenerations and dysplasias in cats

Photoreceptor degeneration is much less commonly observed in cats than in dogs. In the past, the great majority of cases have probably been examples of dietary taurine deficiency causing so-called *feline central retinal degeneration.* This once common disease has now become rare because of changes to virtually all commercial feline diets, but it will still occur in animals fed homemade diets and in those cats habitually eating some types of dog food. It is discussed in greater detail under nutritional retinopathies below.

Inherited retinal dysplasias and degenerations have been reported as sporadic occurrences in a variety of cat breeds, but only in the *Abyssinian breed* has the syndrome been adequately studied. In this breed there are two different diseases: *early-onset rod–cone dysplasia* and *late-onset retinal degeneration* affecting rods much sooner than cones. The early-onset dysplasia is inherited as an autosomal dominant trait. It is histologically and ultrastructurally similar to the disease in Irish Setter dogs, and a similar defect in the activity of cGMP phosphodiesterase has been reported. Affected cats are blind by a few months of age.

The late-onset retinal degeneration is inherited as an autosomal recessive, and affected cats progress slowly to blindness by 5–10 years of age. The earliest structural changes are in rod outer segments in peripheral retina, with jumbling of the rod disks and patchy blunting of the photoreceptors themselves. Only after many years is there histologically detected diffuse photoreceptor loss. A much more prevalent feline retinopathy, caused by deficiency of dietary taurine, is discussed later.

Inherited night blindness in horses

This poorly documented disease affects the *Appaloosa breed* and is probably inherited, and is seen as night blindness with daylight vision that is usually, but not always, normal. No structural lesion is seen in retinas of affected horses, and functional studies point to a defect in intraretinal synaptic transmission in outer plexiform or inner nuclear layers rather than a defect in photoreceptors.

Light-induced retinal degeneration

Light of various wavelengths has a variety of injurious effects on cornea, lens, or retina that vary with the wavelength, duration, and intensity of the light.

The effects also vary with a large but poorly understood group of animal variables that include ocular pigmentation, habitat, previous experience with photoperiod, nutrition, body temperature, age and, most obviously, species. The wavelength of light has the greatest effect; short wavelengths in the *ultraviolet and blue range* (up to about 475 nm) have the greatest energy per photon and are the most damaging. Fortunately, most of these wavelengths are absorbed by cornea and lens, so that their lethal effects on retina are seldom seen. They may cause corneal epithelial injury or cataract, although these effects are apparently rare in domestic animals (see Cataract).

In people, accidental exposure to light from arc welding, solar eclipses, or ophthalmic examination or operating equipment (including lasers) creates the potential for rapid injury from mechanical disruption or heat. While such damage is certainly possible in other animals, most naturally occurring lesions result from the additive effects of much less intense ultraviolet and short wavelength visible light because of unnatural photoperiods. Animals with poorly pigmented eyes, and those adapted for nocturnal vision, are most susceptible. Susceptibility also increases with age and with temperature.

The initial lesion is disruption of rod outer segment disks, with eventual destruction of all photoreceptors and their nuclei. Because the lesion is identical to most inherited, nutritional, and toxic retinopathies, *the diagnosis is made on the circumstantial evidence of abnormally bright light, abnormally long light photoperiod, or a rapid change in photoperiod.* Most instances occur with rodents or fish kept in continuous fluorescent light. Albino rodents or deepwater fish are, predictably, the most susceptible.

The mechanism by which visible light of moderate intensity damages the retina is still incompletely understood, and different experimental models give rise to different theories. Most studies use blue light in the 400–475 nm range, which, unlike shorter ultraviolet wavelengths, is not filtered out by the cornea or lens. The most popular theory is that of light-induced oxidation of the very abundant polyunsaturated long chain fatty acids of the rod disks, with the generation of free radicals to then cause cell membrane damage. This theory gains support from studies showing a protective effect by vitamin C or E, and enhanced injury under conditions of retinal hyperoxia.

Nutritional retinopathy

Nutritional causes of retinal degeneration include deficiencies of *vitamins C, A, or E*, and the amino acid, *taurine*. Retinal atrophy and cataracts have been seen in fish with a dietary deficiency of vitamin C. The lesions were thought to be light induced, with the fish unusually susceptible because of the deficiency in the antioxidant effects of the vitamin. The ocular lesions of vitamin E deficiency resemble those of retinal pigment epithelial dystrophy and were referred to briefly under that heading. Pups fed severely deficient diets develop night blindness within about 6 weeks, and an extinguished electroretinogram suggestive of diffuse photoreceptor damage. These last two effects are not seen in naturally occurring central retinal atrophy. Retinopathy has been described in primates and dogs fed rations deliberately and severely deficient in vitamin E. *Lipofuscin*, seen as eosinophilic cytoplasmic inclusions, accumulated to excess in the pigment epithelium, and was followed by hypertrophy of the pigment epithelium and degeneration of photoreceptor outer segments. Eventually there was full-thickness central retinal atrophy and some small foci of retinal separation. Retinal degeneration with ceroid-lipofuscin accumulation in the retinal pigment epithelium has also been noted in vitamin E-deficient horses, but did not appear to cause visual impairment.

Hypovitaminosis A

Retinopathy caused by hypovitaminosis A is seldom encountered except in growing cattle or swine kept in confinement and fed a ration deficient in the vitamin over months or years. Grains other than corn (maize) are very poor sources of vitamin A, and the level in corn falls markedly with prolonged storage. Green pasture is very rich in carotene, which is converted to vitamin A by intestinal epithelium. Hay that is excessively dry, leached by rain, cut late in the year, or stored for prolonged periods is a much less adequate source. In most pastured animals, the liver reserves are sufficient to prevent clinical signs of deficiency for at least 6 months and often up to 2 years. Young, rapidly growing animals have greater requirements and smaller stores of the vitamin and are thus more susceptible than adults.

Hypovitaminosis A affects bone remodeling and causes epithelial cell atrophy and defects in synthesis of rhodopsin. Ocular lesions can result from each of these three defects.

As previously discussed, *maternal deficiency of vitamin A causes blindness in offspring due to defective remodeling of optic nerve foraminae and subsequent ischemic or pressure atrophy of the nerve.* In piglets, there may be massive ocular dysplasia and such anomalies as cleft palate, skeletal deformities, hydrocephalus, epidermal cysts, genital hypoplasia, and anomalous hearts. *Optic nerve atrophy is preceded by optic disk swelling (papilledema)*, and followed by atrophy of nerve fiber and ganglion cell layers. This sequence of events may occur if very young animals are on deficient diets, with the optic nerve changes being caused in part by stenosis of optic foramen and in part by increased cerebrospinal fluid pressure that itself results from atrophy and metaplasia of arachnoid villi. The papilledema precedes optic nerve necrosis and is reversible. The corneal lesions of hypovitaminosis A have received scant attention and are seldom seen in natural outbreaks.

The acquired ocular effect of hypovitaminosis A involves photoreceptor outer segments. The ophthalmoscopic lesion is multifocal retinal atrophy and scarring in animals with slow or absent pupillary light reflex and apparent blindness. The histologic lesion is patchy-to-diffuse photoreceptor atrophy which first affects the rod outer segments. Night blindness is thus the initial complaint and is often the chief complaint about a deficient herd. Eventually the atrophy affects all photoreceptors and their nuclei, and may progress to full-thickness atrophy with scarring. The lesions have been produced in all domestic species on specially formulated diets, but naturally occurring retinal lesions are almost restricted to cattle with chronic deficiencies.

The pathogenesis of the photoreceptor atrophy demonstrates the structure–function interdependence of retinal cells. Vitamin A is converted to retinene and then to the glycoprotein rhodopsin. Rhodopsin is stored as a component of the lamellar disks of the outer segment. Light initiates a physicochemical change in rhodopsin, resulting in a cascade of events culminating in the hyperpolarization of the outer segment membrane. The resultant electrical impulse is transmitted to bipolar cells, ganglion cells and then to brain. *Deficiency of vitamin A necessarily results in a deficiency of rhodopsin.* The corresponding ultrastructural lesion is swelling, then fragmentation of lamellar disks that can be reversed by therapy with vitamin A, unless inner segments have also been affected. Regeneration simulates normal development and requires about 2 weeks to rebuild outer segments completely. Vitamin A is discussed further in Vol. 1, Bones and joints.

Taurine-deficiency retinopathy

Retinal degeneration caused by taurine deficiency is seen only in cats, although taurine is the predominant free amino acid in the retina of other species. Among domestic mammals, only the cat seems unable to synthesize taurine from cysteine in amounts adequate for retinal function. Taurine is considered a dietary essential for cats, and its deficiency results in *characteristic central retinal atrophy* and in *myocardial failure* (see Vol. 3, Cardiovascular system). Changes in commercial diets, and better recognition of the risk of diseases related to taurine deficiency, have almost eliminated this disease.

The ocular lesion of taurine deficiency was first detected in cats fed semi-purified diets in which casein was the only protein. After several months, such cats developed focal retinal atrophy adjacent to the optic disk, which progressed to generalized retinal atrophy. Supplementation with taurine halted but did not reverse the lesion, presumably because photoreceptor nuclei or inner segments already had been damaged. The clinical and histologic features of this newly recognized nutritional retinopathy were virtually identical to those that had already been recognized in an idiopathic, naturally occurring disease of cats called "*feline central retinal degeneration.*" It is assumed that the two diseases are actually the same, although that may not be true in every single instance. At least some of the cases of idiopathic central atrophy were associated with the feeding of dry dog food, which (for a cat) is deficient in taurine.

The clinical lesion is a *focal lesion of tapetal hyperreflectivity* that is bilateral, dorsolateral to the optic disk and is usually unassociated with visual impairment. *The histologic lesion is photoreceptor degeneration,* initially targeting cone outer segments but eventually affecting rods as well. The rods of the peripheral retina are the last to degenerate. Taurine also seems essential for membrane integrity of the tapetal reflective rodlets, so that dissolution of the membrane surrounding these crystalline intracytoplasmic inclusions is another characteristic lesion. Less clear is the association of taurine deficiency with diffuse retinal atrophy in cats (Fig. 4.67).

Familial atrophy occurs in Abyssinian and Persian cats, but most cases are of unknown cause. Continued deficiency of taurine leads to diffuse retinal atrophy and thus might be responsible.

Toxic retinopathies

Experimental toxic retinopathies have been caused by many chemicals and toxic plants, but only a few toxic plants cause important diseases of domestic animals.

Bracken fern (*Pteris aquilinum*) causes progressive retinal degeneration in sheep in several areas of Great Britain. The common name "bright blindness" refers to pupillary dilation and tapetal hyperreflectivity of the severely affected sheep. The disease has been seen only in flocks grazing hills rich in bracken fern, and has been reproduced by prolonged feeding of the fern to sheep. A similar syndrome has been noted in cattle during long-term exposure to the fern. The lesion is usually seen in middle-aged or older sheep as bilateral and initially central tapetal hyperreflectivity. Diffuse involvement follows. *The histologic lesion is nonspecific, consisting of photoreceptor outer segment degeneration progressing to depletion of all retinal layers.*

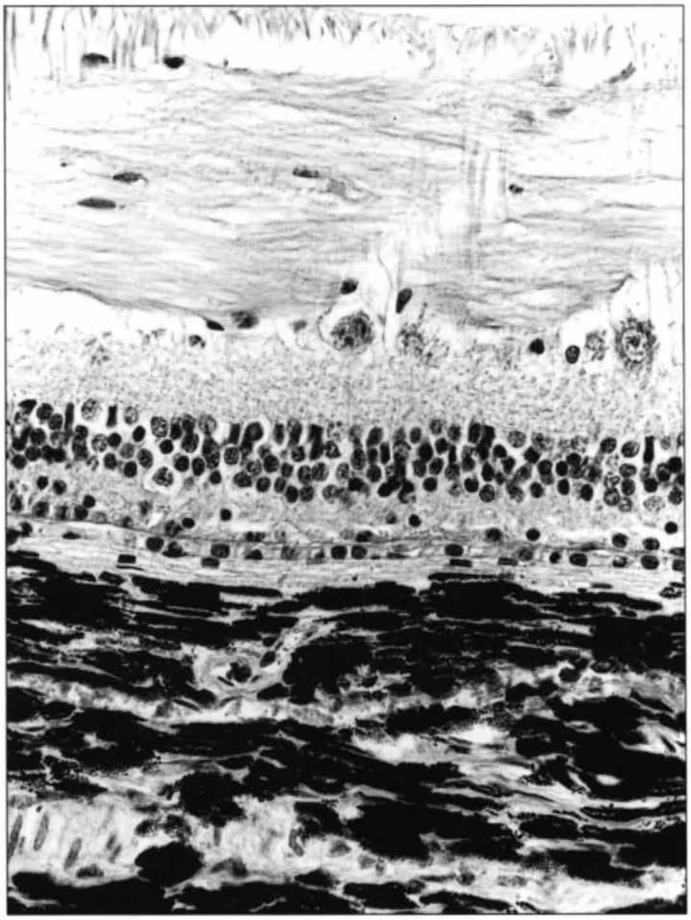

Figure 4.67 Idiopathic diffuse retinal atrophy in a cat. Note complete atrophy of photoreceptors and depletion of outer nuclear layer.

Blindness is one of the features of intoxication with **locoweed,** *Astragalus* and *Oxytropis* spp., in the USA, **darling pea** (*Swainsona* spp.), **blind grass** (*Stypandra* spp.) in Australia, and **selenium indicator plants** worldwide.

Astragalus and *Swainsona* cause a *neurovisceral lysosomal storage disease* analogous to genetically transmitted mannosidosis (see Vol. 1, Nervous system). All members of the genus *Swainsona* contain an indolizidine alkaloid, swainsonine, which is a potent inhibitor of lysosomal mannosidase. At least some *Astragalus* spp. contain a similar alkaloid. Chronic ingestion of the plant occurs in cattle, sheep, and horses forced to eat the plants on dry pastures where nothing more palatable is available. Affected animals develop behavioral abnormalities and defects of gait and vision. The histologic lesion consists of widespread cytoplasmic vacuolation in most organs due to the intralysosomal accumulation of mannose-rich oligosaccharides. Onset of clinical signs may require several months of heavy *Swainsona* ingestion, but ultrastructural vacuolation is seen within a few days. The ocular lesion is, as elsewhere in the central nervous system, vacuolation of neuronal cytoplasm and, later, axonal degeneration. The vacuolation is readily reversible upon cessation of ingestion of the plant and seems not to be the lesion responsible for clinical signs. The axonal degeneration is not reversible and is probably the more important lesion. Whether blindness is retinal or central in origin is unknown.

Poisoning with *Stypandra* spp. occurs in sheep and goats on dry pastures in southwestern Australia. The plant is among the first to reappear after autumn rains end the drought, and is eaten if nothing better is available. Acute intoxication is frequently fatal. Animals surviving the acute stage become blind and ataxic. In retina, there is diffuse photoreceptor atrophy and patchy hyperplasia of retinal pigment epithelium. Axonal degeneration is found within the optic nerve and elsewhere within the central nervous system.

The colloquial term *"blind staggers" refers to chronic intoxication of sheep and cattle with plants known to accumulate organic selenium selectively*. Affected animals wander aimlessly, become weak and ataxic and are finally paralyzed prior to death. There is some question as to whether blindness is genuine or merely the result of stupor. Ocular lesions are not described. The syndrome of blind staggers does not occur in experimental selenium toxicity, and it is possible that the syndrome is of much more complex pathogenesis than simple selenium toxicity. Plants of the genera *Astragalus* and *Oxytropis* are selenium accumulators as well as sources of swainsonine-like alkaloids.

Mycotoxicosis associated with the consumption of *Corallocytostroma* sp. fungus on Mitchell grass is reported to cause "black soil blindness" in cattle in Australia. The disease presents as rapidly progressive blindness and death. The histologic lesion is not described.

Photoreceptor degeneration has been described in cats treated with the antibiotic **enrofloxacin**. Initial reports suggested that this was an idiosyncratic reaction since the toxicity occurred after administration of the drug at recommended dosages. Subsequent analysis suggests that this is a direct toxicity that occurs when the retina is exposed to unusually high levels of this widely used antibiotic, even when administered at the daily recommended dosages (subsequently revised). Retinotoxic levels are likely to be reached when the drug is given by rapid intravenous infusion or when given to cats with impaired renal or liver function that may not properly metabolize and eliminate the drug. *Toxicity is thus most likely to be seen in old cats receiving prolonged therapy*. Similar retinal toxicity is likely to be shared by other fluoroquinolone antibiotics. Most cats had clinically obvious visual impairment within a few weeks of drug administration, and the blindness was permanent in most cases.

Miscellaneous retinopathies

Retinal lesions are found in a number of metabolic disorders and systemic states. Best known among these is diabetes mellitus, but retinal lesions are found also in any of the neuronal storage diseases, coagulation disorders, anemia, disseminated intravascular coagulation, hyperviscosity syndrome, hypertension, and following excessive exposure to oxygen or light.

Diabetes mellitus is *the major cause of blindness in people in North America. The cause of the blindness is chorioretinal vascular disease with subsequent retinal degeneration*. The characteristic lesions are seen only in patients with diabetes of 10–15 years duration. Even though virtually all chronic diabetics develop some retinal lesions, fewer than 10% become blind. Blindness is strongly predictive of the development of fatal diabetic nephropathy. Lesion development is not prevented by insulin replacement. Other ocular lesions include cataract, rubeosis iridis, glycogen-induced vacuolation of iris epithelium, and massive thickening of the ciliary basal lamina. The corneal epithelium may be unduly fragile, and tear production may be reduced.

The retinal lesion in people is mostly the result of microvascular disease. Loss of retinal pericytes, development of microaneurysms, thickening of capillary basal lamina and retinal hemorrhages constitute the early, degenerative phase of the retinopathy. This is followed by a proliferative phase in which more capillary aneurysms, arteriolar–venular shunts and neovascularization occur as the presumed responses to retinal ischemia. The neovascularization is initially bland and confined to the retina, but later there is extension into preretinal vitreous with accompanying fibroplasia (retinitis proliferans). Hemorrhages and hyalinized collections of leaked plasma are common in the retina.

In nonprimates, the naturally occurring retinopathy is seen only in dogs and, even then, infrequently. This low frequency may be due to the fact that affected dogs do not live long enough for the retinal disease to develop. In dogs deliberately made diabetic and kept for up to 6 years, microvascular lesions typical of human diabetes occur. Pericyte loss is accompanied by capillary aneurysms, reactive endothelial proliferation, and perivascular plasmoid exudates or hemorrhages.

Other types of **ischemic retinal injury** are much more frequent in domestic animals than is diabetic retinopathy. *Undoubtedly the most frequent examples are associated with vascular hypertension in cats and, less frequently, in dogs*. Ischemic retinopathy as a consequence of *DIC*, of *tumor metastasis*, or of *bacteremia* is fairly common, with the prevalence varying greatly with species. *Perhaps the most common example of ischemic retinal injury is that resulting from retinal detachment*. The blood vessels of the choriocapillaris supply oxygen and other nutrients to the photoreceptors and outer nuclear layer, hence retinal detachment inevitably results in gradual outer retinal ischemic/malnutritive atrophy.

Hypertensive retinopathy *is in most cases associated with chronic renal failure*. At least 60% of dogs with chronic renal failure are hypertensive. Dogs and cats are most frequently affected. In cats, hypertensive retinopathy is also claimed to be associated with hyperthyroidism, but a study of 100 hyperthyroid cats did not provide any evidence for that anecdotal association.

The macroscopic ocular lesions include retinal or preretinal hemorrhage, retinal edema, and retinal detachment because of serous effusion from injured choroidal blood vessels. *The histologic lesions are primarily in retinal and choroidal vessels*, which have lesions varying from fibrinoid necrosis of tunica media to medial hypertrophy with adventitial fibrosis. Changes that are probably secondary to vessel damage include localized retinal necrosis, exudative retinal separation with resultant atrophy of photoreceptors and hypertrophy of retinal pigment epithelium, and intraretinal hemosiderin deposition (Fig. 4.68). Usually there is ischemic necrosis of RPE, which allows for the leakage of hypertensive edema fluid from the choroid into the subretinal space (which would normally be prevented by the tight junctions between adjacent RPE cells). Vascular lesions and associated necrosis may also occur in anterior uvea. Eyes that are eventually enucleated or obtained at necropsy may have a variety of other lesions that probably occur secondary to chronic retinal detachment and chronic intraocular hemorrhage. Most notable among these is pre-iridal fibrovascular membrane and its resultant hyphema or neovascular glaucoma.

The early lesions, likely to be seen only under experimental conditions, are the result of exaggerated autoregulatory vasoconstriction in response to systemic hypertension. Sustained vasoconstriction leads to ischemic necrosis of the deprived retina, RPE or choroid, as well as necrosis of vascular endothelium distal to the constricted precapillary sphincters. The histologic consequences are focal retinal necrosis, and leakage of

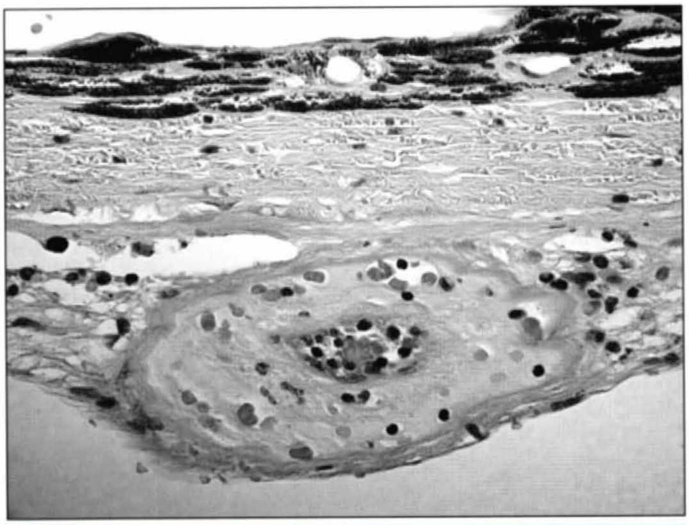

Figure 4.68 Hypertensive retinopathy.

plasma or even erythrocytes through damaged endothelium. This leakage causes intramural fibrinoid change in the vessels and edema or hemorrhage in adjacent retina.

Retinal infarction, usually seen as a combination of hemorrhage and liquefaction, occurs subsequent to retinal vessel thrombosis, occlusion by tumor emboli, or vasculitis associated with immune disease or a few infectious diseases (Fig. 4.69). The most likely to be encountered are thrombotic meningoencephalitis of cattle, and Rocky Mountain spotted fever or ehrlichiosis in dogs. In addition to the vascular lesions themselves, which may have specific characteristics associated with the individual diseases, the retinal lesions vary from focal hemorrhage to areas of hemorrhagic liquefactive necrosis or healed lesions of chorioretinal scarring.

Similar retinal scarring has been seen in horses following massive but sublethal blood loss, as in surgery or from nasal hemorrhage subsequent to severe cranial trauma. Affected eyes have multifocal retinal atrophy and hyperpigmentation. Similar lesions may also result from focal retinal separation. In horses, such separation carries a high risk of causing focal retinal infarction because they have such limited intrinsic retinal vasculature (see Fig. 4.69).

Retinal hemorrhages are seen in a variety of primary clotting disorders, in thrombocytopenia of any cause, and in degenerative or inflammatory vascular disorders. Retinal hemorrhages also recur in cats with profound anemia of any cause; the mechanism is unknown. The lesions heal with scarring if the cat survives the anemia, suggesting that the hemorrhage is only the most visible manifestation of multifocal and probably ischemic retinopathy.

Many of the **neuronal storage diseases** cause retinal lesions identical to those in the brain. The list of those with described ocular lesions probably reflects those in which the eyes have been examined rather than a true reflection of those diseases in which ocular lesions do, or do not, occur. Those interested should consult a useful, referenced table in the text by Slatter.

Senile retinopathy *is characterized by microcystoid degeneration*, which is very common in dogs from middle age onwards (see Fig. 4.63). A similar lesion is found occasionally in horses. The lesion affects peripheral retina adjacent to ora ciliaris and for a variable distance medially. There is formation of small cystic spaces within inner nuclear and plexiform layers, fusion of inner and outer nuclear layers, pigment cell accumulation and haphazard atrophy and mingling of nuclei in a manner simulating peripheral retinal dysplasia. If the cysts rupture to the vitreal face, the retina external to the cyst is seen as an atrophic hole. Such holes are foci of extreme retinal thinning, and only the external limiting membrane separates vitreous from pigment epithelium. The pigment epithelium and choroid are usually normal but they too may show atrophy and fibrosis. Intermingling of cysts and holes in peripheral retina is common. Complete breaks are uncommon and do not usually lead to retinal separation, as occurs in people.

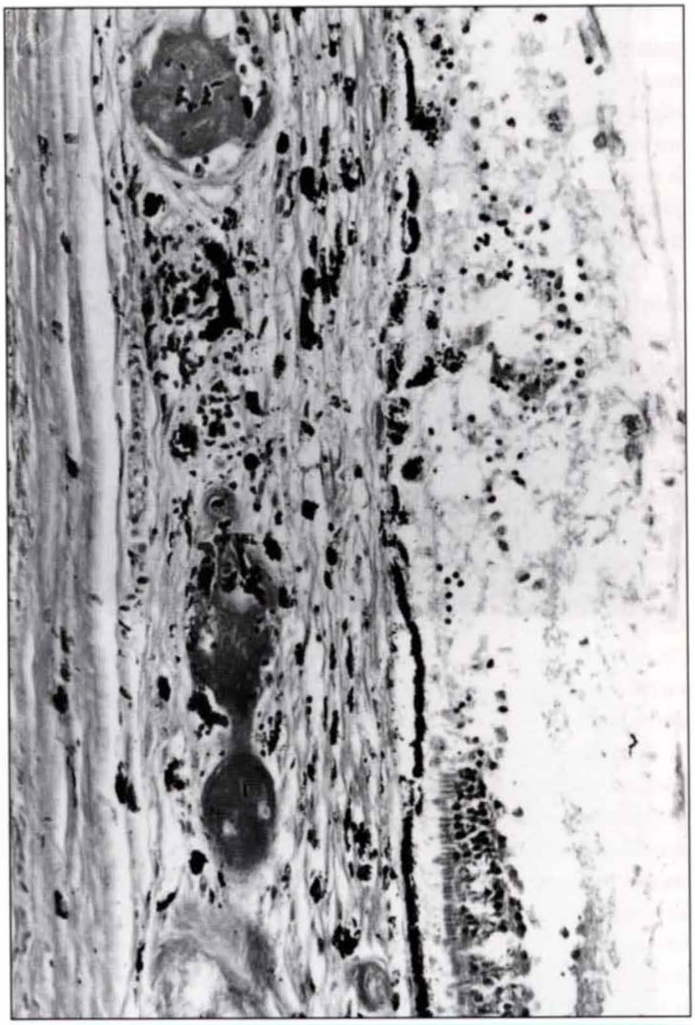

Figure 4.69 Choroidal thrombosis and vasculitis in a horse with idiopathic purpura hemorrhagica. Note **infarction** of adjacent retina.

Multifocal coalescing peripheral retinal atrophy is very frequent in very old dogs and horses, but is of no apparent visual importance.

Retinitis

Retinitis as the sole ocular lesion is rare, but may occur in animals with neurotropic virus infections, with toxoplasmosis, and with thrombotic meningoencephalitis of cattle (Fig. 4.70). In the latter disease, however, it is more usual to find the typical thrombotic, inflammatory lesions in choroid as well as retina. Their character is identical to the lesions in the brain. The multifocal chorioretinal scars expected as sequelae are seldom seen, perhaps because cattle with neurologic and ocular lesions almost inevitably die. The prevalence of the ocular lesion, useful as an aid in the clinical diagnosis, is estimated at 30–50% in animals with the septicemic form of the disease, and as high as 65% in experimentally infected calves.

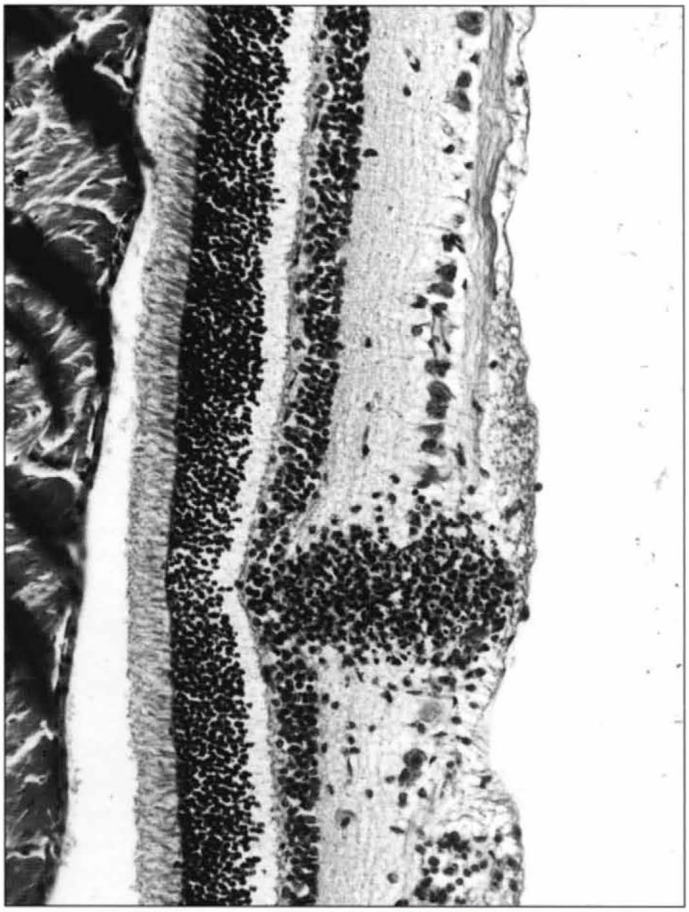

Figure 4.70 Focal destructive retinitis due to *Histophilus somni* infection in a steer.

Multifocal viral retinitis with the same histologic features as the respective brain lesions occurs in animals with classical swine fever, rabies, Teschen disease, Borna disease, pseudorabies in pigs, canine distemper, and scrapie (a prion disease). Undoubtedly the list is incomplete, and is probably limited only by the rarity with which retinas receive histologic evaluation in animals dying with systemic viral, bacterial, and protozoal diseases. *The ocular lesions associated with canine distemper will be described here in some detail as the archetypal example of viral retinopathy* (other aspects of canine distemper are discussed in Vol. 2, Respiratory system).

Retinal and optic nerve lesions occur in most dogs with naturally occurring **canine distemper.** The lesions most often are degenerative rather than inflammatory, although some of the degenerative changes may have been sites of inflammation earlier in the disease course.

Acute lymphocytic-plasmacytic chorioretinitis and optic neuritis are found in about 25% of dogs submitted for laboratory confirmation of the disease. Random perivascular cuffing, edema, focal exudative retinal separation, and hypertrophy of retinal pigment epithelium are present. Eosinophilic intranuclear inclusion bodies occur in ganglion cells or astrocytes in 30–40% of the cases, which is the only etiologically specific change in what is an otherwise nonspecific picture shared by many systemic infections.

The more prevalent lesions are multiple random foci of retinal degeneration and scarring. These usually affect the full thickness of retina, and are most likely sequelae to the previous undetected retinitis. Such foci often contain numerous melanin-laden cells, probably derived from migration of adjacent, injured retinal pigment epithelium. Occasionally only the outer nuclear layer and photoreceptors are missing, probably a sequel to focal exudative retinal detachment.

Optic nerve lesions of one type or another are present in all dogs with ocular lesions. Nonsuppurative neuritis, astrocytic scarring and demyelination similar to that in brain are the three most frequent changes. In those dogs suffering only the demyelinating disease, the ocular lesions may be inapparent, or there may be demyelination of optic nerve and ganglion cell degeneration.

Other infectious examples of retinitis in dogs include **Rocky Mountain spotted fever** (RMSF, *Rickettsia rickettsii*) and **canine ehrlichiosis** (*Ehrlichia canis*). The clinical and histologic ocular lesions are virtually identical and occur in a high percentage (80% for RMSF) of dogs with active infection. Most of the lesions result from injury to vascular endothelium parasitized by the rickettsiae; multifocal hemorrhage, edema, and vascular necrosis occur in all parts of the eye. *Multifocal retinal hemorrhage, perivascular retinal edema, and necrosis of endothelium in retinal venules and arterioles are the characteristic retinal changes.* While often listed along with other agents as a cause of anterior uveitis or endophthalmitis, most naturally occurring infections have clinical signs attributable only to the vascular injury rather than a genuine uveal inflammation. There is one report of unusually severe uveitis occurring 14–28 days after experimental infection with *Rickettsia rickettsii*, following the disappearance of all other signs of the acute systemic disease. Dogs thus affected had neutrophilic and lymphocytic destructive vasculitis, assumed to represent a type III immune reaction to parasitized endothelium.

Viscera larva migrans from *Toxocara canis* has been linked to granulomatous endophthalmitis and chorioretinitis in dogs. It is likely that many of these cases were actually caused by the raccoon roundworm *Baylisascaris procyonis* (see Parasitic endophthalmitis).

OPTIC NERVE

The optic nerve is a white fiber tract of brain formed by the outgrowth of ganglion cell axons from the eye through sieve-like perforations in posterior polar sclera, called the *lamina cribrosa*. The axons travel within a preformed neurectodermal tube formed by the primary optic stalk to reach the optic chiasm and then the lateral geniculate body. The neurectoderm lining the optic stalk induces the surrounding mesenchyme to form the three meningeal layers, similar to and continuous with those of brain itself. Later differentiation of neurectoderm produces astrocytes and oligodendroglia that, together with the ganglion cell, axons, and fibrovascular septa from pia mater, form the substance of the optic nerve. The *optic disk* is the intraocular portion of the nerve and is the only portion available to ophthalmoscopic examination. It is formed by the convergence of ganglion cell axons prior to their exit via the lamina cribrosa. The axons of the nerve fiber layer are unmyelinated, and at what point (relative to lamina cribrosa) the axons become myelinated determines the ophthalmoscopic appearance of the optic disk. Histologically, the disk is unmyelinated in most domestic species except the dog, contains abundant glia and may have a small paracentral excavation – *the physiologic cup* – from which Bergmeister's papilla originates. A few pigmented cells are commonly seen, as are small neuroblastic clusters, both probably minor anomalies of retinal differentiation but of no significance.

There is considerable variation in the normal histology of the optic nerve among animals of different species and ages. Optic disk myelination has already been mentioned. The lamina cribrosa is formed by heavy fibrous trabeculae in horses, dogs, and cattle and is therefore more obvious than in cats and laboratory animals. Fibrous septa within the nerve are prominent in cattle and horses, and their similarity to the axons in hematoxylin and eosin sections may mask a pathologic paucity of nerve fibers. The fibrous tissue reportedly increases with age.

The general pathology of optic nerve shares features of both retinal and neural disease. Because it is in direct continuity with both structures via its axons, and with brain via the perineural cerebrospinal fluid, it is common for optic nerve to be affected by diseases of either retina or brain. Thus optic neuritis is expected in at least a proportion of animals suffering with inflammation of retina or neural white matter, and optic nerve atrophy inevitably follows loss of ganglion cells. Fortuitous hematogenous localization of infectious agents or tumor cells may occur in optic nerve as anywhere else.

Papilledema *is hydropic swelling of the optic disk.* It may result from extraocular events that cause an increase in cerebrospinal fluid pressure within the optic nerve or from local vascular leakage. The former is usually associated with retrobulbar tissue masses, but is also seen with intracranial neoplasms and with hypovitaminosis A. Ocular hypotony may cause optic disk edema as a result of decreased tissue hydrostatic pressure. Serous inflammation within the nerve also results in papilledema. Papilledema is a common clinical diagnosis that rarely is available for histologic examination.

Optic neuritis *is a term sometimes used rather broadly to describe both inflammatory and degenerative diseases of the nerve.* Optic neuritis is seen clinically as swelling, hyperemia, and focal hemorrhage within the optic disk. Affected animals, usually dogs or horses, are blind when the lesion is bilateral. Although described as a clinical entity not associated with other ocular lesions, histopathologic confirmation is lacking. Optic neuritis may, of course, accompany any case of retinitis or endophthalmitis.

The pattern of inflammation within the nerve may provide clues to the pathogenesis of the neuritis. Perineuritis, or optic nerve leptomeningitis, is typical of meningeal spread of bacterial meningitis from the brain. Toxoplasmosis and cryptococcosis frequently cause multifocal and nonselective lesions within the extraocular nerve, as does canine distemper. Optic neuritis originating as endophthalmitis is usually restricted to the optic disk. Feline infectious peritonitis is frequently associated with perineuritis and optic neuritis in which the mononuclear aggregates are around blood vessels in the meninges and in the extensions of the meninges into the nerve.

Chronic optic neuritis, like its counterpart in the brain, is characterized by focal gliosis, astrocytic scarring, and secondary axonal degeneration. The loss of axons may be partially masked by the increased prominence of glia and pial septa.

Degeneration of the optic nerve *is part of optic neuritis, glaucoma, and chronic, severe retinal atrophy of any cause.* Initiation of gliosis and fibrosis may eventually make the chronic degenerative lesion indistinguishable from that of chronic inflammation. The most frequently diagnosed example is that following *trauma* to one or both nerves in dogs or cats struck by cars (Fig. 4.71). The gross lesion may be avulsion or contusion. Injury to the nerve may be instantaneous as caused by tearing or complete severance, or may result from vascular injury with slightly delayed ischemic necrosis. In severed nerves, there is disintegration of the distal axons back to the lateral geniculate body. The proximal portion of each affected axon dies back to the ganglion cell, which eventually also dies. The inner nuclear layer remains unaffected, a useful criterion to distinguish traumatic, "die back," ganglion cell atrophy from that of glaucoma.

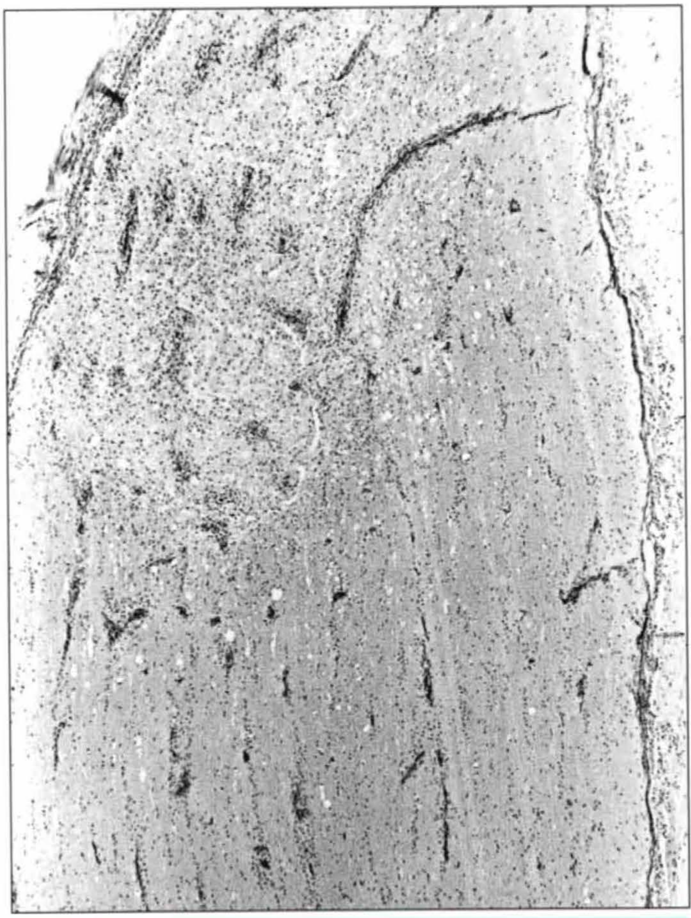

Figure 4.71 Axonal degeneration in the retrobulbar, intraorbital optic nerve in a dog, 11 days after being struck by a car.

Degeneration of optic nerve also occurs in calves *deficient in vitamin A*, and in ruminants ingesting *male fern* or *hexachlorophene*. Ingestion of male fern, *Dryopteris*, on pasture or as a taenicidal extract causes papilledema and subsequent optic nerve demyelination when ingested in large amounts. Retina may be unaffected early, but ganglion cell atrophy occurs eventually. Hexachlorophene administered to calves or sheep as an anthelmintic causes edema and then atrophy and gliosis of optic nerve.

Proliferative optic neuropathy is an unusual lesion of horses. Anecdotal descriptions are numerous, but histologic descriptions are few. The lesion is a raised, gray mass on the surface of the optic disk, unassociated with visual deficit. *The mass is composed of spherical mononuclear cells with hyperchromatic, eccentric nuclei and foamy eosinophilic cytoplasm* (Fig. 4.72). Some of these cells are also found within extraocular optic nerve. The cytoplasmic content may be stored lipid, but its origin is not known. The described lesion bears much resemblance to the proliferation of myelin-laden macrophages that occurs

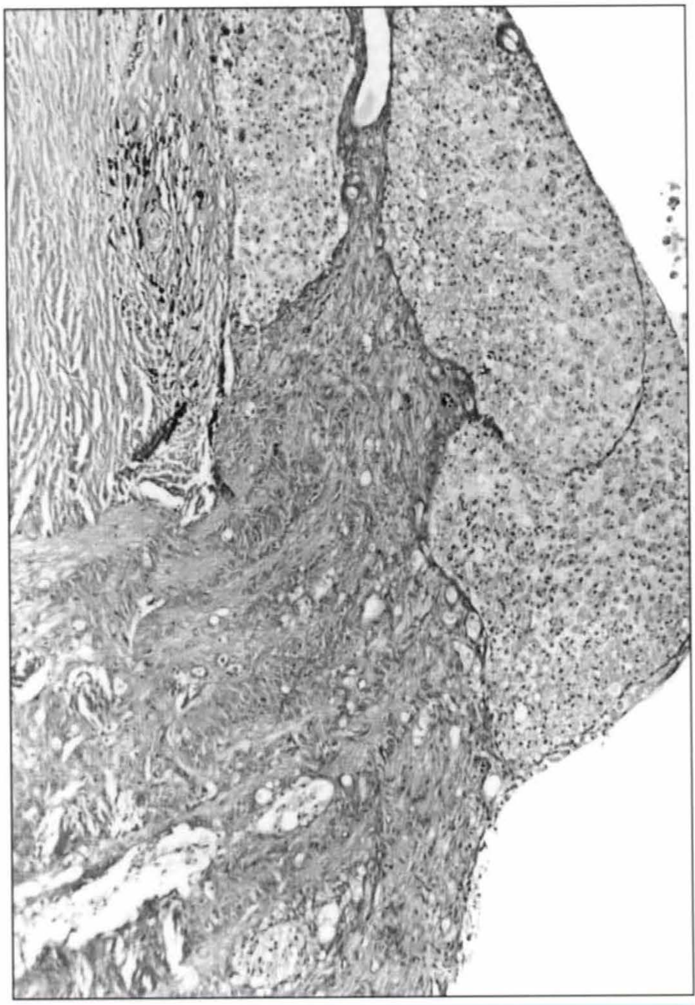

Figure 4.72 Equine proliferative optic neuropathy. The identity of the foamy cells is much debated, but they are probably reactive macrophages full of lipid.

in and on optic nerves injured by trauma or ischemia. Also, the distinction between the proliferative optic neuropathy and gliomas or granular cell tumors described in various reports is unclear.

SCLERA

The **limbus** *marks the transition from the avascular, nonpigmented and very orderly cornea to the vascularized, pigmented and interwoven fibrous tissue that identifies sclera.* The sclera forms the posterior two-thirds of the fibrous tunic of the eye, blending with choroid on its inner aspect and orbital fascia exteriorly. Its thickness increases with age and varies considerably among domestic species. In cattle and horses, it is thickest at the posterior pole (2.2 mm in cattle and 1.3 mm in horses) and thinnest at the orbital equator (1.0 mm in cattle, about 0.5 mm in horses). In dogs and cats, it is much thinner, about 0.3 mm at the posterior pole and 0.1 mm at the equator, varying somewhat with age and globe size. In carnivores, however, there is a circumferential ring of thickened (1 mm) sclera at the limbus in which is buried the venous plexus receiving aqueous drainage. The sclera is perforated by numerous vessels and nerves, the most notable of which are the optic nerve and limbic scleral venous plexus.

The optic nerve fibers exit the globe through extensive scleral fenestrations called the **lamina cribrosa**. Diseases of the sclera are few in comparison to diseases of other ocular structures. Most are inflammatory and arise by extension from within the globe or from orbital cellulitis. *The efficiency with which the sclera resists inflammatory spread is evidenced by the infrequency of panophthalmitis as opposed to endophthalmitis, and the even greater infrequency of intraocular involvement resulting from orbital inflammation.* When the sclera is involved in inflammatory disease originating within the eye, its initial involvement is seen histologically as leukocytes in perivascular adventitia that is in direct communication with the choroid. A similar phenomenon is seen in scleral extension of choroidal neoplasms, in which collars of tumor cells surround scleral vessels but show little inclination to infiltrate directly into scleral connective tissue.

Nodular granulomatous episcleritis (ocular nodular fasciitis) *is the most prevalent disease of dogs that is primarily scleral.* It occurs rarely in cats. It is the proliferative, nodular lesion of the limbus that has been variously termed nodular fasciitis, nodular scleritis or episcleritis, fibrous histiocytoma, proliferative keratoconjunctivitis, conjunctival granuloma, and Collie granuloma. The various names reflect the spectrum of clinical presentations of this lesion. The variations are treated as a single entity, nodular granulomatous episcleritis (NGE), in this discussion. My decision to do so is purely for the sake of simplicity, since there is no compelling evidence to justify splitting this histologic entity into multiple diseases simply because the lesions may occur in various locations within and below the conjunctiva, and clinical management is similar for all.

The usual macroscopic lesion is a firm, painless, moveable, nodular swelling, 0.5–1.0 cm in diameter, below the bulbar conjunctiva at, or just posterior to, the limbus. Infiltrative extension of the mass into the peripheral corneal stroma is accompanied by edema and vascularization (Fig. 4.73A). Although the temporal limbus unilaterally is the most frequent site for initial occurrence, other common locations include the third eyelid and elsewhere along the limbus. Third eyelid involvement is often bilateral, and occurs almost exclusively in rough Collies. Limbic and nictitans involvement may occur in the same dog and even in the same eye.

Ocular nodular fasciitis behaves as would a locally infiltrative neoplasm. Extension is usually into peripheral corneal stroma and posteriorly into sclera, episclera, and Tenon's capsule. The tissue of origin of this lesion is unresolved. Fibrous tissue of sclera, episclera, and Tenon's capsule have all been suggested. Lesions involving the third eyelid, or the rare case of palpebral subconjunctival origin, probably originate from the fascia native to those structures. Histologic examination distinguishes this lesion from extension of intraocular tumors or the rare scleral sarcomas. Occasionally, infiltration of therapeutically refractory fasciitis is so extensive, both into cornea and sclera, as to require enucleation.

Histologically, the lesion is a proliferative, nonencapsulated mixture of histiocytic cells, spindle cells, and mononuclear leukocytes (Fig. 4.73B). The spindle cells may be fibroblasts, histiocytes, or a mixture of both. The spindle cells are haphazardly arranged and, despite a fibrous appearance to the section, surprisingly little collagen is demonstrated by special stains, except in coarse septa that may dissect the mass into irregular lobules. Reticulin, however, is abundant. The mononuclear leukocytes are found loosely throughout the mass but are usually most numerous near the periphery. *Important histologic features are the absence of collagenolysis and the absence of discrete granulomas.* While the lesion may be quite granulomatous, the macrophages are uniformly intermingled with the other cellular elements. When present in peripheral cornea, the above cell mixture affects stroma but spares the epithelium and an adjacent zone of subepithelial stroma.

Necrotizing scleritis *is a rare lesion seen in dogs as a poorly delineated inflammatory and proliferative lesion of the anterior sclera.* The disease incites much more inflammatory reaction, as measured by clinical criteria, than does nodular fasciitis. *The lesion consists of coalescing scleral granulomas centered on remnants of denatured, refractile collagen.* Eosinophils sometimes are seen in the centers as well. The formation of true granulomas may not be prominent, but at least a few are required to distinguish this lesion from nodular granulomatous episcleritis described above. The lesion tends to slowly spread circumferentially and posteriorly to involve the entire sclera, and involvement of uvea and even retina with granulomas eventually occurs. Bilateral involvement is usual, but not necessarily at the same time. Response to anti-inflammatory therapy is poor unless that therapy is very aggressive, and so an unusually high percentage of eyes with this disease eventually become available for histologic assessment. No etiologic agent has been seen.

ORBIT

Diseases of the orbit are few and relatively uncommon in domestic animals except for those resulting from trauma and, in dogs, from neoplasia. Systemic diseases of bone, muscle, blood vessels, and nerves may incidentally

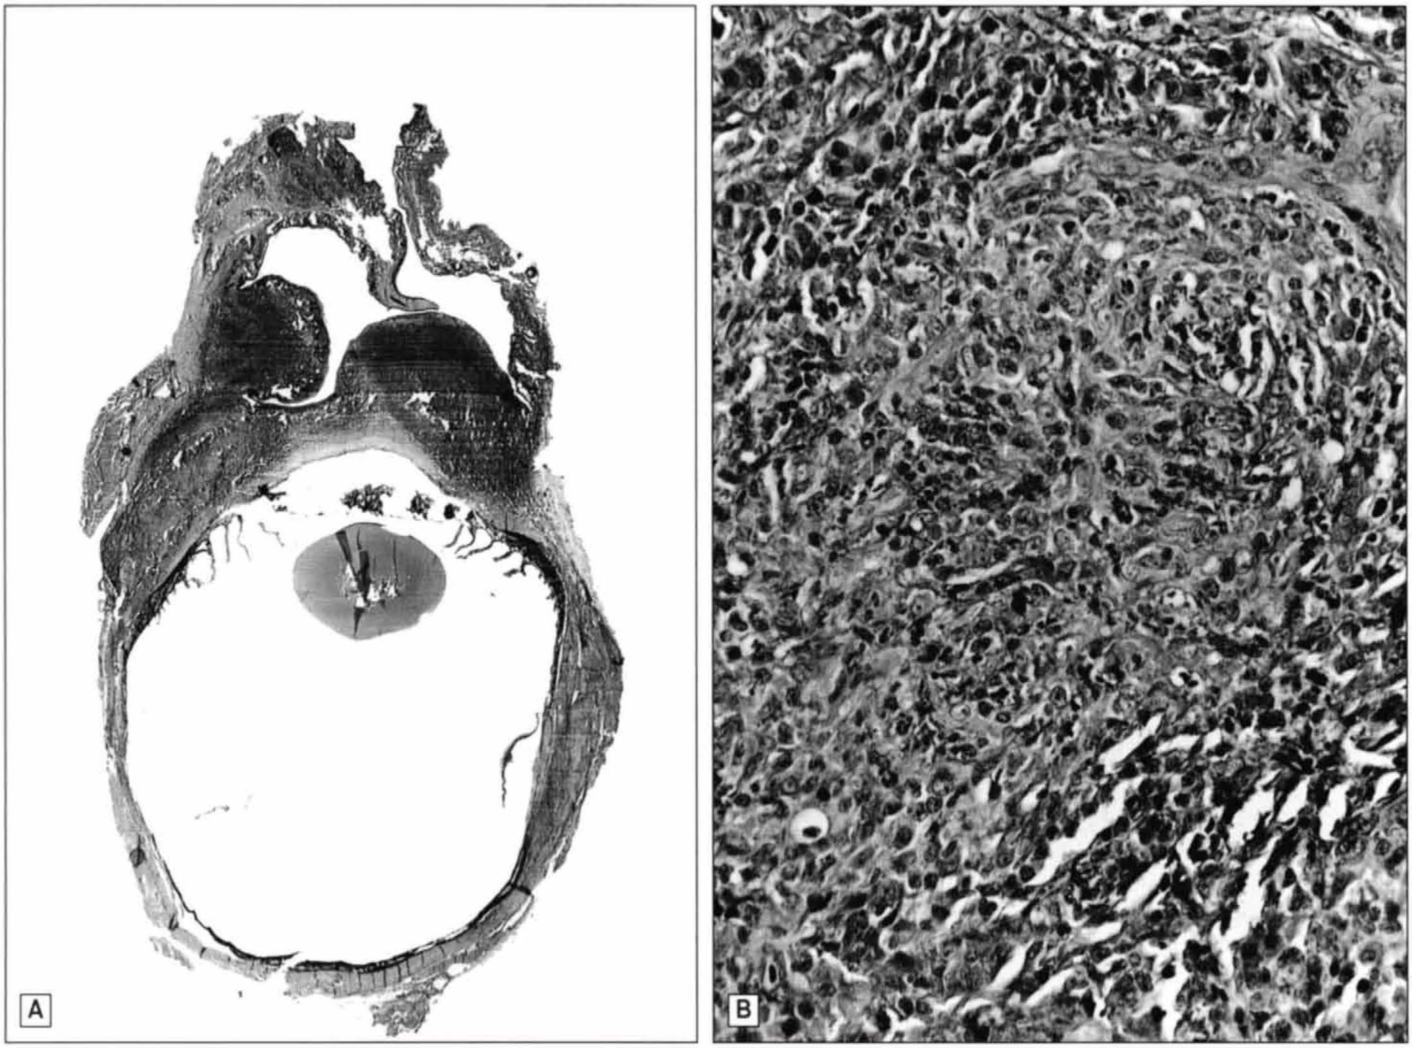

Figure 4.73 Nodular granulomatous episcleritis syndrome. A. Unusually extensive lesion, which progressed for 2 years without adequate therapy. **B.** Higher magnification, demonstrating the characteristic intermingling of lymphocytes, macrophages, and fibroblasts without actual granuloma formation.

affect orbital components. Orbital fat fluctuates with nutritional status contributing to the enophthalmos of malnourished animals. Ordinarily, however, orbital disease arises by extension of inflammatory lesions from the mouth, paranasal sinuses, or from penetrating wounds through periorbital soft tissue. Extension from intraocular inflammation is surprisingly rare, a tribute to the barrier offered by the sclera. Conversely, orbital disease rarely invades the globe. Metastatic orbital neoplasia is rare except for lymphoma of cattle and cats. Direct invasion by malignancies arising in the mouth, facial bone, nasal cavity, or sinus is more common. While theoretically the orbit may suffer from primary neoplasia of any of the bony or soft tissues within it, such occurrences are infrequent. Of these, optic nerve meningiomas, ill-defined spindle-cell sarcomas, and lacrimal gland tumors in dogs are the most common (see Ocular neoplasia).

Orbital cellulitis *is the term commonly used to describe pyogenic orbital inflammation*. The cause is usually bacterial and the pathogenesis involves extension from nearby inflammation of paranasal sinuses, molar tooth socket, or periorbital soft tissue. Only rarely does uncontrolled endophthalmitis spread through the sclera into the orbit. Bacteremic localization within the orbit, while presumably occurring as do such localizations elsewhere, is seldom detected except perhaps for *Streptococcus equi* infection in young horses.

Orbital myositis *occurs as a specific syndrome in dogs, affecting the extraocular muscles.* It affects primarily young dogs of large breeds, and is not associated with masticatory or generalized myositis. The histologic changes are identical to immune-mediated masticatory myositis, with multifocal random interstitial lymphocytic myositis, muscle fiber necrosis, and subsequent fibrosis. Antibodies against type 2M muscle fibers have been demonstrated in affected dogs.

Orbital inflammation most frequently results from *penetrating foreign bodies*, whether by direct penetration or particle migration from conjunctival sac or pharynx. Horses seem particularly prone. Aberrant localization by nematode parasites (*Dirofilaria immitis*, *Ancylostoma caninum*) or *Diptera* larvae is reported.

OCULAR NEOPLASIA

Although the eye is the site of a wide range of primary and metastatic neoplasms, only a few are of sufficient prevalence or importance to justify discussion here. This is not to say that neoplasia is unimportant, and in fact exactly the opposite is true. *At least in dogs and cats, which are the species from which we are most likely to receive histologic specimens for assessment, neoplasia is second only to glaucoma as a cause for enucleation.*

Primary ocular tumors may arise from the eyelids and adnexa, from optic nerve, or from within the globe. Those arising within the globe may originate from any of the tissues, but only those from uveal melanoblasts and iridociliary neurectoderm are anything other than rare. *Most primary intraocular tumors have negligible potential for metastasis.* Dogs and cats are most frequently affected; primary intraocular neoplasms are inexplicably rare in other domestic species.

Metastatic ocular neoplasia is reported rather infrequently but it is common when sought. Multicentric lymphoma in cats, dogs, and cattle regularly involves the eye, although in cattle the retrobulbar tissue is preferred over the eye itself. *With the exception of malignant lymphoma, carcinomas are reported more frequently than sarcomas.* This probably reflects the greater metastatic potential of carcinomas in general rather than any specific difference in ocular tropism. Uveal vessels are the usual sites of lodgement, and ocular disease may result from vessel occlusion, or from inflammation in response to tumor antigen, or to necrosis of either tumor or damaged host tissue. *Hyphema is more common in eyes with tumor-induced uveitis than with uveitis of other causes and is therefore a diagnostically useful sign.*

Eyelid and conjunctival neoplasms

Squamous cell carcinoma

Squamous cell carcinoma arises from the conjunctival epithelium of the limbus, third eyelid, or eyelid in cattle, horses, cats, and dogs, in that order of frequency. **Bovine** *ocular squamous cell carcinoma is one of the most common and most economically significant neoplasms of domestic animals.* Its relative rarity in dogs is peculiar and unexplained.

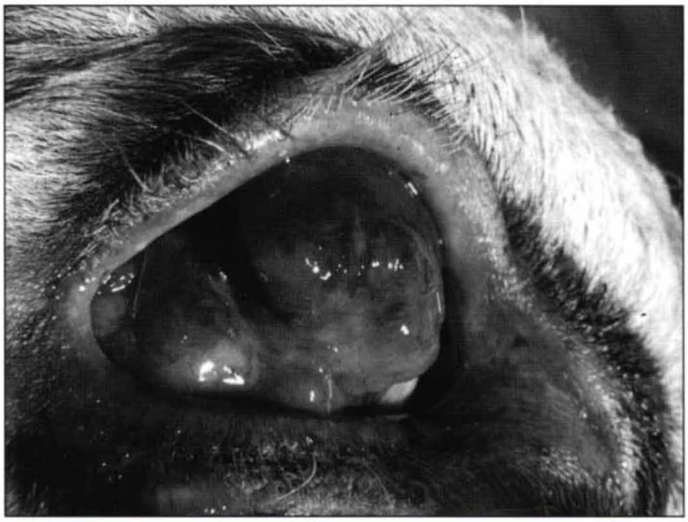

Figure 4.74 Squamous cell carcinoma in an ox.

The prevalence of the disease in all species is related to exposure to ultraviolet radiation and to lack of pigment in lids and conjunctiva. Its geographic prevalence is therefore directly correlated with altitude and inversely correlated with latitude, as well as with the prevalence of animals with poor periocular pigmentation. In cattle, in which this disease is of greatest significance, the prevalence is highest in the "white-faced" Hereford breed and in the high altitude regions of the Canadian and American West. It also occurs in other breeds of cattle, as well as Indian water buffalo, sheep, and cattalo (Fig. 4.74). Variation in prevalence in different lines of Herefords even in the same region has led to speculation that other genetic factors within the breed, other than facial pigmentation, may influence susceptibility. The question of etiology has been further widened by demonstration of papillomaviruses in some of the papillomatous precursor lesions that eventually transform into squamous cell carcinoma. Similar papillomaviruses, as well as being the causative agents of cutaneous warts, have been demonstrated in bovine alimentary papillomas in Scotland, and viral DNA persists in the squamous-cell carcinomas that arise from these papillomas in cattle grazing pastures that contain bracken fern. It remains to be determined whether or not there is any relationship between a viral component of the ocular carcinoma and the fact that in many cases the tumor regresses after immunotherapy. *At least at the moment, no viral particle or viral genome has been consistently demonstrated in ocular squamous cell carcinomas in any species.* Environmental co-carcinogens such as those in bracken fern have not yet been implicated in the induction of ocular tumors.

The tumor in all species develops through a series of premalignant stages, called epidermal plaques and papillomas, before proceeding over months or years to carcinoma in-situ and to invasive carcinoma (Fig. 4.75). Spontaneous regression of the precancerous lesions may occur with an estimated frequency of 25–50%. At least in cattle, plaques are much more common (about 6:1) than papillomas or outright carcinomas. The *epidermal plaque* is characterized by marked acanthosis, with variable presence of keratinization, dyskeratosis, and epidermal downgrowth into the subconjuctival connective tissue. Invasion through basal layer or basement membrane is not seen. *Papilloma* also involves acanthosis but, in addition, there is marked para- and hyperkeratosis with

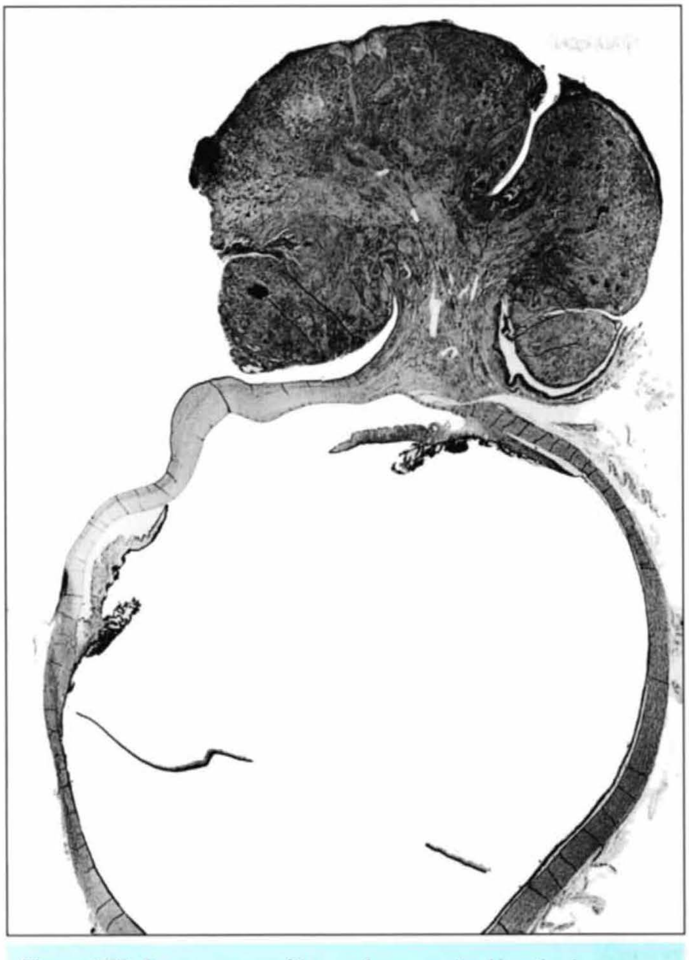

Figure 4.75 Squamous papilloma of corneoscleral junction in an ox.

papillary projections supported by a vascularized connective tissue core. Papillomas may be up to 3.0 cm in diameter, pedunculated or sessile, and are often ulcerated. *Carcinoma in situ* arises by focal or multifocal transformation of increasingly dysplastic cell nests in the deep layers of plaques or papillomas. *Fully developed carcinoma* has squamous cell invasion across the basement membrane. Tumor invasion is almost always accompanied by *intense lymphocytic-plasmacytic infiltration*, presumably the host response to tumor antigen. It is assumed that it is this response that is responsible for regression of some of the precursor lesions, although spontaneous regression of fully developed carcinoma is rare. Stimulation of immune-mediated rejection by intralesional inoculation of antigenic tumor extracts or nonspecific lymphocyte stimulants induces partial or total regression of small tumors.

Histologically, ocular squamous cell carcinoma resembles similar tumors in other sites and ranges from well-differentiated carcinomas with keratin pearl formation to anaplastic carcinomas with marked nuclear size variation and mononuclear tumor giant cells (Fig. 4.76A, B). *Metastatic or invasive potential has not been correlated with histologic criteria, but there is a correlation between site of origin and subsequent behavior.* Most surveys in cattle identify the bulbar conjunctiva of the limbus as the most frequent site of origin, estimated at about 70% of all occurrences. Some surveys consider nictitating membrane as next most frequent, with palpebral conjunctiva of the true eyelid as third. Other reports claim nictitans origin to be uncommon, and eyelid tumors to be as common as those of limbic origin. Tumors arise only very rarely from the cornea because of the limited mitotic capability of that tissue. Apparent corneal tumors are almost always extensions from tumors arising at the limbus. Tumors arising at the limbus are confronted by the dense and poorly vascularized connective tissue of sclera and peripheral cornea, which retards metastasis to extraocular sites. Invasion of corneal stroma and sclera occurs slowly, but intraocular invasion is very uncommon (Fig. 4.77). Tumors arising from the nictitans extend to the root of the membrane and then to the cartilage and bone of the orbit and internal nares. *Metastasis probably will eventually occur in all instances*, with parotid lymph node the initial site. Wide dissemination to thoracic and abdominal organs has been reported and is probably limited only by the limited longevity of the target animals.

Squamous cell carcinoma of the **equine** eye is much less thoroughly documented, but is quite common. In contrast to cattle, *the preferred site is the edge of the third eyelid, followed by limbic bulbar conjunctiva.* This targeting is, again, inversely correlated with the presence of protective melanin pigmentation, and is positively correlated with those factors causing increased exposure to ultraviolet radiation. In some reports, heavy draft horses are predisposed, but all breeds may be affected. The mean age of affected horses is about 9 years. Bilateral involvement is seen in 15–20%. The same range of precancerous lesions occurs in horses as in cattle. Prognosis is strongly influenced by therapy, but even the untreated neoplasm is slow to metastasize and even then it is usually only to local lymph nodes. Retrospective studies document 10–15% of equine ocular squamous cell carcinomas to have regional or distant spread, but the data do not consider duration of the disease prior to therapy.

In **cats,** *ocular squamous cell carcinoma most frequently affects the skin or palpebral conjunctiva of the eyelids.* White cats are particularly susceptible, and squamous cell carcinomas in these animals may occur simultaneously or sequentially on eyelids, ear pinnae, nose, and lips. The early lesion is one of sunlight-induced epithelial necrosis, and even the early neoplasm may be ulcerated and inflamed to a degree that may mask its neoplastic character and delay appropriate therapy. Growth tends to be circumferential around the lid margins, resulting in a palpebral fissure bordered by a thickened, red, and ulcerated tumor. Metastasis to local lymph nodes occurs late in the course of the disease.

In **dogs,** *squamous cell carcinoma infrequently involves the eye.* Proliferative eyelid or conjunctival growths in dogs are much more likely to be Meibomian adenomas, viral and nonviral papillomas, or nodular granulomatous episcleritis. In one study of 202 canine eyelid neoplasms, squamous cell carcinoma accounted for only 2% of lesions. Precancerous changes probably occur but, in contrast to cattle and horses, eyelid papillomas in dogs are usually benign and nonprogressive lesions.

Meibomian adenoma

Meibomian adenoma is the most common ocular neoplasm of dogs, accounting for at least 70% of eyelid tumors. It is comparable in many respects to sebaceous adenomas found elsewhere in the skin. However, these tumors originate specifically from Meibomian gland and not from other eyelid sebaceous glands, and they regularly have at least some histologic features that are infrequently seen in their cutaneous sebaceous counterparts. In the eyelid tumors, *the lobules of foamy, eosinophilic sebaceous cells are intermingled with a prominent population of basal (reserve) cells.* The basal cells often account for 50% or more of the tumor cells. In many instances, the basal cell component is so prominent as to cause diagnosis to be made of basal cell tumor with sebaceous differentiation (comparable to cutaneous sebaceous epithelioma) or even Meibomian adenocarcinoma. Many have substantial melanin within the basal cells. None metastasize, and even the so-called carcinomas show little inclination for invasive growth. Other distinctive but not invariable features are papillary hyperplasia of the overlying epithelium of the eyelid margin, a marked lymphocytic-plasmacytic infiltrate among tumor lobules and around the tumor margins, and a localized granulomatous response (chalazion) to leaking secretion (Fig. 4.78A, B).

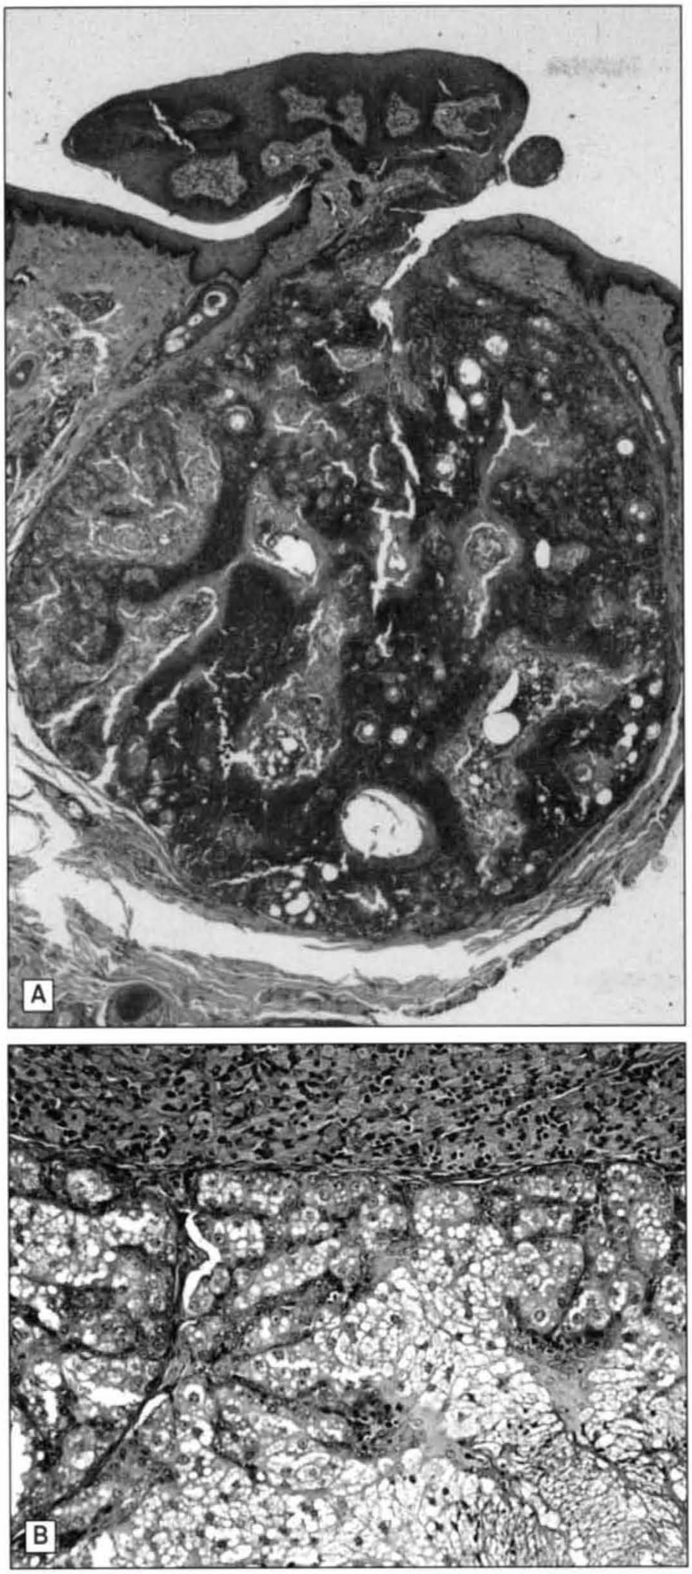

Figure 4.78 Meibomian adenoma. A. The relative proportions of germinal basal cells and mature sebaceous cells vary widely, but without any apparent prognostic significance. Papillary hyperplasia of the overlying eyelid marginal skin is frequently seen. **B.** Meibomian adenoma (below) with a surrounding zone of foamy macrophages (above) typical of chalazion.

Other adnexal and conjunctival tumors

A wide range of neoplasms has been reported to occasionally affect the conjunctiva or adnexa of domestic animals. Most examples are reported primarily in dogs, and they are listed below in order of overall prevalence in that species.

Melanocytoma *is probably the second most common tumor of the eyelid in dogs.* It will occasionally occur in cats and in gray horses. In dogs it is a typical cutaneous benign melanoma, identical to what occur so frequently anywhere else in skin. In cats, they are also similar to those tumors occurring elsewhere in skin, and more than half are both histologically and behaviorally malignant. It is important to note that the behavior of melanocytic tumors associated with the eye is greatly influenced by exact anatomic location, so these comments are applicable only to those melanomas arising in the haired skin of the eyelid.

Other melanomas arising from conjunctiva are described below in the section on Melanotic tumors of the eye. In brief, **limbal (epibulbar) melanocytoma** arises from the melanocytes that inhabit the stroma of the corneoscleral junction. It is benign. In contrast, **primary conjunctival melanoma** arises from the melanocytes of the palpebral or bulbar conjunctiva itself, and most examples are behaviorally aggressive.

Conjunctival papilloma usually arises from bulbar conjunctiva as a series of slender protruding stalks of conjunctival lamina propria covered by bland, often pigmented, stratified squamous epithelium with no cytologic atypia and no ballooning degeneration as is typical of viral papillomas.Viral papillomas associated with *Canine oral papillomavirus*, identical to those affecting the mouth, will occasionally occur in any portion of conjunctiva.

Conjunctival vascular tumors *represent a continuum from telangiectasia to hemangioma and hemangiosarcoma.* They arise with equal frequency in the temporal (lateral) bulbar conjunctiva and along the leading edge of the third eyelid, suggesting that sunlight is important in their pathogenesis.They usually arise in the very superficial subepithelial vascular plexus. *Surgical excision is invariably curative*, with virtually no metastatic risk regardless of cytologic and histologic criteria of malignancy. Some examples are associated with *marked dysplastic pseudocarcinomatous hyperplasia of the overlying conjunctival epithelium that divides the vascular tumor into lobules*, and some use the term **angiokeratoma** to describe this variant. It behaves as do the other conjunctival vascular tumors. Behaviorally malignant examples seem more prevalent in horses, where more than half of the reported cases are solid hemangiosarcomas with very aggressive local infiltration and, usually, distant metastasis. They are easily mistaken for fibrosarcomas because they have such poor channel formation and so little blood. Indeed, some of these might arise from lymphatic endothelium.There is much speculation, but no proof, that sunlight is important in their causation.

Nodular granulomatous episcleritis (also known as ocular nodular fasciitis, ocular fibrous histiocytoma) *is not a neoplasm*, but its clinical appearance is easily confused with neoplasia and samples will be submitted as probable neoplasms. It is more fully discussed under Diseases of the sclera.

Mast cell tumors, with the same histologic range as those rising elsewhere in skin, may occur in the conjunctiva of dogs. Their biological behavior has not been documented. In cats, mast cell tumors more commonly arise within the haired skin of the eyelid.

Adenocarcinoma of the gland of the third eyelid occurs as a nodular swelling in very old dogs (mean age 11.5 years). They occur, albeit very rarely, in cats. *They are locally infiltrative, recur after attempted resection, but are cured by complete removal of the third eyelid.* Only chronically neglected cases metastasize to lung after a very protracted local expansion. Histologically, these are tubular carcinomas with abundant squamous metaplasia. They should not be confused with the prominence of the gland that occurs with prolapse of the gland ("cherry eye") or with lymphocytic interstitial adenitis.

Lymphoma may have several ocular manifestations, the most frequent of which are diffuse uveal metastases as part of generalized lymphoma in dogs or cats, or as retrobulbar tumor in cattle. It may occasionally occur as a conjunctival disease as part of generalized lymphoma or as a mucocutaneous manifestation of epitheliotropic lymphoma. There are several reports of conjunctival or third eyelid lymphoma occurring in horses and in cats as an apparently isolated lesion that can be cured by local excision, suggesting that they have actually arisen in those locations.

Melanotic tumors of the eye

Our understanding of the biology of primary ocular melanomas in animals has suffered greatly from the premature assumption that they were similar to the much-studied human ocular melanomas. Perhaps because of this error, a great many enucleated globes were available for histologic evaluation, inadvertently allowing the flurry of retrospective studies that eventually established ocular melanomas in dogs and cats as distinct entities quite different in structure and behavior from the human neoplasms.

Primary melanocytic tumors of the eye or adnexa are common in dogs and cats, rare in horses, and almost nonexistent in other domestic species. Even in dogs and cats, the prevalence and behavior of the various types of ocular melanomas and melanocytomas differ markedly, so that generalizations must be studiously avoided.

In **dogs**, this list of distinct clinical/histologic entities includes benign eyelid melanocytoma, malignant conjunctival melanoma, limbal melanocytoma, anterior uveal melanocytoma, and choroidal melanocytoma. In **cats**, the list is the same but it is dominated by diffuse iris melanoma. Malignant cutaneous melanomas occasionally affect the eyelid or arise within the conjunctiva, and there are a few reports of limbal and anterior uveal melanocytomas similar to those occurring in dogs. In **horses**, one encounters cutaneous melanocytomas in the skin of the eyelids, primarily in gray horses. There are a few reports of benign anterior uveal melanocytomas, and one report of a locally invasive, histologically malignant conjunctival melanoma.

Melanocytomas and malignant melanomas arising within the haired skin of canine and feline eyelid, respectively, are identical to those arising elsewhere in the skin and they will not be further discussed here.

Melanomas arising in the conjunctiva are very infrequent compared to most other ocular melanocytic tumors. The few case reports do not allow for generalizations about behavior, but *they often are histologically and behaviorally malignant.* Their relationship to eyelid melanoma seems analogous to those of the lip, where melanomas of the haired exterior lip are benign like most skin melanomas, while those of the mucous membrane of the inside of the lip are malignant like those elsewhere in the mouth. Conjunctival melanomas may appear as well-pigmented tumors of bland, plump melanocytes with little anisokaryosis or mitotic activity, or as cytologically malignant tumors with marked anisocytosis, anisokaryosis, hyperchromasia, and even multinucleation. Primary conjunctival melanomas often are poorly melanotic. The most reliable histologic criterion in such cases is the observation of intraepithelial nests of tumor cells. Local recurrence and spread after excision is frequent, and metastasis to lung has been reported.

Limbal (epibulbar) melanocytoma *is a histologically and behaviorally benign tumor* of the melanocytes normally found in an oblique line that demarcates the junction of corneal stroma with sclera at the limbus. The tumor is composed of large plump melanocytes with a central nucleus and abundant cytoplasmic pigment. Mitotic figures are absent and nuclear variation is minimal. The tumor grows outwardly as a protruding spherical nodule, hence the alternative name of *epibulbar melanoma.* There may be nodular expansion into peripheral cornea, but virtually never into the uvea or anterior chamber. *Except for location, these tumors are identical to anterior uveal melanocytomas.* This creates a problem when one encounters the tumor that occupies both the anterior uvea and the limbus. These should be assumed to be anterior uveal melanocytomas extending outwardly, since it appears that primary limbal melanocytomas have essentially no ability to invade the globe.

Anterior uveal melanocytoma *is the most frequent intraocular tumor in dogs.* It is topographically, histologically, and behaviorally unrelated to human epithelioid ocular melanomas to which it was long compared. The typical tumor arises from melanocytes of the iris root or adjacent ciliary body, and is composed of variable proportions of lightly pigmented spindle cells and heavily pigmented plump melanocytes identical to those of limbal melanomas. The spindle cells are assumed to be the proliferative population, and the plump cells probably represent the mature, end-stage melanocytes with a storehouse of cytoplasmic pigment (Fig. 4.79A, B, C).

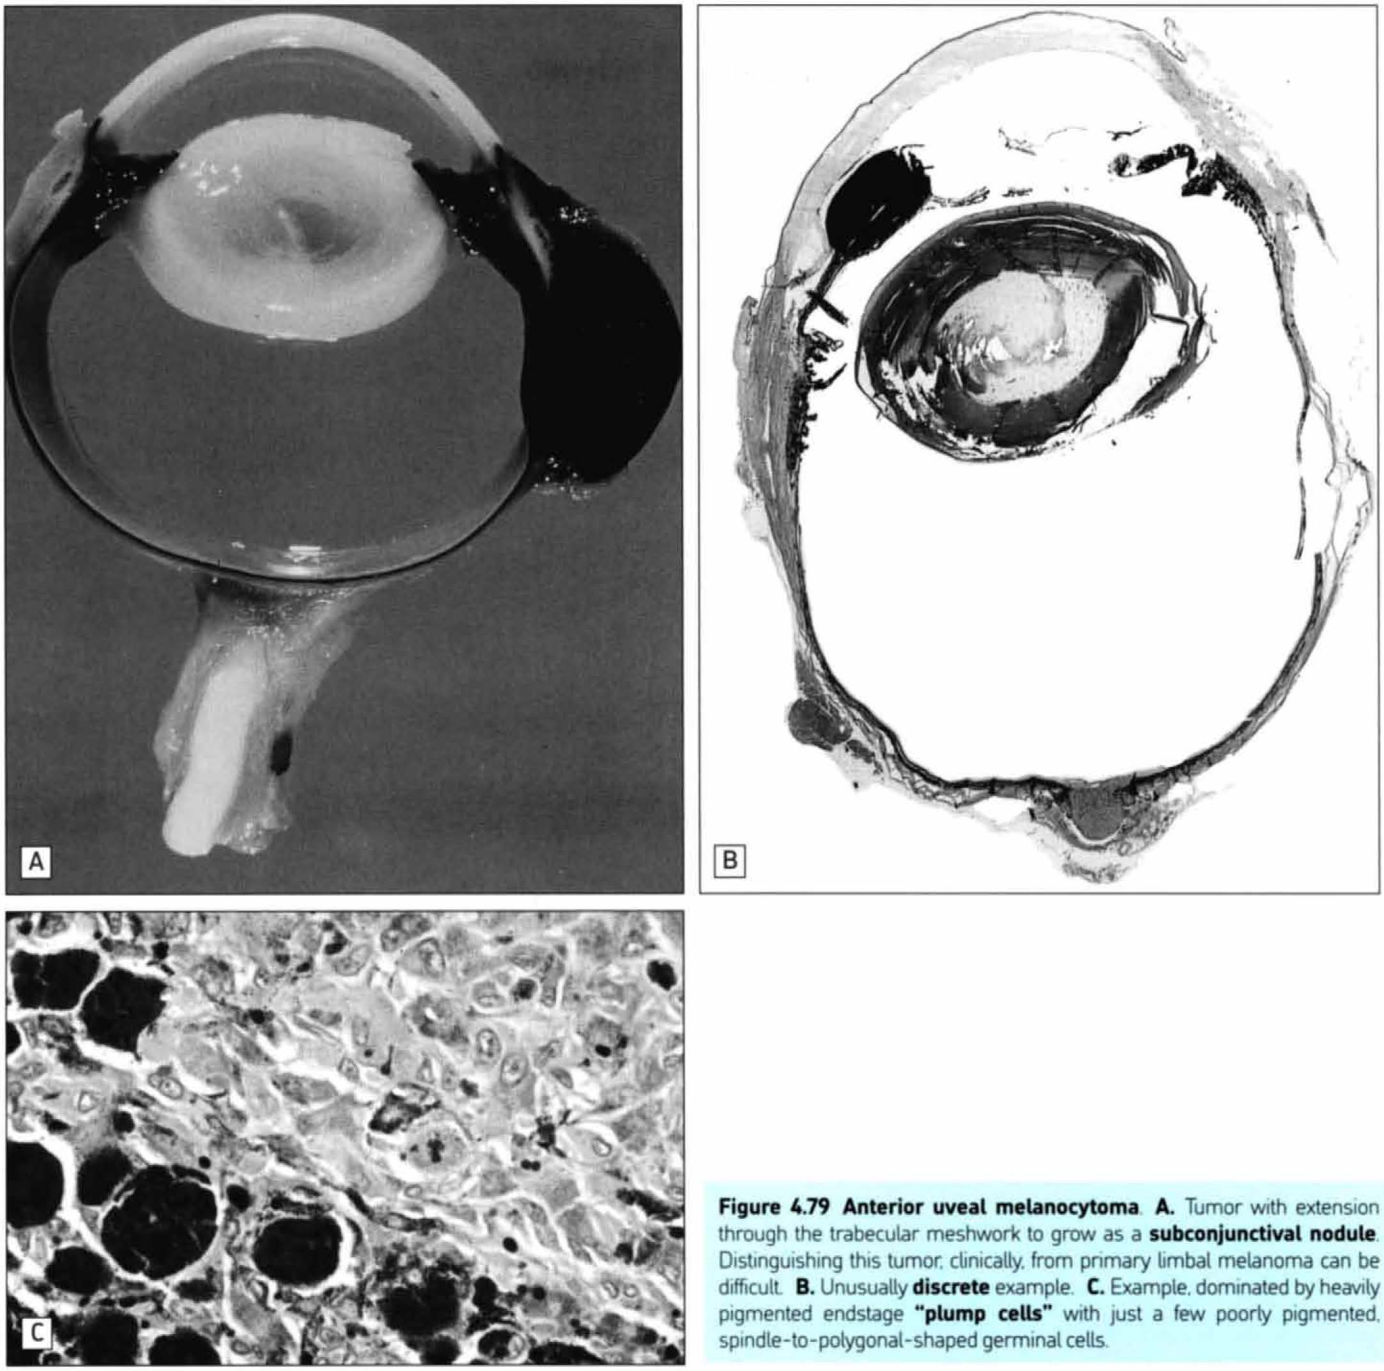

Figure 4.79 Anterior uveal melanocytoma. A. Tumor with extension through the trabecular meshwork to grow as a **subconjunctival nodule**. Distinguishing this tumor, clinically, from primary limbal melanoma can be difficult. **B.** Unusually **discrete** example. **C.** Example, dominated by heavily pigmented endstage **"plump cells"** with just a few poorly pigmented, spindle-to-polygonal-shaped germinal cells.

The diagnosis itself presents no problem, but offering an accurate prognosis is more complex. About 15% of all canine anterior uveal melanocytomas are histologically malignant, and one-third of these (or about 5% of all uveal melanocytomas) have been confirmed to be behaviorally malignant by virtue of extraocular metastases. *This small group of genuine malignancies can be predicted by mitotic index.* Histologically malignant tumors are dominated by the spindle cells rather than the plump cells, are more lightly pigmented, have much more anisokaryosis and more mitotic figures than the benign tumors. Of these, mitotic index is the most reliable predictor of behavior. Benign tumors have virtually no mitotic figures. Those confirmed as behaviorally malignant have three or more (usually many more!) mitoses in ten high-power (40×) microscopic fields; conversely, not all tumors with high mitotic index are destined for metastasis.

Even these benign melanocytomas are eventually significant to the eye, spreading transsclerally and circumferentially within the globe. *Glaucoma* from occlusion of ciliary cleft is probably the eventual fate of all eyes with this neoplasm. *Uveitis* from tumor necrosis or *hyphema* from tumor-induced uveal neovascularization are other frequent accompaniments.

Feline multifocal uveal melanocytoma *is a rare tumor of cats* that looks histologically identical to the canine uveal melanocytomas. They are sufficiently different from the much more common diffuse iris melanoma of cats to justify a separate classification. There is no published information about metastatic risk. They seem to arise as multiple foci randomly throughout the uveal tract, expanding inwardly to create multiple nodules within the ocular cavities, and sometimes outwardly as space-occupying scleral nodules.

Equine anterior uveal melancytomas occur most often in gray horses, many quite young (less than 8 years). Most involve anterior uvea and are histologically similar to the benign uveal melanocytomas of dogs. None has metastasized. Although almost all intraocular melanocytic tumors of cats are diffuse iris melanomas, one will occasionally encounter focal or **multifocal melanocytomas** similar to those of dogs. Other than having a more unpredictable site of origin within the uveal tract, they seem histologically and behaviorally identical to their more common canine counterparts.

Choroidal melanocytomas account for about 80% of all human ocular melanomas, but are rare in other species. The few cases described in dogs were discovered as incidental findings on fundoscopic examination, and grew very slowly. They seem very similar to the benign melanocytomas of limbus or anterior uvea: well pigmented, cytologically bland, and cause clinical signs only by their slow expansion to cause retinal detachment or compression of optic nerve. There is a single report of systemic metastasis from a tumor that looked histologically benign.

Clinically insignificant **iris nevi** or **freckles** occur in dogs as nonprogressive pigmented spots. Their only significance is to cause unnecessary enucleation. Histologically, the lesions are well-circumscribed clusters of bland melanocytes adjacent to the anterior border layer of the iris.

Feline diffuse iris melanomas are unique. The usual clinical presentation is of patchy iris hyperpigmentation that very slowly progresses to diffuse iris hyperpigmentation and thickening over several years. *The eventual outcome is virtually always glaucoma* (Fig. 4.80A).

It was at first considered an interesting but benign lesion. Subsequent retrospective studies have been unanimous in documenting a *moderate metastatic risk*. Because cats seem even more elusive than dogs in terms of follow-up studies, the actual number of cases with good postoperative data is small, and considerable debate persists among ophthalmologists about the real risk of metastasis by these tumors. It seems clear that the probability that a cat will die from metastatic disease is low, but the prevalence of clinically silent visceral metastasis is quite high. This contrast is probably related to the very slow growth rate of the metastatic tumor foci, which is exactly what happens within the globe itself.

Histologically, these tumors diffusely infiltrate the stroma of the iris and the ciliary cleft, and then the overlying sclera, peripheral cornea, and ciliary body. They are notoriously pleomorphic, and are apt to be misdiagnosed by those pathologists not aware of this disease as malignant lymphoma or anaplastic metastatic malignancy. Tumor cells vary from spindle-shaped cells to multinucleated epithelioid cells (Fig. 4.80B, C). Pigmentation often is light and the cytoplasm may be foamy and eosinophilic. Balloon cells with foamy cytoplasm and very distinct cell boundaries are frequent in some tumors. The accurate prediction of tumor behavior is compromised, in all published studies, by the low percentage of affected cats available for follow-up. Metastasis has been correlated with large tumor size, intrascleral spread, and mitotic index.

It remains unclear whether cats also can have focal-to-coalescing hyperpigmentation of the anterior iris stroma that is not precancerous. Some cases, as in dogs, seem nonprogressive and harmless (although follow-up information is anecdotal). Others slowly coalesce and thicken, at which time they are indistinguishable from diffuse iris melanoma. When sampled for histology, virtually all such lesions look like early melanomas, but of course, most of these apparently harmless, nonprogressive lesions do not receive histologic evaluation!

Pigmentary (melanocytic) glaucoma *is included here because it is histologically indistinguishable from a diffuse uveal melanocytoma.* The syndrome was originally described as a bilateral but asymmetrical massive pigmentation of the uveal tract of Cairn Terrier dogs that seemed to be causing glaucoma. Histologically, the anterior uvea and even the choroid are thickened by a heavy, diffuse accumulation of large plump cells histologically indistinguishable from those of ordinary canine anterior uveal melanocytoma. The syndrome has been described in a few other breeds in association with glaucoma, but the syndrome remains controversial because one can encounter equally heavy pigmentation in clinically normal globes from breeds that typically have very heavy pigmentation, such as Kerry Blue Terriers, Scottish Terriers, black Labradors, and others. *The causal relationship between the pigmentation and glaucoma therefore remains somewhat controversial.* Some would prefer to refer to the disease as "canine diffuse uveal melanosis," or even as diffuse uveal melanocytoma. Original claims that these accumulating cells are abnormal melanocytes have been challenged by recent electron microscopy indicating that the majority of the accumulating cells are melanin-laden macrophages. That is perhaps not surprising and it does not rule out the possibility that this is indeed a melanocytic proliferative disorder that, over time, has had a lot of leakage of melanin and thus a lot of macrophage recruitment.

Tumors of ocular neurectoderm

These tumors include iridociliary epithelial tumors from mature anterior uveal neurectoderm, and medulloepithelioma and retinoblastoma from embryonic neurectoderm. The prevalence of these neoplasms is second to anterior uveal melanomas and melanocytomas, although it is perhaps underestimated because the most common examples are small, slowly expansive tumors within the posterior chamber that are unlikely to cause clinical signs. They are relatively common in dogs, uncommon in cats, and virtually unknown in other species except for medulloepitheliomas in horses.

Iridociliary epithelial tumor (iridociliary adenoma, iridociliary carcinoma) is the most common of this group. Most examples are well-differentiated papillary or tubular adenomas arising from the nonpigmented inner layer of ciliary or iris epithelium (Fig. 4.81). There are certainly examples in which the histologic and cytologic character is more primitive, but metastasis is so rare (if indeed it exists at all) that there is *no justification for diagnosing any of these tumors as iridociliary carcinomas.* Most originate from the pars plicata, but occasionally the histologic evidence points to origin from posterior iris epithelium. The tumor cells usually resemble mature ciliary epithelium and usually have very little associated stroma. Nuclei are basilar, regular, and are surrounded by eosinophilic cytoplasm (Fig. 4.82A). The tumor cells are not pigmented, although melanophages are occasionally seen within tumor stroma. *They make an abundance of basal lamina* oriented, as in normal ciliary epithelium, toward the inside of the eye. Its abundance, easily seen with periodic acid-Schiff reagent, is useful in distinguishing ciliary tumors from carcinomas metastatic to the eye. Examples that have little tubular or papillary organization, or a more primitive cytologic character, may be difficult to recognize as being of iridociliary epithelial origin. They almost always retain abundant basement membrane production that can be accentuated with PAS staining. *The cells also stain for vimentin, S-100, and neuron-specific enolase, which makes them unique among tumors that otherwise look epithelial.* Such additional staining may occasionally be necessary to distinguish primitive iridociliary epithelial tumors from metastatic carcinomas.

Even small iridociliary epithelial tumors may cause hyphema or glaucoma, attributed to this tumor's strong propensity to induce pre-iridal fibrovascular membranes (Fig. 4.82B). This is, presumably, the result of absorption through the porous anterior border layer of the iris of fibrovascular growth factors produced by the tumor cells in an effort to ensure their own survival. Iridociliary tumors are more likely to induce such neovascularization than is any other ocular disease.

Medulloepitheliomas and retinoblastomas *arise from the primitive neurectoderm of the optic cup.* Retinoblastoma is the second most frequent neoplasm of children, yet a critical review of the veterinary literature reveals only a single acceptable diagnosis of this tumor. Conversely, *medulloepitheliomas* are rare in children but many examples have been observed in animals, mainly in the *horse* in which these are probably the *most common primary intraocular tumor.* The neoplasm may originate from any portion of embryonic neurectoderm and may show differentiation into any neurectodermal derivative, i.e., retina, ciliary epithelium, vitreous, or neuroglia (Fig. 4.83A, B). The typical neoplasm is a loose network of branching cords of small basophilic neuroblasts resembling those of embryonic retina. Mitotic figures are numerous. The cords have definite polarity; they rest upon a basement membrane analogous to the inner limiting membrane of retina and some have adjoining apical terminal bars analogous to outer limiting membrane. A typical feature is the clustering of neuroblasts around an empty central lumen defined by the terminal bars, creating a true rosette (Fig. 4.84). The basilar portion of the rosette or cord faces a hyaluronic acid-rich myxoid matrix analogous to the vitreous. This histologic feature may be found in only a few foci within a huge mass that is otherwise composed of poorly differentiated, neuroblast-like cells. Many tumors also contain foci of cartilage, skeletal muscle, or brain tissue and are classified as *teratoid medulloepitheliomas.* Metastases are not recorded, despite many of these being classified histologically as "malignant."

Feline post-traumatic sarcoma

This syndrome seems unique to cats. As the name implies, eyes subjected to *trauma, especially penetrating injury*, are prone to develop pleomorphic spindle-cell sarcomas that destroy the globe and have substantial risk of metastasis. The interval between injury and observed tumor varies from 5 months to 11 years. Those skeptical about claiming such neoplasia to be the result of an injury 10 years previously prefer to call these tumors "primary ocular sarcomas," although such lag times are common in experimental models of carcinogenesis. The risk for injured eyes to develop sarcoma is unknown. Almost all recorded cases have perforated lenses. Most of these tumors appear to be fibrosarcomas, but some have a mixed epithelial–mesenchymal phenotype, and elaborate basement membrane-type matrix as well as express vimentin strongly. Based on immunopositivity for collagen type IV and crystallin alpha A, at least some of these tumors are of lens epithelial origin. Of relevance to ocular surgeons is the development of sarcomas in cat eyes receiving prosthetic lens implants, presumably viewed by the eye as just another form of unwanted lenticular trauma.

The tumor itself varies from fibrosarcoma to osteosarcoma to giant cell tumor, varying even within the same eye. The tumor tends to first surround the lens, then to line the inside of the eye, and finally to extend via scleral venous plexus or optic nerve to involve the orbit (Fig. 4.85). *The inclination to "line the globe" is a repeatable feature that is useful in distinguishing primary ocular sarcoma from rare metastatic sarcomas.* Most cases are presented with advanced disease, and follow-up data to document the prevalence of metastasis are scant. Available evidence documents a metastatic risk of at least 60%, and in many cases there is remarkably rapid development of post-enucleation neurologic signs attributable to invasion of brain via the optic foramen.

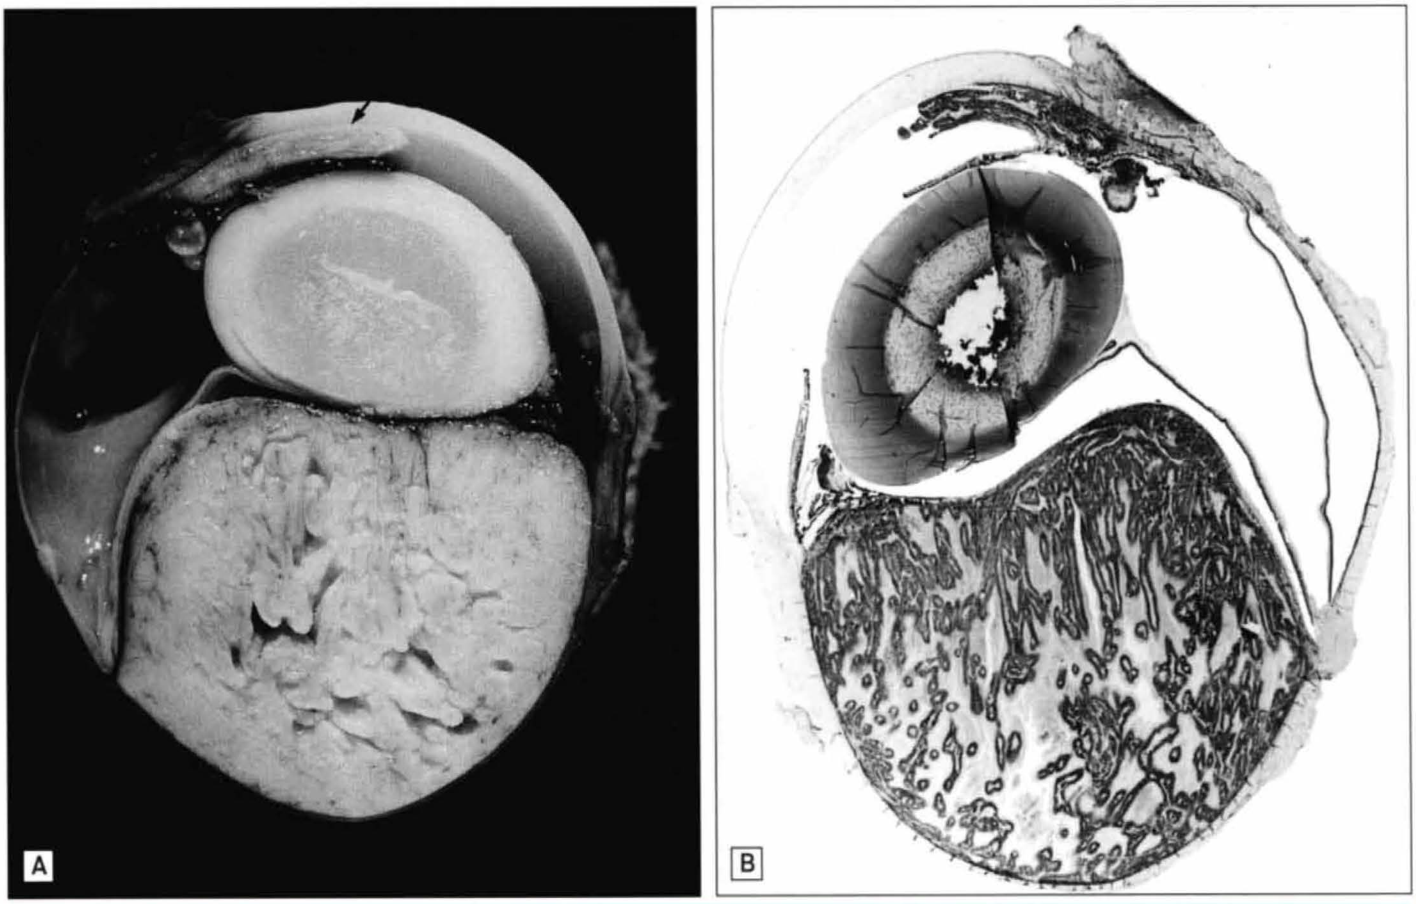

Figure 4.83 Medulloepithelioma in a dog. **A.** The main tumor lies between choroid and retinal pigment epithelium. There is also tumor in anterior chamber (arrow). **B.** Histologic section of (**A**). Note tubular latticework of the tumor.

Optic nerve tumors

While the optic nerve and adjacent retina can presumably develop all of the neoplasms of the central nervous system (excepting those from tissues such as ependyma that are not present in the eye), documented examples are few indeed. Most are reported as individual case reports prior to the era of immunohistochemical markers that would have permitted more precise classification.

Optic nerve meningioma *has a distinctive macroscopic and histologic appearance.* It has been described only in dogs, although it will probably be seen in other species as we begin to look. The tumor probably arises from meningial rests of arachnoid cells that project through the dura mater of the optic nerve into the orbital connective tissue. Tumors arising from these cells create a conical soft tissue mass that surrounds the optic nerve, but usually remains within the cone created by the extraocular muscles. Limited extension into the choroid or posterior vitreous through the optic nerve occurs only occasionally; more often, there is infiltration into the muscle and fat of the orbit. Most often, *the histologic appearance is of large stellate mesenchymal cells that can be confused with epithelial cells.* They have abundant glassy eosinophilic cytoplasm, and may or may not form the *characteristic swirling pattern* typical of central nervous system meningiomas in general (Fig. 4.86). Myxoid, chondroid, or even osseous metaplasia is quite common. Metastasis appears to be extremely infrequent.

Tumors published as **optic nerve astrocytomas** or as less specific "gliomas" were, in retrospect, *more likely to be examples of proliferative optic neuropathy* with the accumulation of reactive astrocytes and macrophages.

Primary orbital neoplasms

Tumors may be primary within the orbit, or arise by extension from adjacent structures or by hematogenous localization. They usually produce deviation or protrusion of the globe with secondary desiccation keratitis. Only those arising as primary tumors within the orbit are considered here. After saying that, *it is not always easy to decide whether the tumor is indeed primary or not,* and the decision is often made only after failure to find any credible primary tumor elsewhere. Of the primary orbital tumors reported in dogs and in horses, *sarcomas are much more prevalent than epithelial tumors.* The sarcomas are a bewildering array of locally infiltrative spindle cell tumors of unknown origin, with the abundance of diagnoses probably reflecting the diversity of pathologists' opinions rather than actual proof of histologic identity. Metastasis is rare but their infiltrative growth habit in this difficult site makes eventual elective euthanasia a frequent outcome.

Among the primary sarcomas, the only ones deserving specific consideration because of a distinctive histologic appearance are

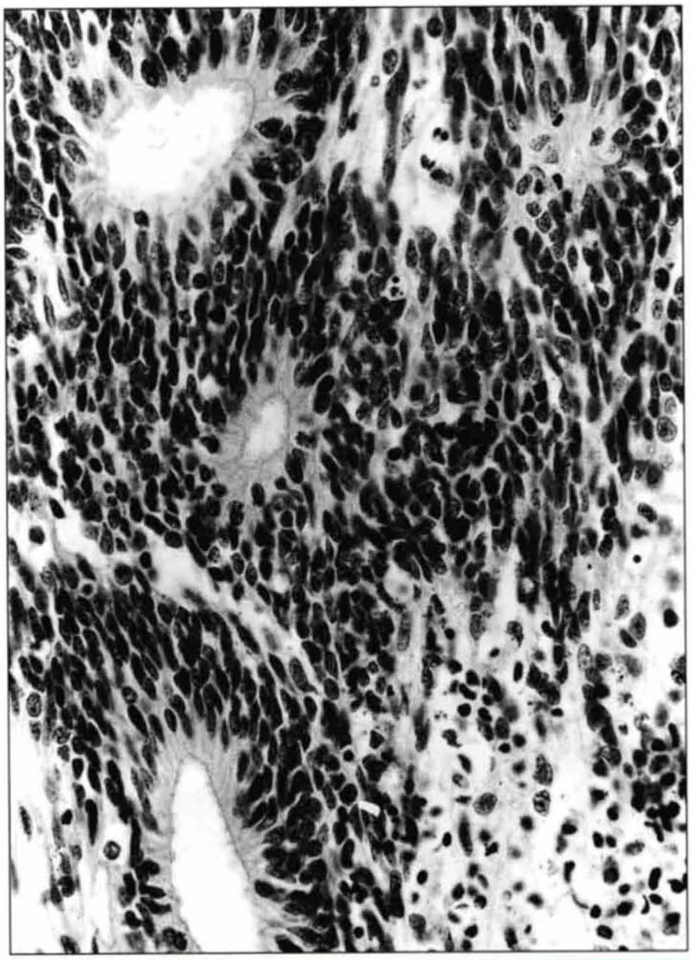

Figure 4.84 Medulloepithelioma in a dog. Note rosette with rudimentary formation of retinal outer limiting membrane and photoreceptors.

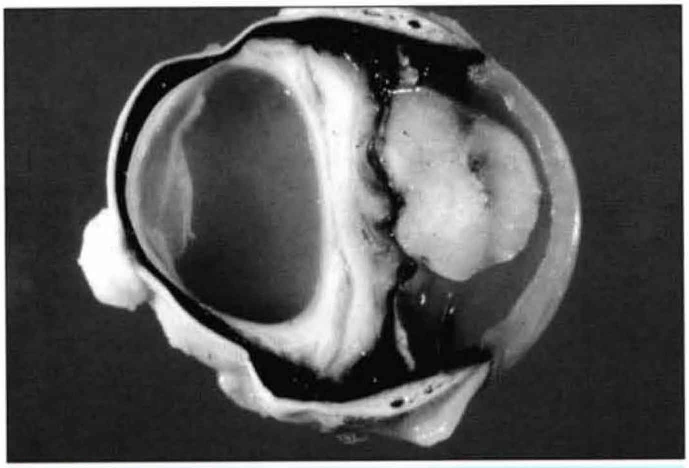

Figure 4.85 Primary feline ocular sarcoma arising from the lens and growing to "line" the posterior half of the globe.

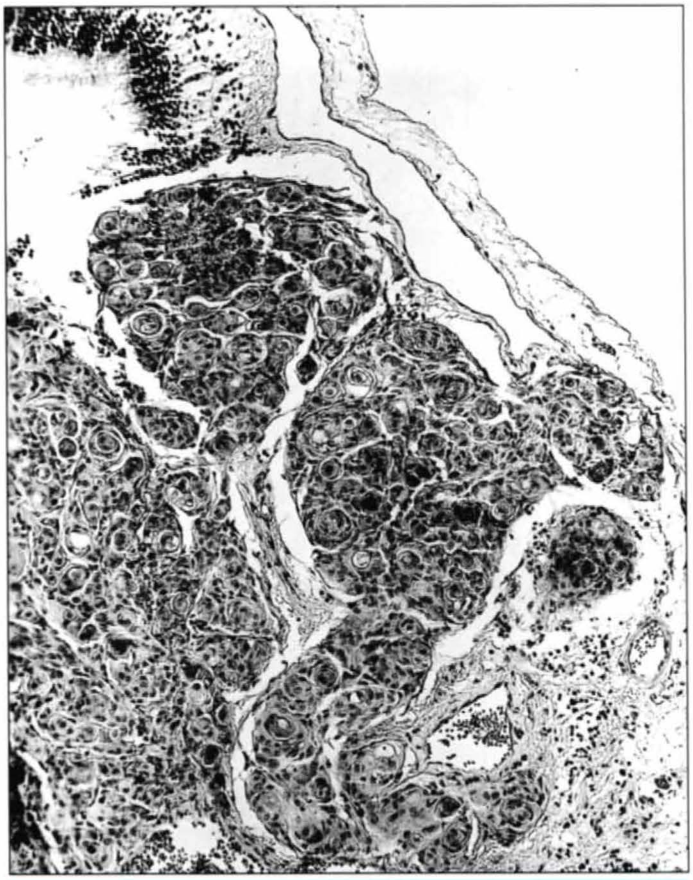

Figure 4.86 Meningioma of optic nerve invading eye in a dog.

multilobular osteochondrosarcomas and *optic nerve meningiomas*. The latter were described in the preceding section. The **multilobular osteochondrosarcomas** arise from the aponeuroses between adjacent bones of the orbit, and are identical in appearance and behavior to this tumor arising elsewhere in the canine skull.

Most primary epithelial tumors of the canine orbit are **lacrimal adenocarcinomas**, *which are locally invasive, recur after attempted resection, but which apparently have little metastatic potential.* In truth, there is so little follow-up information about these uncommon tumors that any statement about metastatic risk is premature. Both adenoma and nodular hyperplasia occur, but seem much less frequent than the malignant tumors. Tumors infiltrating the orbit from the nearby *zygomatic salivary gland* are similar histologically and behaviorally to lacrimal adenocarcinomas. They can sometimes be distinguished on the basis of location alone, but it is also helpful that the zygomatic gland is a mixed salivary gland with a prominent mucinous component that may be retained in well-differentiated tumors. The lacrimal gland is purely serous.

Primitive neuroepithelial tumors of unknown origin are occasionally seen in young dogs and in horses. They are composed of nests, cords, and rosette-like structures formed by small hyperchromatic neuroblastic cells with a very high mitotic index. Very rapid spread throughout the orbit and into brain occurs in affected dogs, but the extremely sparse information on these tumors in horses (four cases in two reports) suggest that they may be much less aggressive in horses than in dogs.

Tumors metastatic within the globe and orbit

The list of tumors that may be found as metastatic localizations within the globe or orbit is the same as any list of metastatic neoplasms in general. Any estimates of prevalence are unreliable because the globe is not routinely investigated in animals dying from disseminated malignancy. *Most of the reported cases are carcinomas*, simply because carcinomas are more likely to undergo hematogenous dissemination than are sarcomas (with the round cell "lymphoreticular" malignancies being a notable exception). In dogs, the most common are probably transitional cell carcinomas and mammary carcinomas, whereas in cats mammary adenocarcinoma and bronchial adenocarcinomas are probably the most prevalent. Across all species, however, *malignant lymphoma* is undoubtedly at the top of the list both as an intraocular and as an orbital metastatic tumor.

Ear

GENERAL CONSIDERATIONS

Diseases of the ear of domestic animals are of limited interest to most veterinary pathologists. Of the three broad categories – *defects of hearing, otitis media, and otitis externa* – only otitis media in farm animals regularly receives some attention, but even that is usually restricted to macroscopic examination at necropsy. Otitis externa is almost exclusively the realm of the clinical practitioner and microbiologist, although hyperplasia of chronically inflamed epithelium within the external ear canal may simulate neoplasia and be submitted for histologic interpretation. Disorders of hearing certainly occur in domestic animals, but their prominence in the medical literature is the result more of their usefulness as models for human deafness than of their intrinsic importance in animals. The growing availability of equipment for evaluation of hearing may, however, see a resurgence of interest in deafness in specific breeds or colors of dogs and cats. The tedious task of preparing adequate sections of the cochlea and labyrinth when related to the relative importance or prevalence of the diseases makes examination of the inner ear a rare event in most veterinary institutions. The gross and microscopic anatomy of the ear in the various species is reviewed in specialized texts and the appropriate references are included in the bibliography.

EXTERNAL EAR

Diseases of the external ear may be a local manifestation of generalized skin disease or may specifically affect the ear because of some anatomic or physiologic peculiarity. Disorders of skin that only incidentally affect the ear are discussed in Vol. 1, Skin and appendages.

Ear tip necrosis *may result from frostbite, cold-agglutinin disease, ergot poisoning, thrombosis during the course of septicemia, or from trauma inflicted by the animal itself or by cannibalistic herdmates.* Particularly in pigs, the prevalence of atrophic and misshapen ears may be quite high in individual herds. This usually results from septicemia, sarcoptic mange, or cannibalism. In some instances, however, no such history can be elicited, and a syndrome of infectious ear necrosis has been proposed. Culture of ears showing marginal lesions results in isolation of a variety of bacterial agents, and claims for a primary bacterial etiology are not convincing. The one that comes closest is the spirochete *Borrelia suilla*. It usually acts as an opportunistic contaminant of abraded skin in pigs, giving rise to localized (usually ear margins) or generalized ulcerative dermatitis.

Auricular hematoma *occurs as a consequence of trauma, usually from excessive head shaking by dogs with otitis externa.* Dogs and pigs with *pendulous ears* are particularly prone to hematoma formation, but cats are occasionally affected as well. Hematomas usually develop on the concave side of the pinna and are initially fluctuant but become firm as the hematoma (or blood-contaminated seroma) organizes. As it is converted to granulation tissue by fibroblastic and capillary ingrowth, the lesions become hard. Subsequent fibroblastic contraction may result in disfigurement of the pinna.

The location of the initial damage is unclear. Subcutaneous and subperichondrial sites are suggested, but a predominantly intrachondral location seems most likely. The cartilage plate of the pinna is cleaved by a longitudinal fracture and then by the hemorrhage. Granulation tissue forms at the interface of blood and cartilage, and the lesion is eventually converted to a fibrous scar. Late in the reparative process, regeneration of cartilage occurs adjacent to perichondrium or the ruptured edge of the cartilage. The intrachondral location of the hematomas is thought to be the result of rupture of vessels as they pass through minute foraminae in the cartilage plate. The conventional view that the initial lesion results from shear forces or outright trauma caused by head shaking has recently been challenged by one study of 40 dogs and 20 cats with auricular hematoma. No association with ear configuration or otitis externa was found, but most affected animals had serum and local tissue changes interpreted as *evidence for a lupus-like autoimmune disease*. The link between this proposed pathogenesis and the observation of the early cartilaginous fractures and hemorrhages was not made.

Dermatologic disease of the ear pinna may be part of a generalized skin disorder, but a few diseases seem unique to the ear. *Pigs with chronic sarcoptic mange* may have gross lesions only on the ears, consisting of reddening, crusting, and thickening of the pinna. *Short-haired* *dogs with pendulous ears* (Dachshunds, Pointers, Bloodhounds) are predisposed to chronic dermatitis of the ear margin, variously termed *marginal auricular dermatosis* or *ear margin seborrhea*. The gross lesion is a multifocal, greasy, gray, nodular encrustation that may coalesce to cause thickening of the entire ear margin. The histologic lesion resembles that of seborrhea elsewhere, with hyperkeratosis, acanthosis, and mild superficial perivascular dermatitis in which mononuclear leukocytes predominate.

Chronic ulcerative dermatitis of the ear margin of white cats (*feline solar dermatitis*) is discussed below as a premalignant lesion under squamous cell carcinoma, as is a similar disease of sheep.

Alopecia of the pinna occurs in dogs and in Siamese cats. In dogs, the alopecia appears gradually and progresses slowly. There is a strong *breed predilection* for Dachshunds, but it can be seen in other breeds including Italian Greyhounds and Whippets. The cause is unknown. The microscopic lesion is miniaturization of anagen follicles, without follicular destruction and without inflammation. In cats the lesion may wax and wane at irregular intervals throughout life. The histologic changes, in cats, have not been described.

Pinnal vasculitis is surprisingly frequent and resembles the lesion of cutaneous vasculitis elsewhere. In its mildest form, it may cause only pilosebaceous atrophy and thus may mimic the lesions of idiopathic pinnal alopecia when examined clinically.

Otitis externa

Otitis externa is a very common disorder in dogs and cats, and is probably equally common in many other species if they were to be examined. It may involve predisposing, primary, and perpetuating factors. In dogs, the pathogenesis is complex, while in cats, cattle, and goats, the *ear mite* is by far the major initiating factor. In tropical climates, infestation with rhabditiform nematodes (*Rhabditis* spp.) can be an important cause of otitis externa in cattle. *Otitis externa in dogs is most prevalent in breeds with pendulous ears or with abundant hair within the ear canal*, which implies that inadequate circulation of air and entrapment of moisture are important predispositions to the disease. *Foreign bodies*, usually foxtail or grass awns, may be important mechanical irritants, creating a breach for microbial infection, but since otitis is common in city dogs, other factors apparently are involved. The role of microorganisms in the pathogenesis of otitis externa is, as elsewhere, intimately linked to environmental circumstances that permit their uncontrolled proliferation. The bacteria and fungi cultured from diseased ears almost invariably are members of the normal aural flora. *Staphylococcus* spp., *Pseudomonas* spp., *Proteus* spp., and the yeast *Malassezia pachydermatis* are cultured much more frequently or in greater numbers from ears with otitis than from normal ears, but this may be related as much to their resistance to antimicrobial treatment as to their causative role. The lipid-rich environment of the ear canal favors the lipophilic *Malassezia*, which is the best candidate for a primary pathogen in the causation of canine otitis externa inasmuch as it frequently is the only pathogen isolated, and affected ears improve dramatically with antifungal therapy.

Otitis externa in species other than dogs is closely correlated to infestation with ear mites, and even in dogs acariasis can be an important contributor.

Otodectes cynotis *is the ear mite of carnivores*. The importance of the mite in initiating otitis externa is not entirely clear because the ear canal, once inflamed, becomes an environment unsuitable for the mites and thus gives rise to misleadingly low estimates of the prevalence of ear mites in dogs with otitis. As few as five mites can initiate otitis externa in dogs, with bacterial and mycotic opportunists rapidly masking the role of mites in the development of the lesion. Estimates vary from 2–50% prevalence of mites in dogs with otitis externa.

In cats, the role of mites is firmly established. In contrast to dogs, all cats have erect and sparsely haired pinnae and the role of ear carriage and hair is negligible. There is a poor correlation between the number of mites, the severity of inflammation in the external meatus, and clinical signs.

The mites are obligate parasites, spending their entire 3–4-week life cycle on the host. Transmission between animals of the same or different species readily occurs, and spread of the mites from their preferred aural niche to paws as the animal scratches, or tail as it sleeps with tail curled to touch the ear, is occasionally seen.

The mechanism by which the mites initiate otitis is controversial. Some maintain that the mites feed only on epithelial debris, while others claim that the mites pierce the epithelium and ingest blood and lymph. The latter claim is supported by the demonstration of host-specific serum components within the mites, but such components could exist in exudates, and should not be considered proof of penetrating feeding behavior.

The variation in the number of mites necessary to cause clinically obvious otitis, the species variation and some tenuous age resistance to disease (if not infection) suggest an allergic basis for the otitis. Most cats, and perhaps dogs, probably are infected with mites at some time. They may react to subsequent minor infection with immune-mediated inflammation of a severity not predicted by the small number of mites within the ear canal.

Psoroptes cuniculi, *the ear mite of rabbits*, also affects goats, horses, and deer. Its prevalence among domestic animals seems to be greatest in *goats*, ranging from about 20–80%. Careful examination may be required to find the mites. Clinical signs in goats, if present at all, are usually mild, consisting of ear twitching and head shaking. The ear canal of goats is the best site for isolation of several pathogenic *Mycoplasma* species in clinically normal animals. The same mycoplasmas were isolated from ear mites (*P. cuniculi* or *Raillietia caprae*) of infected goats, fuelling speculation that the mites are important vectors of the mycoplasmas in endemic herds. Similar coexistence of ear mites and mycoplasmas has been observed in cattle, but identification of the bacteria within the mites was not reported.

Psoroptes cuniculi may be quite common in horses (20% of horses in one Australian report) but it is unclear how frequently it causes clinical signs. Head shaking and resentment of handling of the ears are the usual signs.

Raillietia auris, *the ear mite of cattle*, occurs in most areas of the world. Infection seems to be common but is rarely of clinical significance. Manifestations of disease may follow extension of the otitis externa through the tympanum, and affected animals show head tilt and circling due to otitis interna. As with so many other agents observed or isolated from the external ear canal, it is difficult to prove a direct causal association between the presence of the mites and lesions or clinical signs of otitis.

Otobius megnini, *the spinose ear tick*, is parasitic on domestic ruminants, pigs, horses, and dogs and cats in restricted geographic areas. Infestation may be so heavy that the ear canals are full of ticks, making diagnosis easy. In light infestations, they occur deep in the folds of the ear, at the bottom of the external meatus. Only the larvae and nymphs are parasitic. The larvae attach themselves to the skin below the hairline and, biting through the skin, suck lymph until they are engorged. The parasites irritate the external auditory meatus and the ensuing exudate may completely fill it. In addition, secondary bacterial infection may occur in the inflamed areas around the bite wounds, and this infection may extend downward and cause otitis media. The microscopic appearance of the ear in this infestation has not been described.

The lesions of **otitis externa** *are nonspecific.* The relationship between type of exudate and causative agent has not been critically evaluated. The initial macroscopic lesion is hyperemia of the external auditory meatus followed by accumulation of serum, cerumen, leukocytes, and epithelial debris. A predominance of leukocytes tends to produce a suppurative exudate whereas cerumen yields a dry, dark-brown crumbly accumulation.

The histopathology of otitis externa varies with the duration of the inflammation and is rather typical inflammation of any epithelial surface. Only chronic lesions are likely to be seen by the pathologist. Such specimens show epidermal hyperplasia with acanthosis, atrophy of hair follicles, hyperkeratosis, and parakeratosis. Crusts of inflammatory debris adhere to the epithelial surface. Ulceration may be present, particularly if *Pseudomonas* is predominant, and *Malassezia* yeasts may be seen in the surface keratin or debris. The dermis contains numerous lymphocytes, plasma cells, mast cells, and neutrophils, the latter usually within dilated venules or adjacent to ulcers. Neutrophils are very sparse in mite-induced otitis. In very chronic and severe examples, dermal fibrosis is marked and ossification may occur. A feature of chronic otitis externa is *increased production of cerumen.* Histologically, there is hyperplasia of the normally very large sebaceous glands and cystic hyperplasia of the coiled tubular apocrine ceruminous glands, which are distended by eosinophilic cerumen. The combination of epithelial hyperplasia, glandular hyperplasia, and stromal fibroplasia may create proliferative lesions that occlude the ear canal and simulate neoplasia.

MIDDLE EAR

Otitis media

Otitis media *is inflammation of the tympanic cavity within the temporal bone. Its cause is almost always bacterial, the organisms reaching the poorly drained cavity via the Eustachian tube or following perforation of the tympanum.* In swine and lambs, the infection usually ascends from the pharynx via the Eustachian tube. In calves, the pathogenesis may depend on the age of the calves and a variety of management factors. In young dairy calves, *Mycoplasma bovis* causes unilateral or bilateral fibrinopurulent otitis media, sometimes even with bone lysis and remodeling. Affected animals may have no other lesions of *M. bovis* infection, or may have concurrent polyarthritis and/or necrotizing bronchopneumonia. In feedlot cattle, outbreaks of otitis media have been associated with isolation of *Pasteurella multocida.* Those organisms are normal inhabitants of the bovine ear canal, so the significance of these isolates is hard to evaluate: mycoplasma was not sought.

In dogs and cats, chronic otitis externa is the major predisposition, although the tympanum is quite resistant to inflammatory lysis. There are insufficient cases recorded in other species to permit generalization. *In all species, there is circumstantial evidence for hematogenous localization of infection in the middle and inner ear,* perhaps occurring most often in pigs. Otitis media with subsequent vestibular disease can be the presenting clinical complaint in cats with cryptococcosis.

Otitis media as a clinically obvious entity is most frequent in *feeder pigs.* The infection is usually unilateral and associated with hemolytic streptococci, but may involve *Actinobacillus pleuropneumoniae* or *Mycoplasma hyorhinis.* The clinical signs of head tilt, circling, and ataxia suggest involvement of the inner ear in most instances. Otitis media in swine may occur as small epizootics involving a dozen or more pigs. The basis for the clustering of the disease is unproven, but its sporadic association with atrophic rhinitis suggests spread from the upper respiratory tract. In *lambs,* the lesion is usually clinically undetected and unilateral, and often occurs in association with pneumonia. *Mannheimia haemolytica* is the usual isolate from both ear and lung. Bottle-feeding also increases the prevalence of otitis media in lambs. Otitis media/interna is uncommon in *horses,* but can occur as a chronic, insidious infection with the unique sequel of temporohyoid osteoarthropathy in some horses. Head shaking may be the only presenting clinical sign.

Regardless of the route of entry, the lesion and its progression are similar. The epithelium lining the tympanic cavity is hyperemic, edematous, and may be ulcerated. Neutrophils exuding from the reactive vessels under the epithelium enter the tympanic cavity, joining the initially serous or serofibrinous exudate to make it progressively more purulent. Exudate may temporarily drain into the pharynx via the Eustachian tube, which is soon sealed by inflammatory swelling of its epithelium. In severe infections, the exudate escapes via inflammatory lysis of the tympanum or, rarely, the bone on the ventral floor of the tympanic bulla. Chronic inflammation is characterized by inspissation of exudate, lysis of the ossicles and, occasionally, the tympanum, and spread to inner ear and brainstem. Another sequel noted in dogs with otitis media is mineralization of necrotic material within the tympanic bullae to form **otoliths**. Otolithiasis may cause signs of vestibular disease.

The presence of **inflammatory polyps**, either unilateral or bilateral, of the middle ear in dogs is an unusual association with, and possible cause of, otitis externa/media. Surgical removal of aural polyps has resulted in a good prognosis. Nasopharyngeal polyps have also been noted in this location in cats (see Neoplasms and like lesions below).

Primary secretory otitis media (PSOM) has been diagnosed in Cavalier King Charles Spaniels with signs of moderate-to-severe pain in the head or neck, and/or neurological signs. A highly viscous mucus plug filled the middle ear and caused the tympanic membrane to bulge outwards. The prognosis was good following removal of the mucus plug, flushing of the middle ear, and local and systemic medical therapy.

INNER EAR

Otitis interna

Otitis interna *is almost always the result of infection spreading from the middle ear.* The inflammation is usually of bacterial origin and thus suppurative. Ascension via the eighth cranial nerve is relatively frequent, and results in focal suppurative meningitis or encephalitis in the region of the pons. *The usual clinical syndrome is vestibular dysfunction*, described in a subsequent section.

Deafness

Deafness is difficult to assess in animals, and its diagnosis by simply observing behavioral abnormalities is almost impossible unless the animal is totally and bilaterally deaf. The recent introduction of electrodiagnostic tests has identified a higher prevalence of deafness, especially in dogs, than was suspected. **Conductive deafness** results from interference with the conduction of sound to the sensory end organ (of Corti) by diseases of external or middle ear. Alternatively, **sensorineural deafness** results from maldevelopment or degeneration of the sensory organ, eighth nerve, or auditory pathways within the brain. The last is very unusual and, because of the multitude of possible pathways, is seen only in massive destructive lesions with their neurologic signs overshadowing the hearing loss. *Nerve deafness usually involves the organ of Corti, and is by far the most prevalent type of deafness encountered in animals by virtue of hereditary deafness in several breeds of dogs, and in dogs or cats with color dilution anomalies.* Conductive deafness may result from obliteration of the external auditory meatus by chronic proliferative inflammation or tumor, from inflammatory or traumatic rupture of the tympanum, or from entrapment of the ossicles in exudates or granulation tissue. Rarely there is destruction of the middle or inner ears by osteomyelitis or neoplasia.

The anatomy of the auditory apparatus is complex. The sensory fibers of the eighth cranial nerve terminate at the base of sensory hair cells within the organ of Corti, the latter a sensory specialization of the epithelium lining the cochlear duct. Excitation of the hair cells results from pulsations within the endolymph fluid that fills the entire membranous labyrinth including the cochlear duct. The precise mechanism of such excitation remains unknown. Sound waves in the environment reach the endolymph via the tympanum and ossicles. Vibration of the tympanum is transmitted to the ossicles, and vibration of the ossicles causes vibration of the oval window that separates the footplate of the stapes from the endolymph. Any lesion that interferes with vibration of the tympanum or ossicle interferes with the establishment of fluid waves within the endolymph. Traumatic fracture of ossicles, rupture of tympanum, or dampening of vibration by exudates within the middle ear can do this.

Hereditary cochleosaccular degeneration

Hereditary deafness *in association with incomplete pigmentation of the hair coat and uvea is seen in cats, dogs, mink, and mice. Incompletely documented examples exist in other domestic species.* The pigmentary defect is not true albinism but is white spotting or merling, the distinction being the absence of melanocytes in white areas in the latter instance and functionally defective melanocytes in the former. In some instances, the hearing defect is associated with inheritance of the merling gene. All homozygotes and many of the heterozygotes are deaf and have some degree of iris heterochromia. In other instances there is heterochromia iridis but no apparent coat color dilution (Dalmatian dogs), while in others both eyes and coat are phenotypically normal. Even when the coat color is white, as in deaf Bull Terriers, the genetic basis for the white coat and the associated deafness need not be the merling gene. Out of this confusing picture one should rescue the concept that *color-dilute animals have ocular heterochromia and deafness much more frequently than normal animals, but that other genetic bases for deafness also exist.* Ocular anomalies and deafness commonly are encountered in the same animal, probably the result of the inductive influence of pigmentation on both organs. For example, all white cats with blue irises are deaf as are many Dalmatian dogs with iris heterochromia. Several dog breeds, particularly Dalmatians and English Setters, have a prevalence of early-onset deafness in excess of that predictable from their prevalence in the overall canine population. Prominent also are merle dogs such as Australian Shepherds, Australian Blue Heelers, Old English Sheepdogs and Great Danes.

The fully developed lesion of **cochleosaccular degeneration** *is atrophy of the sensory and supporting cells of the organ of Corti and the saccular macula, collapse of the dorsal or lateral walls of the cochlear and saccular membranous labyrinth, and secondary degeneration of the neurons within the spiral ganglion.* The osseous portion of the labyrinth is unaffected as is the vestibular portion of the inner ear. With minor variations, all cases in dogs and cats are similar. Initial structure and function are normal, but there is failure to achieve normal maturation and, subsequently, degeneration occurs.

The carnivore ear is completely developed at birth and continues to mature for 2 (organ of Corti) to 4 (stria vascularis) weeks. Thereafter, the epithelial lining of the cochlear duct is incapable of mitotic regeneration. In white kittens, the ear is morphologically and physiologically normal at birth but shows arrested development as early as 1 week of age. At this time there is inward sagging of the free dorsolateral wall of the cochlear duct (Reissner's membrane) and saccule, and hydropic change in the stria vascularis. The degeneration within the organ of Corti and adjacent nutritive stria vascularis is so rapid that there is no consensus as to the initial or causal lesion. It may be that degeneration of the stria vascularis results in ischemic degeneration of the avascular organ of Corti, or there may be a primary defect within the sensory cells themselves resulting from an inborn metabolic error.

Senile deafness

Many animals become hard of hearing as they reach old age. This phenomenon, called **presbycusis**, is more frequently observed in old dogs because dogs tend to be kept well into their advanced years and because hearing loss is more readily noticed in them than in other species. In humans, the loss of hearing is progressive from about the fortieth year of life and particularly affects hearing of high tones. The cause seems to be inherent age-related degeneration of the epithelial tissues within the cochlea and of the spiral ganglion, a process that may be accelerated by excessive noise, arteriosclerosis, and nutritional factors. The essential lesions are atrophy of all epithelial structures within the cochlear duct and the associated auditory nerves, as well as neuronal atrophy within the spiral ganglion. Occasionally, the major lesion is atrophy within the stria vascularis or the basal membrane supporting the organ of Corti.

Presbycusis in animals has been studied in guinea pigs, rats, mice, dogs, and cats. *Degeneration of the hair cells in the organ of Corti and loss of neurons from the spiral ganglion are the common denominators in all such instances, and presumably is the aging change common to all mammalian species.* Stria vascularis atrophy has not been seen in these animals.

Acoustic and chemical ototoxicity

Noise, *either as a sudden loud noise or as moderate but prolonged environmental background, causes degeneration of the sensory hair cells within the organ of Corti.* Loud noise causes hair cell necrosis and even outright disruption of the organ of Corti or Reissner's membrane by mechanical trauma mediated via fluid waves within the endolymph, which must be the otic equivalent of tidal waves. Environmental noise is frequently an occupational hazard. The eventual lesion is hair cell necrosis, but whether this results from repeated sublethal microtrauma by noise peaks or by interference with hair cell metabolism is not known. That animals are susceptible to such trauma is well established in experimental models, but investigation of naturally occurring examples is not reported.

The list of chemicals that are ototoxic is very long, and is even longer if idiosyncratic drug injury is included. Only a few major examples likely to be encountered in veterinary practice are included here.

Aminoglycoside antibiotics *(gentamicin, streptomycin, kanamycin, neomycin, and others) are all nephrotoxic and ototoxic in proportion to their blood levels and duration of administration.* Overdosing, or administration to animals with decreased renal function, markedly increases the risk of toxic injury to the inner ear. Clinical signs of vestibular dysfunction precede evidence of hearing impairment. The initial lesion affecting hearing is degeneration of the apical portion of cochlear hair cells. The earliest visible lesion is mitochondrial swelling and increased number of myelin figures. The early lesion is reversible but later becomes permanent, presumably as mitochondrial swelling leads to structural disintegration of cellular respiratory enzymes and cell death. Cats are particularly susceptible and vestibular toxicity (defects of posture, balance, and gait) precedes clinical evidence of hearing loss. Ordinarily, these signs appear only after several weeks of aminoglycoside therapy.

The **diuretics** *furosemide, bumetanide, and ethacrynic acid are chemically related and all are ototoxic to dogs and cats.* Other domestic species have not been tested. Electrophysiologic evidence of hearing impairment occurs within a few hours of even a single high dose but is unaccompanied by structural changes within the cochlea. The exception is ethacrynic acid intoxication in which edema of the stria vascularis is seen ultrastructurally. There is a corresponding alteration in the composition of the endolymph produced by the stria. The hearing impairment, which occurs frequently in people receiving therapeutic doses of the drugs, is assumed to result from structural or physiologic lesions in the hair cells nourished by this abnormal endolymph.

Acetylsalicylic acid (aspirin) and its derivatives are ototoxic for man and several laboratory animal models, but no structural lesion has yet been detected.

The antibacterial-anthelmintic agent, **hygromycin B**, as well as causing cataracts in swine (see Eye) also causes permanent deafness in dogs if therapeutic dosages are given. The drug is not approved for use in dogs. Deafness is reported occasionally in swine receiving the medication in excess of recommended levels. Histologic descriptions of cochlear lesions are not available.

The antiseptic combination of **chlorhexidine and cetrimide** (Savlon7) is a widely used antiseptic that occasionally is used to cleanse the external ear canal. If used in dogs or cats with a ruptured typanic membrane, this solution is *toxic to both vestibular and cochlear cells*, although the clinical signs in affected animals are primarily vestibular.

Other causes of deafness

Deafness is reported in people with various *storage diseases*, but few animal counterparts have been studied for this specific defect.

Goats with β-mannosidosis have deformed ear pinnae, bony exostoses within the tympanic cavity, and deforming accumulation of oligosaccharides within lysosomes of many tissues of middle and inner ear. Epithelial and mesothelial cells of Reissner's membrane, most structural cells of the organ of Corti, and cochlear neurons of the spiral ganglion are all affected, even at a few days of age.

Vestibular dysfunction

Vestibular dysfunction is characterized by head tilt and falling towards the affected side, ataxia without weakness, and nystagmus. Clinical signs are most obvious with unilateral disease. The lesion may be in brain or in the vestibular apparatus, or both. Animals with vestibular dysfunction caused by brain lesions, as in listeriosis or canine distemper, usually show other signs of neurologic dysfunction. Since vestibular signs are more readily detected than is partial hearing loss, *mild lesions of the inner ear are more frequently associated with vestibular abnormalities than with hearing deficits.*

The causes of peripheral vestibular disease are the same as those causing deafness: uncontrolled otitis media, trauma, invasive neoplasia, and a number of drugs. Congenital vestibular disease has been reported in several dog breeds, but no morphologic observations were given. *Nonspecific destruction of part or all of the vestibular apparatus as a sequel to otitis media is by far the most common cause of labyrinthitis in all species.*

Idiopathic vestibular disease occurs in old dogs and in cats of any age. In old dogs, it is often mistakenly diagnosed as an acute cerebrovascular accident (stroke), but there is no demonstrable brain lesion in such dogs, and most have rapid, spontaneous remission of clinical signs unless prevented by premature euthanasia. No histologic examination of the labyrinth has been reported. An equally mysterious acute vestibular dysfunction affects cats of any age. Recovery usually occurs over a few days to weeks. No lesions are reported.

Neoplasms and like lesions

Neoplasms of the ear include those capable of affecting skin elsewhere, as well as primary tumors of ceruminous glands and, very rarely, tumors of Eustachian or auditory epithelium and of cranial nerves. Inflammatory polyps are included in this section because of their gross resemblance to neoplasia.

Squamous cell carcinoma *is by far the most important skin tumor affecting the ear,* although the predilection of *canine histiocytoma* for the ear pinna probably makes it the most frequent tumor affecting the pinna. Squamous cell carcinoma of the ear occurs commonly in *white cats*, with a frequency more than ten times that of nonwhite cats, and in *sheep* in sunny climates. In cats, the tumor has a long precancerous phase consisting of erythematous, ulcerative dermatitis of the ear margin known as *feline solar, or actinic, dermatitis* because of its association with exposure to sunlight. Other sparsely haired areas, such as the nose, lips, and eyelids, may be affected. Histologically, the lesion consists of multifocal coalescing epidermal necrosis overlying a diffuse superficial dermal infiltrate of lymphocytes and plasma cells. The lesion waxes and wanes with the intensity of sunlight. *Epidermal hyperplasia proceeds to dysplasia, carcinoma in situ and invasive squamous cell carcinoma in a manner analogous to bovine ocular squamous cell carcimona.* The lesion is bilateral but not necessarily of synchronous progression. The progression to invasive neoplasia usually occurs over 3 or 4 years. Metastasis is a late occurrence and prevented (at least in the case of ears) by amputation. Rarely, squamous cell carcinoma occurs within the external ear canal or even within the tympanic cavity of the middle ear. Local infiltration results in damage to cranial nerves VII and VIII with resultant signs of vestibular dysfunction and facial paralysis.

Ceruminous adenomas and adenocarcinomas *occur in dogs and cats.* The tumors represent a continuum from histologically benign to histologically malignant, and are thus very similar to tumors of apocrine sweat glands elsewhere in skin. The ceruminous glands are modified sweat glands within the deep portion of the external auditory meatus. Tumors are relatively more prevalent in cats than in dogs, and in both species they tend to occur in very old animals. In dogs most are benign, but in cats about half are histologically malignant. The adenomas are smooth nodular or pedunculated masses seldom exceeding 1 cm in diameter. The epithelium overlying the tumor is intact unless there is concurrent otitis externa. Ceruminous gland tumors cannot be distinguished in the live animal from cystic dilation with epithelial hyperplasia typical of chronic otitis externa. Carcinomas may occasionally invade from the auditory meatus into the region of the parotid salivary gland or into bone, and when very anaplastic may be confused with salivary carcinoma. The diagnosis of carcinoma usually is based on histologic criteria of anaplasia and local invasiveness rather than on behavioral evidence of metastasis.

Histologically, adenomas are well-differentiated tubular and cystic growths. The epithelial cells are cuboidal and eosinophilic. They may be flattened when the tubular or acinar lumen is dilated. *The most typical feature is the presence within lumina of deeply eosinophilic or orange, colloid-like secretion typical of cerumen.* Mixed ceruminous tumors analogous to mixed apocrine sweat glands or mammary tumors occur infrequently. Carcinomas do not differ markedly from adenomas but have less secretion and more cellular anaplasia, and show invasion by tumor cells into an abundant fibrous stroma rich in mononuclear leukocytes. Mixed tumors with cartilage and bone are described.

Benign cutaneous plasmacytoma occurs with unexplained frequency in the external ear canal of dogs. It has the same histologic appearance here as it does in other locations such as the larynx and skin.

As expected, *various other neoplasms* have been described in the external ear canal or tympanic cavity of dogs and cats. All would seem to be rare, and no prognostic statements are justified by the small numbers. In one small series in dogs, eight of 11 middle ear neoplasms originated in the external ear and perforated the tympanic membrane. Two were papillary adenomas formed by ciliated columnar epithelium and goblet cells, thought to have arisen from the epithelium of the dorsal portion of the tympanic cavity. The final case was an anaplastic carcinoma of unknown origin involving oropharynx and ear.

Nasopharyngeal polyps *occur quite frequently in cats*. The distinctive histologic lesion is a loose mass of connective tissue containing numerous small blood vessels and mononuclear leukocytes, covered by epithelium that may be either stratified, nonkeratinized squamous, or simple-to-bilayered ciliated columnar. *The detection of ciliated epithelium is a prerequisite for the histologic confirmation of nasopharyngeal polyp*. Often the ciliated epithelium is found only focally in protected subepithelial glands, but nonetheless it is the characteristic feature distinguishing this lesion from nonspecific proliferations of glands and connective tissue seen in many cases of chronic otitis externa. The presence of this ciliated epithelium is used to support theories that such polyps originate from the Eustachian tube, but in fact the only proven origin is from ciliated epithelium of the tympanic cavity itself. Some of these polyps are grotesque, protruding from outer ear, hanging into the oropharynx, or even protruding through the nose. A familial occurrence has been seen in Abyssinian and Himalayan kittens, further confusing the debate about the cause of these distinctive lesions.

Under the umbrella of **inflammatory polyp** fall many of the tumor-like proliferations excised from the external ear canal of dogs (rarely cats) with chronic otitis externa. The lesion consists of variable proportions of hyperplastic surface epithelium, hyperplastic or dysplastic sebaceous and ceruminous glands, fibroplasia, and leukocytes. The rupture of the glands often adds the lesions of sterile foreign body periadenitis to the chronic inflammation associated with the bacteria, yeast, or foreign bodies causing the initial otitis itself. Such masses are macroscopically indistinguishable from genuine ceruminous neoplasms; *the histologic distinction is made by observing a mixture of inflammation, fibrosis, and hyperplasia of both sebaceous and apocrine glands within the hyperplastic polyps, whereas the tumor is represented by the proliferation of a single cell type.*

Another nodular lesion, clinically resembling neoplasia, is the **dentigerous cyst** of heterotopic polydontia in foals, seen as a draining nodule on the rostral aspect of the base of the pinna.

GENERAL CONSIDERATIONS

The skin is the largest organ of the body and, because of its visibility, it is familiar to all, veterinarians as well as laymen. Consequently, any change in the skin or hair is noticeable and may be a cause for concern. While serious internal organic conditions may be ignored or overlooked because of their covert nature, even mild dermatologic diseases are likely to be brought to veterinary attention. In many veterinary practices, dermatologic cases constitute a major component of the caseload. The diseases range from minor, esthetic problems to life-threatening conditions. Many diseases produce severe economic losses because of damage to wool, hides, and meat or from decreased milk production or growth rates. Even apparently mild hair and skin changes may affect the health of the animal and have serious consequences.

The skin serves numerous functions but one of the most important is protection of the individual from the external environment. The hair and stratum corneum, composed of tightly packed keratinized cells permeated by an emulsion of sebum and sweat, form a physical barrier against potential physical, chemical, or microbial damage. The skin also has a protective chemical barrier composed of inorganic salts, proteins, and fatty acids. A number of proteins have been identified in skin washings from various species and some of these include immunoglobulins of various classes, interferon, albumin, transferrin, and complement. Fatty acids, such as linoleic acid, have antibacterial and antifungal properties. The skin also has *normal microflora* that contribute to skin defense. A mixed population of symbiotic bacteria lives and multiplies permanently on the skin surface and thereby inhibits invading microorganisms. Occasional yeasts and fungal hyphae may also comprise the resident microflora. The skin is also a major sense organ and it protects the organism from desiccation. It is involved in photoprotection, immunosurveillance, nutrient and fat metabolism, and water balance. The skin is involved in temperature regulation by virtue of the hair coat, blood flow, and, in some species, sweating. Lastly, the skin can serve as a window to internal diseases.

As dermatologic cases are more commonly presented to veterinary clinicians for examination, skin biopsies have become a routine diagnostic procedure. An understanding of the pathologic processes in skin, as in any tissue, requires a thorough understanding of the normal structure and function of skin. *As a general rule, the clinician is more familiar with the gross pathology than is the pathologist because the majority of the cases are examined by the pathologist only in the form of a limited number of very small skin biopsies.* This fact underscores the importance of the inclusion of the gross findings in the surgical pathology request. The pathologist must be aware of normal variations in skin components from different body regions and from different species to correctly interpret deviations from normal. The basic architecture is similar in all mammals but skin thickness varies between species and region of the body within the same species. The dermis contributes most to the difference in skin thickness. The epidermis varies less markedly, but tends to be thinner in areas with thick hair and thicker in those areas without hair, such as mucocutaneous junctions. In general, skin thickness decreases dorsally to ventrally on the trunk and proximally to distally on the limbs. The skin is thickest over the dorsal surface of the body and lateral aspect of the limbs and thinnest on the ventral aspect of the trunk and medial limbs.

The integument is composed of epidermis, dermis, hair follicles, adnexal glands, and the subcutis. The appendages include nails, hooves, and claws.

Epidermis

The epidermis is a continually renewing tissue in which keratinocytes move from the basal layer outward to the skin surface where they are ultimately shed. During their migration through the epidermis, cells undergo changes in shape, structure, and composition until they are shed as dead, cornified husks of cells. Protection of an individual from the environment is largely dependent on the structural integrity of the epidermis. *To maintain uniform epidermal thickness and normal barrier function, basal cell proliferation, orderly cell differentiation through the various layers, and cell death must be balanced.* Knowledge of the regulation of this complex, dynamic process is incomplete and primarily based on cultured keratinocytes. Epidermal growth factor, insulin-like growth factor-I, keratinocyte growth factor, basic fibroblast growth factor, interleukin-1, interleukin-6, transforming growth factor-α, vitamin D_3, and retinoids are some of the factors thought to be involved in the growth and differentiation of keratinocytes.

One of the most important and abundant products of keratinocytes is *keratin*. It forms the cytoskeleton of keratinocytes and is thus responsible for the shape of the cells. It is also responsible for structural stability and it contributes to the impervious nature of the stratum corneum. Keratin is composed of acidic and basic pairs of subunits that are differentially expressed by keratinocytes of various layers of the epidermis. Basal cells express keratins K5 and K14, while commitment to differentiation in suprabasal keratinocytes is associated with induction of differentiation-specific keratins K1 and K10.

The epidermis is divided into four layers:

- The **stratum basale** (*basal layer*) is the deep germinative layer of the epidermis and is composed of a single layer of cuboidal to low columnar cells resting on the basement membrane. These cells are mitotically active and their daughter cells continually migrate upward to replenish cells in overlying layers. The basal layer is thought to be *composed of two populations of cells*: (1) *stem cells*, which have a long lifespan, long cycling phase, and short S period; and (2) *transit amplifying cells*, which undergo only a limited number of divisions before terminally differentiating. Mitotic figures and apoptotic cells are occasionally evident. The basal cells are attached to the underlying basement membrane by *hemidesmosomes* and to adjacent and overlying keratinocytes by *desmosomes*. Desmosomes are anchoring structures that mediate adhesion between cells. They have a complex structure that includes *cadherin proteins* of two types, desmocollins and desmogleins. These proteins have different isoforms and they are differentially expressed in different layers of the epidermis. While basal cells express a pair of desmogleins and desmocollins of simple epithelia, desmosomes of the spinous layer express a more varied array of isoforms. These adhesion molecules have been identified as the target in several blistering autoimmune diseases.
- The **stratum spinosum** (*prickle cell layer*) is characterized by *prominent intercellular bridges that are the desmosomal attachments between cells.* The spinous appearance is due to shrinkage artifact that occurs during tissue processing. The cells are polyhedral to

slightly flattened and are arranged in one or two layers in haired skin of dogs and cats and up to four layers in large animals. This layer is much thicker in lightly haired or nonhaired skin and may be up to 20 cells thick in the footpads and nasal planum. Cells of the upper spinous layer synthesize the protein *involucrin*, which is a constituent of the cornified envelope of the stratum corneum.

- The **stratum granulosum** is variably present in haired skin and is one or two cells thick when present. It is usually four to eight cell layers thick in nonhaired skin or at the infundibulum of hair follicles. The stratum granulosum is composed of flattened cells with shrunken nuclei and deeply basophilic keratohyaline granules of variable size and shape. The granules are composed of the precursor of *filaggrin*, a histidine-rich interfibrillary matrix protein that *functions as a biologic glue* that aggregates and aligns keratin filaments together. Stratum granulosum cells also contain *laminar granules* (membrane-coating granules, Odland bodies, keratinosomes), small organelles containing a mixture of lipids that are released to the intercellular space where they coat the cells and contribute to the hydrophobic barrier of the stratum corneum. The cells also synthesize the cysteine-rich protein *loricrin*, a major precursor of the cornified envelope. Dissolution of the nucleus and other organelles begins in upper layers of the stratum granulosum, probably through the action of lysosomal enzymes.
- The **stratum corneum** is the *impermeable, insoluble, highly protective layer* that keeps microorganisms out and essential body fluids in. It is composed of anucleate, dead, flattened eosinophilic cells (*squames*) that are continually shed. Thickness varies greatly according to body region and species. It is thickest in nonhaired areas such as footpads and nasal planum. Routine fixation and processing usually result in loss of approximately 50% of this layer. The cells are arranged in vertical interlocking columns in which intercellular spaces are filled with lipids derived from the laminar granules. The *basket-weave pattern* commonly visible in formalin-fixed sections is an artifact caused by loss of soluble intracellular constituents during routine processing. Structural support for these cells is provided by the cornified cell envelope. The cornified envelope is a complex structure composed of a number of proteins, including involucrin, loricrin, and keratolinin. The proteins are deposited on the inner membrane of the keratinocytes and are cross-linked by transglutaminases to form a highly insoluble, electron-dense band. The keratin in these cells is organized into large macrofilaments that confer mechanical resistance to the cells. The structural stability of the horny layer is derived from the association of the keratinized cells and insoluble extracellular lipids, a structure likened to a wall in which the cells represent the bricks and the lipids the mortar.

Epidermal non-keratinocytes

In addition to keratinocytes, which comprise approximately 85–90% of the cells of the epidermis, *small numbers of dendritic cells also reside in the epidermis*. These include *melanocytes, Langerhans cells, and Merkel cells*. **Melanocytes** are located in the basal layer of the epidermis and outer root sheath of hair follicles; and in HE sections they appear as clear cells with a small dark-staining nucleus due to shrinkage artifact. There is ∼1 melanocyte per 10–20 keratinocytes. They can be visualized more specifically with silver stains, which demonstrate their dendritic processes. Derived from the neural crest, melanocytes migrate into the epidermis during early fetal life. Their processes are intertwined between the surrounding keratinocytes to which they transfer melanin pigment. A melanocyte and its surrounding constellation of keratinocytes is termed the "*epidermal melanin unit*." Melanogenesis occurs in membrane-bound organelles called *melanosomes*, which originate from the Golgi. The melanosomes migrate to the tips of the dendrites and are phagocytosed by adjacent keratinocytes. Most melanin pigment in skin is in the basal layer; but in dark-skinned animals, melanin may be present throughout the epidermis. Melanin is photoprotective and exposure to ultraviolet light increases melanin production, often resulting in a cap of pigment granules over the nucleus. Skin pigmentation is affected by local inflammation because melanocytes respond to inflammatory mediators by increasing or decreasing melanogenesis and by altering melanin transfer to keratinocytes.

Langerhans cells *are bone marrow-derived dendritic cells that are functionally and immunologically related to monocyte-macrophage cells*. They appear as clear cells on routine HE sections and may be distributed from the stratum basale to the stratum spinosum, depending on species and region of the skin. They are usually less numerous than melanocytes, however. Langerhans cells are characterized ultrastructurally by rod- or racket-shaped cytoplasmic granules called *Birbeck granules*. Birbeck granules have been identified in Langerhans cells of the pig, cat, cattle, sheep, goat, horse, and human, but not in the epidermal dendritic cells of the dog. Histochemical markers expressed by Langerhans cells include CD1, class II MHC (major histocompatibility) antigens, CD45, vimentin, and S-100. The long dendritic processes of Langerhans cells traverse the intercellular space to the granular cell layer where *they function in immunosurveillance as antigen-presenting cells*. Langerhans cells trap antigens in the epidermis and migrate via afferent lymphatics to draining lymph nodes where they present antigen to T cells in paracortical areas, resulting in proliferation of a population of sensitized T cells. Exposure to UVB radiation decreases Langerhans cell numbers in the epidermis and interferes with their antigen-presenting capacity. Langerhans cells are involved in development of contact hypersensitivity, and increased numbers of epidermal Langerhans cells have been found in horses with insect hypersensitivity and dogs with discoid lupus erythematosus, hypersensitivities, and deep pyodermas.

A second type of clear cell in the basal layer is the **Merkel cell** whose *origin is unknown*. Unlike melanocytes, Merkel cells are connected to adjacent keratinocytes by desmosomes. Merkel cells are also located in the external root sheath of hair follicles. They are identified ultrastructurally by characteristic *dense-core cytoplasmic granules*. Immunohistochemical markers include cytokeratin, neurofilaments, neuron-specific enolase, and desmosomal proteins. Merkel cells have been identified in the dog, cat, sheep, pig, monkey, various laboratory animals, birds, reptiles, and amphibians. Their density in the epidermis is variable and they are in highest numbers in areas involved with sensory perception. Merkel cells form *Merkel cell–neurite complexes* with axons in tylotrich pads that are thought to function as slow-adapting mechanoreceptors and in sinus hairs. Their exact function in these structures is uncertain but they are thought not to act as sensory cells but rather to function as abutments for deformation of the mechanosensitive nerve endings. Merkel cells are also thought to have various neuroendocrine effects and to be involved in control of the hair cycle.

Basement membrane zone

The basement membrane zone (BMZ) is the structurally and biochemically complex junction between the epidermis and dermis. Both the epidermis and dermis contribute to production of the various components of the BMZ. The area is indistinct in HE sections but visible as a thin, homogeneous band with PAS stain. It varies in thickness in different sites and is most prominent in nonhaired areas of skin and mucocutaneous junctions. In all animals but the pig, the dermal–epidermal junction is straight and the BMZ parallels the skin surface; while in pigs and humans, the dermal–epidermal junction is thrown into undulating folds called rete ridges. *The BMZ has a crucial role in anchoring the epidermis to the dermis; and abnormalities of the BMZ result in serious and potentially fatal bullous diseases.* The BMZ also influences growth and differentiation of keratinocytes and acts as a selective barrier for passage of molecules between the epidermis and dermis.

Ultrastructurally, the BMZ is composed of: (1) the **plasma membrane** of basal keratinocytes with their specialized attachment structures, *hemidesmosomes*; (2) the electron-lucent **lamina lucida**; (3) the electron-dense **lamina densa**; and (4) the subbasal **lamina fibrous zone**. Hemidesmosomes are located on the basal aspect of basal keratinocytes and they consist of a cytoplasmic plaque that connects to the cytoskeleton and a transmembrane portion that binds to the underlying basement membrane. The *cytoplasmic plaque* is composed of a number of proteins, including bullous pemphigoid antigen 230 (bullous pemphigoid antigen 1) and plectin, which connect keratin 5 and 14 intermediate filaments to the plasma membrane. Hemidesmosomes also have a transmembrane portion that includes $\alpha6\beta4$ integrin and bullous pemphigoid antigen 2 (type XVII collagen). The proposed ligand for $\alpha6\beta4$ integrin is laminin 5, which is a component of the anchoring filaments of the lamina lucida, and this binding mediates the stable adhesion of keratinocytes to components of the BMZ. *Anchoring filaments* are 2–4 nm diameter filaments composed of laminin 5 (also called epiligrin, kalinin, and BM600). They pass from the plasma membrane through the lamina lucida to attach to the lamina densa. The lamina densa is composed of multiple molecules, including collagen type IV, laminin, nidogen, and several glycoproteins. The lamina densa is connected to anchoring plaques of the underlying dermis by anchoring fibrils. The subbasal lamina fibrous zone of the superficial dermis is composed of anchoring fibrils, anchoring plaques, and microfibrils. Anchoring fibrils are composed of collagen type VII and form looping arrays with one or both ends of the fibrils attached to the lamina densa, thereby anchoring the BMZ to the dermis.

Dermis

The dermis is involved in maintenance and repair of the skin and is the major component responsible for the tensile strength and elasticity of the skin. In addition, the thickness of the dermis largely determines the thickness of the skin. *The dermis is composed of collagen and elastic fibers embedded in a ground substance, blood and lymphatic vessels, nerves, and low numbers of mixed cells.* Except for pigs, domestic animals have no dermal papillae as occur in human skin. Thus, instead of papillary and reticular dermis, the dermis is divided somewhat arbitrarily into *superficial and deep dermis* in domestic animals.

The **dermal fibers** include collagen, reticulum fibers, and elastic fibers, all of which are synthesized by dermal fibroblasts. Collagen fibers are the most abundant constituent of the dermis and they confer tensile strength to skin. The majority of *dermal collagen is types I and III.* The superficial dermis is composed of fine, loosely arranged collagen fibers. The deep dermis consists of thick, densely arranged collagen fibers that roughly parallel the skin surface. Reticulum fibers represent a special thin type of collagen. *Elastic fibers* are inconspicuous in routine HE sections. They can be visualized with special stains such as orcein stain or Verhoeff–van Gieson elastin stain. They are thicker and less numerous in the deep dermis and arranged parallel to the skin surface. The elastic fibers become progressively thinner near the epidermis.

The **ground or interstitial substance** is an amorphous gel-sol that fills the space between dermal structures but allows electrolytes, nutrients, growth factors, and cells to pass through. It consists of *proteoglycans and glycoproteins.* Proteoglycans are high-molecular-weight complexes composed of glycosaminoglycans linked to proteins and those most abundant in the dermis include hyaluronic acid and various chondroitin sulfates. Proteoglycans bind various chemical mediators and thereby function as storage matrix as well as provide lubrication and structural support. *Fibronectins* are a family of glycoproteins involved in mediating cell–cell and cell–matrix interactions that are required for various cell functions including cell adhesion, phagocytosis, and cell migration. The ground substance is usually not visible in normal HE sections; however, a fine granular to fibrillar basophilic material is occasionally evident between collagen fibers. This material is especially abundant in the dermis of Chinese Shar-Peis as a normal variant for this breed.

The **dermal vasculature** is arranged in three intercommunicating plexuses. The *deep plexus* is located at the junction of the dermis and subcutis and it supplies branches to the *middle plexus*, which is located at the level of the sebaceous glands. It, in turn, supplies branches to the *superficial plexus.* The capillary loops parallel to the skin surface immediately beneath the epidermis arise from the superficial plexus. An unusual vascular arrangement is present in the dermis of the llama. It consists of clusters of capillary-size, thick-walled vessels lined by plump endothelial cells distributed throughout the superficial and middle dermis. Dermal lymphatic vessels are inconspicuous in normal skin and only become visible when they become dilated because of increased lymphatic drainage. The skin is supplied with sensory and autonomic nerves that are usually associated with blood vessels.

The dermis is normally **sparsely cellular**. *Fibroblasts* are distributed in low numbers throughout the dermis. They synthesize most of the fibrillar and ground substance proteins of the dermis as well as various growth factors and cytokines. *Melanocytes* in the dermis are usually located near superficial dermal vessels. In contrast to melanocytes of the epidermis and hair follicles ("secretory melanocytes"), dermal melanocytes do not transfer their melanin to surrounding cells ("continent melanocytes"). Normal dermis also contains small numbers of perivascular *monocytes and lymphocytes,* which are indistinguishable from each other. Dermal lymphocytes are T cells of the helper subtype primarily.

Mast cells are tissue-dwelling cells that are most numerous in sites, such as the skin, that interface with the environment. Mast cell numbers in skin vary greatly depending on body location, with numbers ranging from 0–60 per high-power field in cats, and 0–40 per high-power field in dogs. They are in highest numbers in the skin of the caudal pinna in both dogs and cats. They are concentrated around blood vessels, especially postcapillary venules. Mast cells are not present in normal epidermis. Although mast cells are evident in routine HE sections, they are better visualized with Giemsa and toluidine blue, which stain mast cell granules metachromatically.

Mast cells originate in the bone marrow and are released as unidentifiable precursors into the blood. These *immature mast cell precursors are thought to home to the skin* because of mast cell growth factor expression by dermal endothelial cells. Their final differentiation and maturation is controlled by the local microenvironment, including stem cell factor, which is a fibroblast-derived growth factor, and various T-cell-derived cytokines (IL-3, 4, 9, 10). Mast cells have laminin receptors that mediate their adhesion to the extracellular matrix. The perivascular space is rich in laminin, which contributes to the localization of mast cells to this site. Mast cells are a heterogeneous population based on differences in histochemical, biochemical, and functional characteristics that vary between species and different tissues within a single species. Mast cell heterogeneity has been demonstrated in the skin of cattle, dogs, and sheep. A subpopulation of mast cells that does not exhibit metachromasia following formalin fixation has been demonstrated in the skin of dogs and cattle, and heterogeneity of protein content has been identified in dermal mast cells of sheep.

Mast cell granules contain an array of *preformed mediators*; but they are also capable of *synthesizing mediators* such as leukotrienes (LTC_4) and prostaglandins (PGD_2) following stimulation. Tumor necrosis factor-α, a potent pro-inflammatory cytokine, is both preformed and newly synthesized upon activation of mast cells. Mast cells have long been known to be the *critical effector cell* in initiation of acute type I hypersensitivity reactions and in protection against parasitic infections with helminths and ectoparasitic arthropods. More recently, however, it has become apparent that mast cells also function in persistent chronic inflammatory reactions, tissue repair and remodeling, pathologic fibrosis, angiogenesis, hemostasis, hematopoiesis, antibody production, protection against bacterial infections, response to neoplasms, and possibly in control of the hair cycle.

Dermal muscles

Arrector pili muscles are smooth muscles present in all haired skin. They arise in the connective tissue of the superficial dermis and attach to the connective tissue sheath of the hair follicle below the level of the sebaceous gland duct. They are situated on the obtuse angle of the hair follicle and when the muscles contract, the hair follicles are pulled into a vertical position (*piloerection*). This results in formation of air pockets in the hair coat, which provides insulation. Contraction of arrector pili muscles may also be involved in emptying of sebaceous glands. These muscles are largest in skin of the dorsal midline from the neck to the tail. They may be vacuolated in normal animals, especially aged dogs. In addition to arrector pili muscles, pigs also have **interfollicular smooth muscles**. These muscles span the triad of hair follicles at a level midway between the sebaceous and apocrine glands. Their contraction draws the hair follicles together and rotates the outer follicle of the triad. The functional significance of this muscle is uncertain.

Skeletal muscles may be present in the muzzle, forehead, eyelid, and perianal regions. These muscle fibers originate from cutaneous trunci muscle that penetrates into the dermis to allow voluntary movement of the skin. Skeletal muscle fibers also are associated with the large sinus hairs of the face.

Immunologic function

The skin has been proposed to function as an immunosurveillance organ and the term skin-associated lymphoid tissue (SALT), analogous to gut and bronchial-associated lymphoid tissues (GALT, BALT), has been suggested to describe those cellular elements of the skin that deal with antigenic challenges at the skin surface. However, this concept has been disputed because of presumed differences in immune function between the common mucosal immune system and normal skin. The alternative name, **skin immune system (SIS**), has been suggested as a more appropriate term to encompass the skin-specific immune response-associated cells and humoral factors present in normal skin. Key components of this system *include keratinocytes, Langerhans cells, the dermal perivascular unit, and skin-homing T cells.*

- **Keratinocytes** produce multiple inflammatory cytokines, adhesion molecules, and chemotactic factors following nonspecific stimulation, and thereby have a nonspecific proinflammatory and up-regulating effect.
- **Langerhans cells** are thought to trap antigens in the epidermis, migrate out to regional lymph nodes via lymphatics, and present the antigen to T cells. Thus, induction of the immune response does not normally occur within the skin itself but rather in the skin-draining lymph nodes.
- The **dermal perivascular unit** consists of the mast cells, monocytes and macrophages, tissue dendritic cells, and T cells situated around postcapillary venules. As a result of cytokines such as IL-1 and TNF-α released by injured keratinocytes, endothelial cells increase their expression of addressins ICAM-1 and E-selectin and vascular cell adhesion molecule (VCAM-1). These vascular endothelial molecules promote adhesion of circulating leukocytes, especially granulocytes and memory T cells.
- E-selectin is thought to act as an adhesion molecule or vascular addressin for a specific subset of **skin-homing memory T cells**, which have the ligand cutaneous lymphocyte antigen (CLA) on their surface. A circulating pool of such skin-homing T lymphocytes, identified by CLA antigen, represents the cellular basis of immunologic memory of skin.

Thus, it appears that the proinflammatory, up-regulating effects of keratinocytes prepare the dermis for specific immunologic activity, while migrating antigen-presenting Langerhans cells induce expansion of specific lymphocytes in skin-draining lymph nodes. T cells are then recruited to the skin because of binding of skin-specific adhesion molecules to the vascular addressins of dermal endothelial cells.

Hair follicles

Hair serves a number of functions including protection, thermal insulation, social communication, and sensory perception. Arrangement and type of hair follicles vary with species, breed, individual, and body region. In general, however, hair follicle density is greatest over the dorsolateral aspect of the body and least on the ventral aspect. Hair follicles are classified as *primary or secondary*, and *simple or compound*. **Primary hairs** have a large diameter, are rooted more deeply in the dermis, and are associated with sebaceous and sweat glands and an arrector pili muscle. **Secondary hair follicles** are smaller in diameter, are more superficially rooted, and may be accompanied by a sebaceous gland but lack a sweat gland and arrector pili muscle. Follicles in which a single hair emerges from the follicular orifice are termed **simple follicles**; while those in which multiple hairs emerge from a single opening are called **compound follicles**. Each hair of the compound follicle has its own *papilla*; but at the level of the sebaceous gland opening, the follicles unite to exit from a single external follicular orifice. Horses and cattle have simple hair follicles that are evenly distributed. Pigs have simple follicles that are grouped in clusters of two to four surrounded by dense connective tissue. In sheep, the hair-growing areas consist predominantly of simple follicles whereas the wool-growing areas have many compound follicles and consist of clusters of three primary follicles and a number of secondary follicles. Goats have primary follicles in groups of three with three to six secondary follicles associated with each group. Follicular arrangement in dogs and cats consists of two to five large primary hairs surrounded by groups of smaller secondary hairs. The primary hairs tend to be simple while the secondary hairs are compound. As many as 15 hairs may emerge from a single follicular orifice. In cats, secondary hairs far outnumber primary hairs (10–24 secondary hairs : one primary hair).

The hair follicle is formed by a downward invasion of the surface ectoderm (*primary hair germ*) into the underlying mesoderm of the embryo. As they grow down, the epithelial cells envelop a small group of mesenchymal cells in the underlying dermis. These mesodermal cells eventually become the **follicular papilla** that repeatedly induces and maintains growth of the hair follicle throughout the life of the individual. If the papilla is somehow damaged or destroyed, the hair follicle fails to regrow. The epithelial downgrowth eventually becomes canalized to form the hair follicle. In longitudinal section, the fully developed hair follicle consists of three segments:

- the **lower or inferior portion**, from the base of the follicle to the point of insertion of the arrector pili muscle;
- the **isthmus**, the short section from the attachment of the arrector pili muscle to the entrance of the sebaceous duct; and
- the **infundibulum**, extending from the entrance of the sebaceous duct to the follicular orifice.

The entire hair follicle beneath the isthmus, i.e., the inferior segment, can be considered temporary because it disappears during the involution stage of the hair cycle and reforms again during the active phase. In contrast, *the isthmus and infundibular portions of the hair follicle are permanent.*

The **base of the hair follicle** consists of a terminal bulbous expansion of epithelial cells, the hair bulb, with a concavity at its bottom that is occupied by the connective tissue papilla. The *bulb* is composed of the highly proliferative matrix cells and melanocytes and they are separated from the papilla by a thin extension of the basement membrane. The *matrix cells* give rise to six different cell types arranged in concentric layers. *The three innermost layers form the medulla, cortex, and cuticle of the emerging hair.* The next three layers form the *cuticle, Huxley layer, and Henle layer of the inner root sheath.* These layers are further surrounded by the outer root sheath, which is an extension of the epidermis and becomes continuous with the epidermis in the upper portion of the follicle. *External to the outer root sheath* are the *glassy membrane*, corresponding to the basement membrane of the epidermis, and finally the *connective tissue sheath*. All three layers of the inner root sheath keratinize by means of eosinophilic trichohyaline granules and become fully keratinized and disintegrate at the level of the isthmus. The inner root sheath is responsible for providing the rigid support for the developing hair and its final shape, e.g., twisted hair follicles produce curly hairs. From the base of the hair follicle to the isthmus, the outer root sheath is covered by the inner root sheath and it does not keratinize. In the isthmus, where the inner root sheath is no longer present, the outer root sheath undergoes trichilemmal keratinization, i.e., without keratohyaline granules. In the infundibulum, the outer root sheath is identical to surface epidermis and undergoes keratinization with formation of keratohyaline granules.

Hair does not grow continuously but rather in *cycles* consisting of a growth phase, **anagen**; a transitional or involuting phase, **catagen**; and a resting phase, **telogen**. This cyclic activity is thought to be an adaptive response to seasonal variation in ambient temperature. The hair growth cycle varies between different species, breeds, body sites, and hair follicle type. In domestic animals, *neighboring hairs cycle independently of each other and are in different stages of the hair cycle at any one time.* Hair shaft length is directly related to the duration of anagen phase, which is preordained according to body region and genetics. At the onset of catagen, mitotic activity of matrix cells and melanin production by melanocytes of the hair bulb cease. The keratinocytes of the inferior segment of the follicle undergo a controlled process of involution via a burst of apoptosis. This results in the upward migration of the hair follicle and the lower follicle becoming a thin cord of epithelial cells surrounded by a fibrous root sheath. Growth of the inner root sheath stops so that the lower end of the hair shaft is surrounded by thick trichilemmal keratin. The thin cord of epithelial cells is surrounded by a thickened, corrugated glassy membrane; and as it retracts upward, it is followed by the shrunken, contracted papilla. In telogen phase, the base of the bulb is located at the level of attachment of the arrector pili muscle and is approximately one-third of its former length. The base of the hair is encased in trichilemmal keratin and surrounded completely by outer root sheath (*club hair*). A population of stem cells (secondary hair germ) remains somewhere in the permanent portion of the hair follicle. These cells eventually reform the hair follicle during the next growth cycle. In rodents, the *bulge region of the follicle* appears to be the site that contains slow-cycling relatively undifferentiated cells from which arise a population of transient amplifying cells that become the matrix keratinocytes of the new hair bulb. *The bulge region is an area on the outer root sheath at the base of the permanent portion of the hair follicle to which the arrector pili muscle attaches.* It is not yet clear whether or not hair follicles of other domestic species have a similar bulge region of the hair follicle.

Hair growth in many animals has been shown to be regulated by photoperiod, ambient temperature, various hormones, nutritional status, and general health. However, the exact mechanisms that control the cycle are incompletely understood. Growth and development of hair are influenced by many growth factors; these include fibroblast growth factor (FGF), epidermal growth factor (EGF), insulin-like growth factor-1 (IGF-1), transforming growth factor-β (TGF-β), and keratinocyte growth factor (KGF, same as FGF-7). Both IGF-1 and KGF are produced by the dermal papilla and their receptors are found in the overlying anagen hair follicle matrix cells. Factors from the papilla mesenchymal cells are thought to act on a stem cell population in the permanent upper portion of the hair follicle. These competent cells respond to the signals from the papilla by growing deep into the dermis to form the full-length anagen hair follicle. Transition between anagen and catagen appears to be regulated by FGF-5.

The *histologic appearance* of the hair follicle changes considerably during the hair cycle. The **anagen** stage is characterized by a well-developed flame-shaped plump dermal papilla that is capped completely by the hair bulb. The bulb is located in the deep dermis or subcutis and even bulbs of secondary hairs are surrounded by fat because tracts of fatty tissue extend upward from the subcutaneous fat. A layer of columnar matrix cells lines the papilla and melanocytes are dispersed among the matrix cells in pigmented hair follicles. **Catagen** stage is characterized by a thick glassy membrane that is irregular and undulating above the bulb of the hair follicle. The basement membrane between the dermal papilla and matrix is also thickened. The papilla is smaller, more compact because of decreased extracellular matrix and loss of capillary loops, and it is ovoid or round rather than spindle-shaped. The overlying matrix cells are no longer columnar and they appear disorganized. **Telogen** phase is distinguished by the club hair that has a brush-like appearance produced by keratinized fibers extending between the base of the club hair and the cells of the outer root sheath. The dermal papilla is a condensed ball of cells separated from the matrix cells and surrounded by its basement membrane.

Sinus hairs *(tactile hairs, vibrissae) are highly specialized mechanoreceptors that respond to vibratory stimuli as well as static hair displacements.* They are located on the muzzle (whiskers, vibrissae), face, throat, and palmar aspect of the carpus. They are thick, stiff hairs which are tapered distally. Histologically, they are composed of large single follicles surrounded by an endothelial cell-lined blood-filled sinus situated within the dermal connective tissue sheath. The sinus is supplied with numerous nerves; and skeletal muscles attach to the outer sheath of the follicle to confer some voluntary control of the hairs.

Sebaceous glands

Sebaceous glands are distributed throughout the haired skin and are essential for maintaining normal skin and hair. *Sebaceous glands produce sebum, an oily secretion composed of triglycerides, phospholipids, and cholesterol.* This material combines with sweat to form an emulsion that coats the skin to act as a physical barrier to retain moisture and maintain normal hydration, and as a chemical barrier against microbial pathogens. In addition, the oily film coats the hair shafts to give them a glossy sheen; it also acts as a *pheromone*. Lastly, sebaceous glands also appear to be involved with normal hair development, because, in the absence of sebaceous glands, the hair shaft fails to separate normally from the sheath.

Sebaceous glands consist of a solid mass of epithelial cells surrounded by a connective tissue sheath. The periphery of the gland consists of a single layer of cuboidal mitotically active cells resting on a basal lamina, analogous to basal cells of the epidermis. As the cells move inward toward the duct, they enlarge and accumulate lipid that is lost during routine processing. Sebaceous glands are *holocrine glands* and their secretion is formed by decomposition of cells. This is brought about by release of lysosomal enzymes in cells nearest the duct causing them to disintegrate and form sebum, which empties via a squamous epithelium-lined duct into the upper portion of the hair canal. All primary hairs and some secondary hairs have sebaceous glands. They are usually largest in areas with lowest hair follicle density such as mucocutaneous junctions, interdigital spaces, coronet, and dorsal neck and rump. Sebaceous glands are especially numerous and well developed in the chin of cats (*submental organ*), dorsal surface of the tail in dogs and cats (*tail gland*), base of the horn in goats, and infraorbital, inguinal, and interdigital regions of sheep. The footpads and nasal planum are devoid of sebaceous glands, and they are rare in glabrous skin where they empty directly to the skin surface.

Perianal glands

These are specialized secretory glands in the perianal regions, and they are commonly sites for the development of lesions.

- *Anal glands.* These are *specialized apocrine glands* that open directly onto anal skin and into specialized cystic structures on the lateral aspects of the anal canal, the anal sacs. The anal sacs are usually flaccid cystic cavities containing odoriferous secretions, presumably with some territorial marking function. They are present in many species, including domestic and wild felids, ferrets, raccoons, mink, rodents, pigs, and canids.
- *Perianal glands.* These glands are presumed to be *modified sebaceous glands* based on their typical histology, and are comprised of small glands and nests of cells without a prominent ductular network. Islands of these glands are concentrated in the subcutis around the perimeter of the anus, but foci are commonly present over lateral and ventral aspects of the base of the tail, less commonly on the dorsum of the tail, and in the skin of the prepuce and rump. The glands are distinctive, comprised of lobules of large eosinophilic epithelial cells (*hepatoid cells*) surrounded by low numbers of small basal reserve cells. Larger ducts are often lined by stratified squamous epithelium. *Perianal (circumanal) glands are best described in the dog,* and are most developed in entire males. Their function is uncertain, but they may have a role in steroid metabolism, in production of pheromones, and in territorial marking. Similar glands are also present in cats and in pericloacal glands of reptiles, where they probably have similar roles in territorial marking.

Sweat glands

Two types of sweat glands are present in the skin of mammals; they differ in origin, distribution, and possibly in the mode of secretion. These glands have been called apocrine and eccrine glands; but because of questions concerning the mechanism of the secretory process of these glands, the names *epitrichial and atrichial glands have been proposed for apocrine and eccrine glands, respectively.* **Apocrine (epitrichial) sweat glands** develop embryologically from primary hair germ and they are distributed throughout all haired skin, usually deep to the sebaceous glands. *Apocrine glands are associated with primary hair follicles only* and they tend to be largest in areas with lower hair follicle density, such as mucocutaneous junctions, interdigital spaces, coronet, and dorsal midline. Sweat mixes with sebum to form the protective skin surface film. Apocrine sweat glands function in thermoregulation only in horses and cattle. In other species, the secretion may contribute to scent that is involved in social communication. Apocrine secretion may also provide a means of excreting waste products and secreting immunoglobulins that are present on the skin surface. They are *simple saccular or tubular glands* with a coiled secretory portion and straight duct. The secretory portion is composed of a single row of flat cuboidal to columnar epithelial cells surrounded by a single layer of myoepithelial cells situated between the secretory cells and basal lamina. *The duct empties into the pilary canal usually above the entrance of the sebaceous duct or, rarely, directly to the skin surface.* The name apocrine refers to the mode of secretion, which was originally thought to involve pinching off (apo = off) of a portion of the cell. The existence of an apocrine secretory process has been questioned; however, ultrastructural examination of these glands in humans, pigs, horses, and dogs indicates that *several modes of secretion are involved*, including the apocrine type.

In contrast to apocrine glands, **eccrine (atrichial) sweat glands** are derived from the embryonal epidermis rather then from the primary hair germ and they are located only in specialized areas. They occur in the *footpad of dogs and cats, frog of ungulates, snout of pigs, planum nasolabiale of cattle, and medial surface of the carpus of pigs (carpal glands).* The function of eccrine glands is uncertain. The secretion may be involved with scent signaling and in the footpad of cats it may improve frictional capacity of the paw. Eccrine glands are histologically similar to apocrine glands but their ducts open directly to the skin surface. There is no recent detailed examination of eccrine gland secretion to identify the mode of secretion conclusively.

Subcutis

The deepest layer of the skin is the subcutis. It is composed of lipocytes subdivided into lobules by thin bands of collagen and small vessels. The collagenous septa provide structural support by compartmentalizing the subcutis and anchoring the dermis to the fascial planes deep to the subcutis.

DERMATOHISTOPATHOLOGY

The pathology of the skin, more than that of any other organ, has a specialized vocabulary because many histopathologic changes are unique to the skin. The following is a glossary of terms used in dermatopathology.

Glossary

Acantholysis is a *loss of cohesion between epidermal cells* resulting in intraepidermal clefts, vesicles and bullae (Fig. 5.1). This process may also involve the outer root sheath of hair follicles. Acantholysis is caused by the breakdown of desmosomes between keratinocytes and is characteristic of the *pemphigus complex*. It can also be the result of the action of proteolytic enzymes released by neutrophils or eosinophils in an inflammatory process.

Acanthosis specifically indicates an *increased thickness of the stratum spinosum*, and is due to hyperplasia and occasionally to hypertrophy of cells of the stratum spinosum. Acanthosis, however, is *often used synonymously with hyperplasia* when referring to the epidermis.

Apoptosis refers to *individual programmed cell death*. It is usually seen in the basal layer but can be seen in any layer of the epidermis. Apoptotic keratinocytes histologically resemble dyskeratotic keratinocytes and are eosinophilic and shrunken. They are sometimes referred to as *apoptotic bodies* (colloid bodies, hyaline bodies, Civatte bodies).

Atrophy, in regard to the epidermis, is decreased thickness of the epidermis due to *decreased thickness of the stratum spinosum*. An early sign of epidermal atrophy is the loss of the rete ridges in areas of skin where they are normally present. *The extremely thin normal epidermis of domestic animals makes atrophy very difficult to detect.* It is

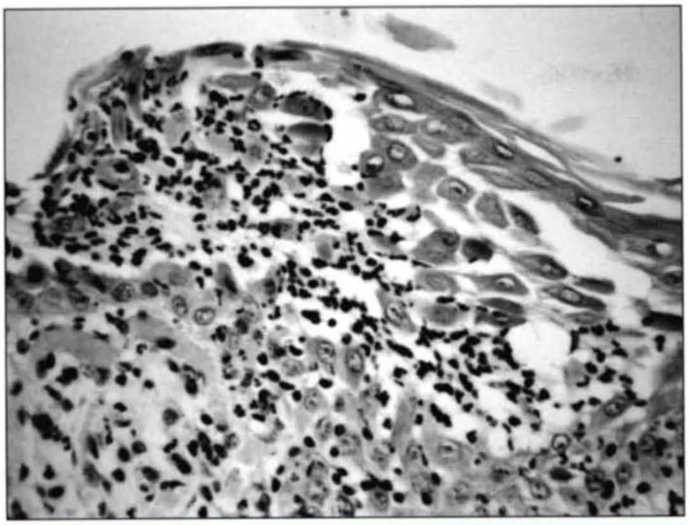

Figure 5.1 Acantholysis in pemphigus foliaceus. Loss of cohesion between keratinocytes leads to individualization of cells. Note cells have normal nuclear morphology.

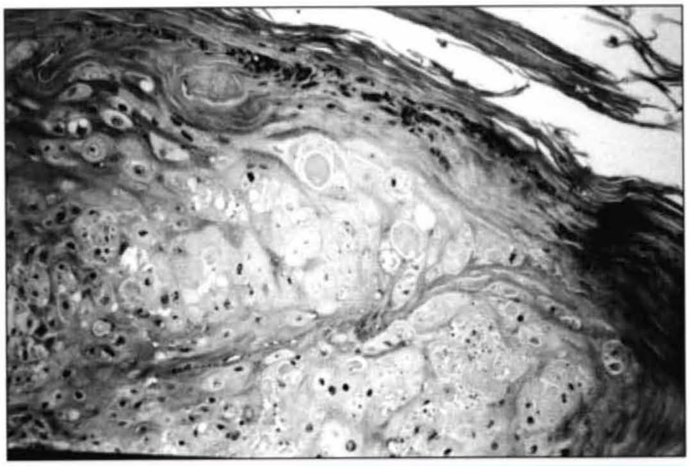

Figure 5.2 Ballooning degeneration in viral dermatitis. Keratinocytes are enlarged and pale due to marked intracellular edema.

seen with endocrine, some immune-mediated dermatoses, and as a result of ischemia. *Dermal atrophy* is thinning of dermal collagen fibrils resulting in decreased dermal thickness, as is seen in some endocrine dermatoses.

Ballooning degeneration of the epidermis is due to *intracellular edema* (Fig. 5.2). It is characterized by swollen eosinophilic cytoplasm, enlarged or condensed nuclei, and a loss of cohesion resulting in acantholysis and sometimes vesicle formation. Ballooning degeneration is a *characteristic feature of viral infections*, particularly of herpesviruses and poxviruses.

Bullae are *collections of fluid* within or below the epidermis greater than 1.0 cm in diameter. They may be caused by severe intercellular or intracellular edema, ballooning degeneration, acantholysis, hydropic degeneration of basal cells, subepidermal edema or other factors resulting in dermoepidermal separation such as the autoantibodies in bullous pemphigoid. Bullae may be *subcorneal, intragranular, suprabasilar or intrabasal, or subepidermal in location.*

Clefts are *slit-like spaces*, which do not contain fluid, within the epidermis or at the dermoepidermal junction. Clefts may be caused by acantholysis or hydropic degeneration of basal cells. However, clefts may also result from handling artifacts.

Collagen degeneration is a *structural and tinctorial change* characterized by slight basophilia, a granular appearance and frayed edges of collagen fibrils, seen with feline, canine and equine eosinophilic granuloma, or other eosinophil-rich conditions, such as mast cell tumors.

Comedo *is a cystically dilated, keratin-filled hair follicle.* Comedones are characteristically seen in Schnauzer comedo syndrome, some endocrine dermatopathies, and actinic dermatitis.

Crusts are consolidated, desiccated surface masses composed of various combinations of keratin, serum, cellular debris and often microorganisms. Crusts are further described on the basis of their composition: *serous* (mostly serum), *hemorrhagic* (mostly blood), *cellular* (mostly inflammatory cells), and *serocellular* (a mixture of serum and inflammatory cells). Crusts should be examined closely for dermatophyte spores and hyphae, *Dermatophilus congolensis*, or large numbers of acantholytic keratinocytes which can be indicators of pemphigus complex. Bacteria are commonly seen in crusts and are not necessarily of diagnostic importance.

Dells are *small depressions or hollows* in the surface of the epidermis independent of adnexal structures. They are usually associated with focal epidermal atrophy and orthokeratotic hyperkeratosis.

Dermal edema is recognized by *dilated lymphatics* (not visible in normal skin), widened spaces between blood vessels and perivascular collagen (*perivascular edema*) or widened spaces between dermal collagen fibers (*interstitial edema*). The dilated lymphatics and widened perivascular and interstitial spaces may or may not contain lightly eosinophilic, homogeneous, proteinaceous fluid. Dermal edema is a common feature of any *inflammatory dermatosis*. Severe edema of the superficial dermis may result in subepidermal vesicles and bullae, necrosis of the overlying epidermis, and predisposition to artifactual dermoepidermal separation during handling and processing of biopsy specimens. Severe edema of the superficial dermis may result in vertical orientation and stretching of collagen fibers, producing the "gossamer" (web-like) collagen effect seen in severe urticaria.

Desmoplasia usually refers to *fibroplasia and collagenous stroma induced by neoplastic processes.*

Dyskeratosis is *premature or abnormal keratinization of individual keratinocytes* in the epidermis or follicular epithelium. Histologically, dyskeratotic cells are eosinophilic and shrunken with condensed, dark-staining nuclei (Fig. 5.3). Dyskeratosis may be seen in a number of dermatoses including lupus erythematosus, erythema multiforme, and graft versus host disease. It can also occur in neoplastic dermatoses, especially papillomas. Dyskeratosis is a feature of the severe epidermal dysplasia that precedes the development of some squamous cell carcinomas.

Dysplasia refers to *faulty or abnormal development* of the epidermis, hair follicles, or any component of the skin. It is an abnormal but nonneoplastic change, however it can accompany neoplastic changes.

Dystrophic mineralization is the deposition of *calcium salts as basophilic, amorphous, granular material along collagen fibrils* as in hyperglucocorticism. Dystrophic mineralization of the hair follicle basement membrane can be seen in hyperglucocorticism, and as a senile change in dogs, especially poodles.

Epidermolytic hyperkeratosis (*granular cell degeneration*) is a change in the stratum granulosum characterized by perinuclear

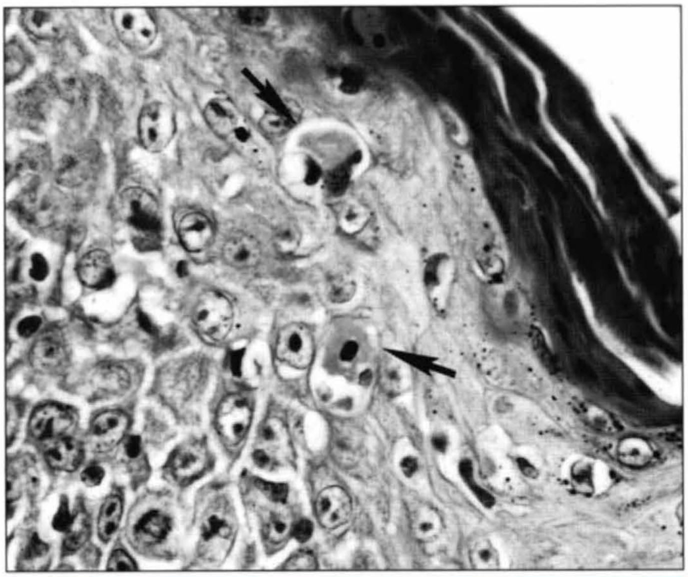

Figure 5.3 Dyskeratosis. Individual keratinocytes have premature or abnormal keratinization. They are shrunken, dark-staining, and have pyknotic nuclei (arrows).

clear halos, large irregular keratohyaline granules, a markedly thickened stratum granulosum, and orthokeratotic hyperkeratosis. It may be seen in certain types of ichthyosis, linear epidermal nevi, or can be an incidental finding in a variety of conditions.

Epidermal mast cells are frequently seen in biopsies from cats with inflammatory dermatoses. They are found within the epidermis as well as the hair follicle outer root sheath, and are most commonly found in diseases associated with tissue eosinophilia, such as feline eosinophilic plaque and feline eosinophilic granuloma.

Exocytosis *is the migration of inflammatory cells and/or erythrocytes through the intercellular spaces of the epidermis.* Exocytosis of inflammatory cells is a common feature of any inflammatory dermatosis. Exocytosis of neutrophils implies an infectious process, whereas exocytosis of eosinophils suggests a hypersensitivity, such as ectoparasitism and feline eosinophilic plaque. Exocytosis of erythrocytes implies purpura, severe vasodilation, or trauma.

Festoons are *dermal papillae, devoid of attached epidermal cells, which project into a vesicle or bulla.* Festoons can be seen in porphyria, bullous pemphigoid and epidermolysis bullosa.

Fibrinoid degeneration is the deposition of fibrin in vessel walls, or in dermal collagen.

Fibroplasia is a reactive process and is the formation and development of fibrous tissue due to increased number of fibroblasts.

Flame figures *are areas of refractile collagen surrounded by eosinophils and eosinophil degranulation products.* In chronic lesions, the eosinophil content decreases, histiocytes increase in number and *palisading granulomas* may be formed. Flame figures may be seen in eosinophilic granuloma, sterile eosinophilic pustulosis, insect/arthropod bite reactions, and other eosinophil-rich conditions.

Flame follicles *are catagen and telogen follicles with pronounced eosinophilic trichilemmal keratin* (Fig. 5.4). These can be seen in endocrinopathies, and are also prominent in normal haired skin of plush-coated breeds of dog, such as the Nordic breeds and Pomeranians.

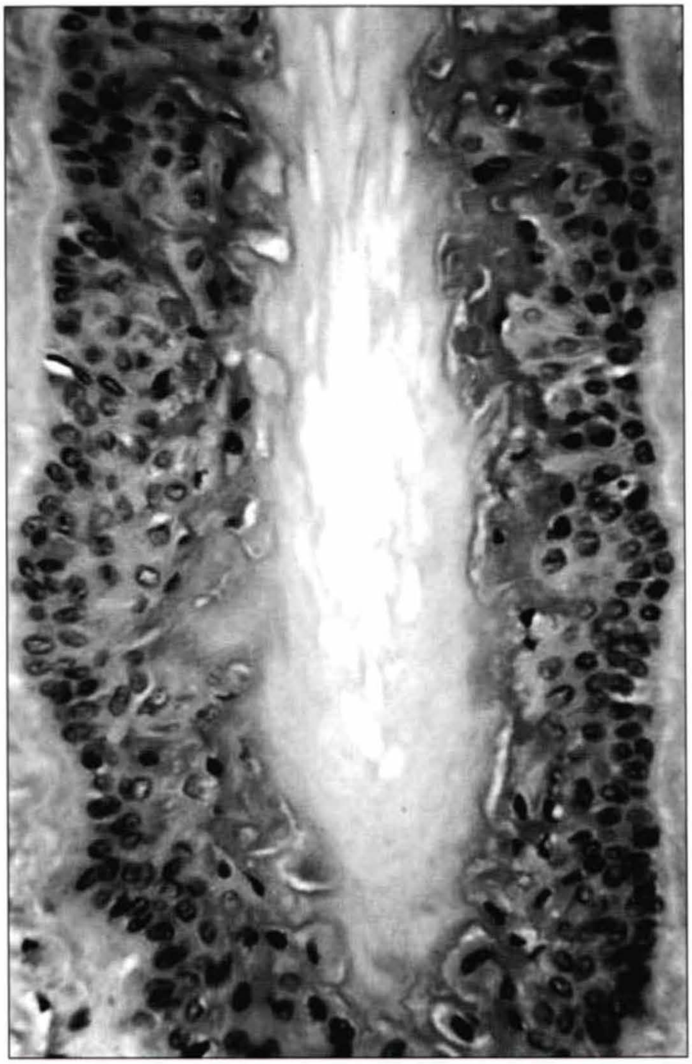

Figure 5.4 Flame follicle. Follicle with pronounced eosinophilic trichilemmal keratinization. The keratin has a serrated border resembling a flickering flame. (Courtesy of B Dunstan.)

Follicular atrophy refers to the *gradual involution and disappearance of hair follicles* characteristic of hormonal dermatoses, follicular dystrophies and ischemia.

Follicular dystrophy indicates *abnormally formed hair follicles.*

Follicular keratosis refers to *keratin-filled hair follicles.* This is a common feature of diverse conditions such as endocrine and many inflammatory dermatoses.

Folliculitis is inflammation of the hair follicle. It can further be divided into *mural folliculitis* (inflammation of the follicular epithelium) (Fig. 5.5A), *luminal folliculitis* (inflammation in the follicular lumen) (Fig. 5.5B), and *perifolliculitis* (inflammation around but not significantly impinging on the follicle) (Fig. 5.5C).

Furunculosis is *inflammation of the hair follicle that has resulted in destruction of the follicular epithelium and release of the luminal contents into the dermis, causing dermal inflammation* (Fig. 5.6). This can be seen in any process that is destructive to hair follicles, such as bacterial infection, dermatophytosis, demodicosis, and trauma.

Granulation tissue formation is a reparative process that is characterized by the presence of fibroblasts, edema, inflammatory cells, and neocapillaries. The blood vessels have plump endothelial cells and

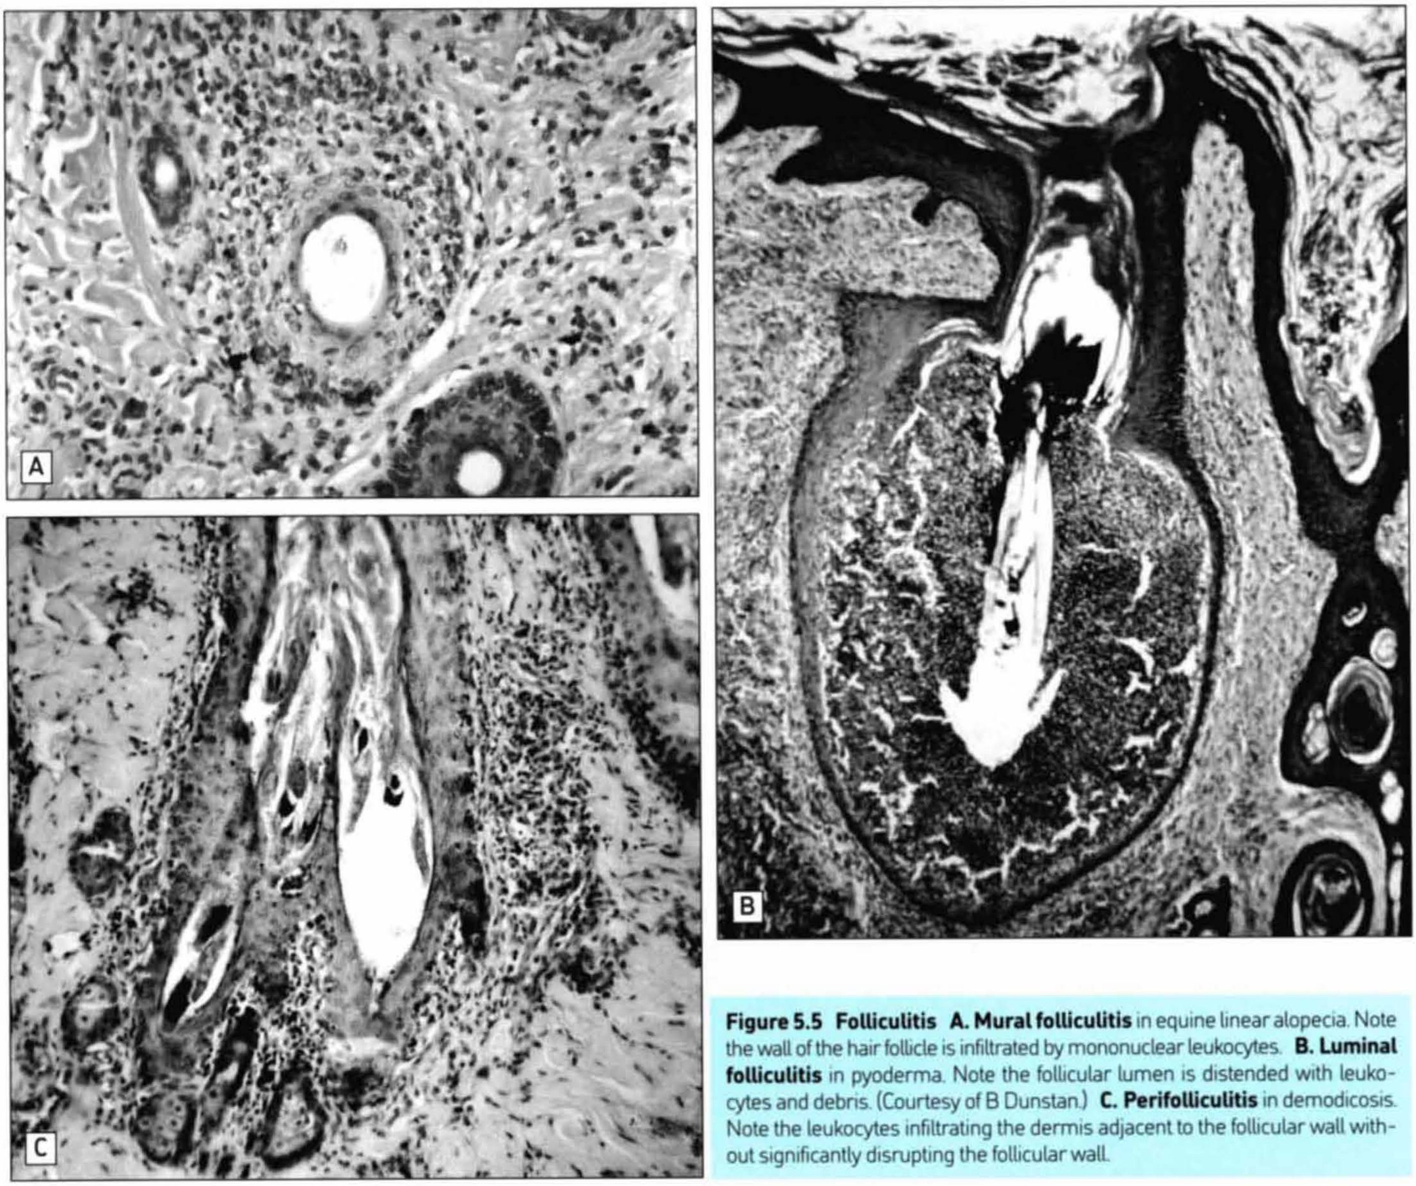

Figure 5.5 Folliculitis A. Mural folliculitis in equine linear alopecia. Note the wall of the hair follicle is infiltrated by mononuclear leukocytes. **B. Luminal folliculitis** in pyoderma. Note the follicular lumen is distended with leukocytes and debris. (Courtesy of B Dunstan.) **C. Perifolliculitis** in demodicosis. Note the leukocytes infiltrating the dermis adjacent to the follicular wall without significantly disrupting the follicular wall.

are oriented perpendicular to the surface of the skin. Fibroblasts and collagen fibrils are oriented parallel to the surface of the skin.

Grenz zone is a *zone of relatively normal collagen that separates the epidermis from an underlying dermal alteration.* A Grenz zone may be seen in neoplastic conditions, such as plasma cell tumors, and granulomatous disorders.

Hamartoma is *a tumor-like malformation composed of an abnormal mixture of normal tissue elements or an abnormal proportion of a single element.* Unlike a **choristoma**, the components of a hamartoma are normal to the location. By definition, hamartomas are congenital lesions, however they may not be detected until later in life and the term is often used interchangeably with nevus, which can be congenital or tardive in onset.

Hidradenitis *is inflammation of apocrine (peritrichial) sweat glands.* These glands commonly become involved secondarily in suppurative and granulomatous dermatoses. Periglandular accumulation of plasma cells is commonly seen in chronic infections, lichenoid dermatoses, and acral lick dermatitis.

Horn cysts (keratin cysts) are circular cystic structures surrounded by flattened epidermal cells. *They contain concentrically arranged lamellar keratin.* Horn cysts are features of a number of follicular and epithelial tumors. **Pseudo-horn cysts** are keratin-filled, cyst-like structures formed by the *irregular invagination of a hyperplastic, hyperkeratotic epidermis.* They are seen in numerous hyperplastic or neoplastic epidermal dermatoses.

Horn pearls (squamous pearls, keratin pearls) are focal, circular, *concentric layers of squamous cells showing gradual keratinization toward the center*, often accompanied by cellular atypia and dyskeratosis. Horn pearls are features of squamous cell carcinoma, keratoacanthoma and pseudocarcinomatous hyperplasia.

Hyalin is an eosinophilic, glassy, homogeneous, refractile material composed of *type IV collagen.* The term is often used as an adjective in descriptions (**hyaline**).

Hypergranulosis indicates *increased thickness of the stratum granulosum*, often accompanied by larger, more intensely stained granules. Hypergranulosis may be seen in any dermatosis in which there is epidermal hyperplasia.

Hyperkeratosis, *increased thickness of the stratum corneum*, is a common finding in many chronic dermatoses. It can be either **orthokeratotic** (without nuclei) (Fig. 5.7A), or **parakeratotic** (nuclei

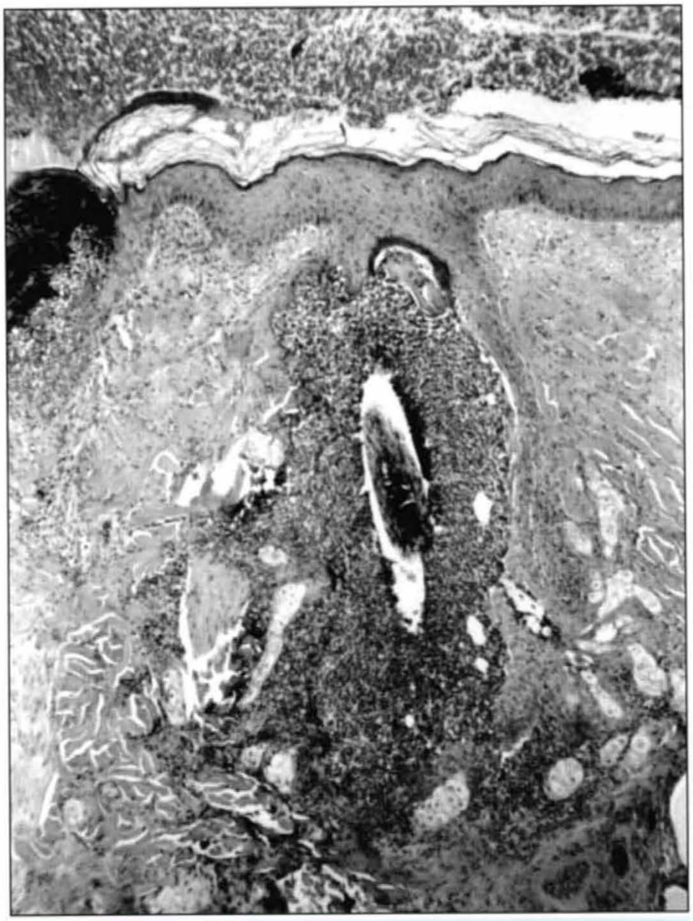

Figure 5.6 Furunculosis in bacterial folliculitis. The wall of the follicle has been perforated and follicular contents are in the dermis.

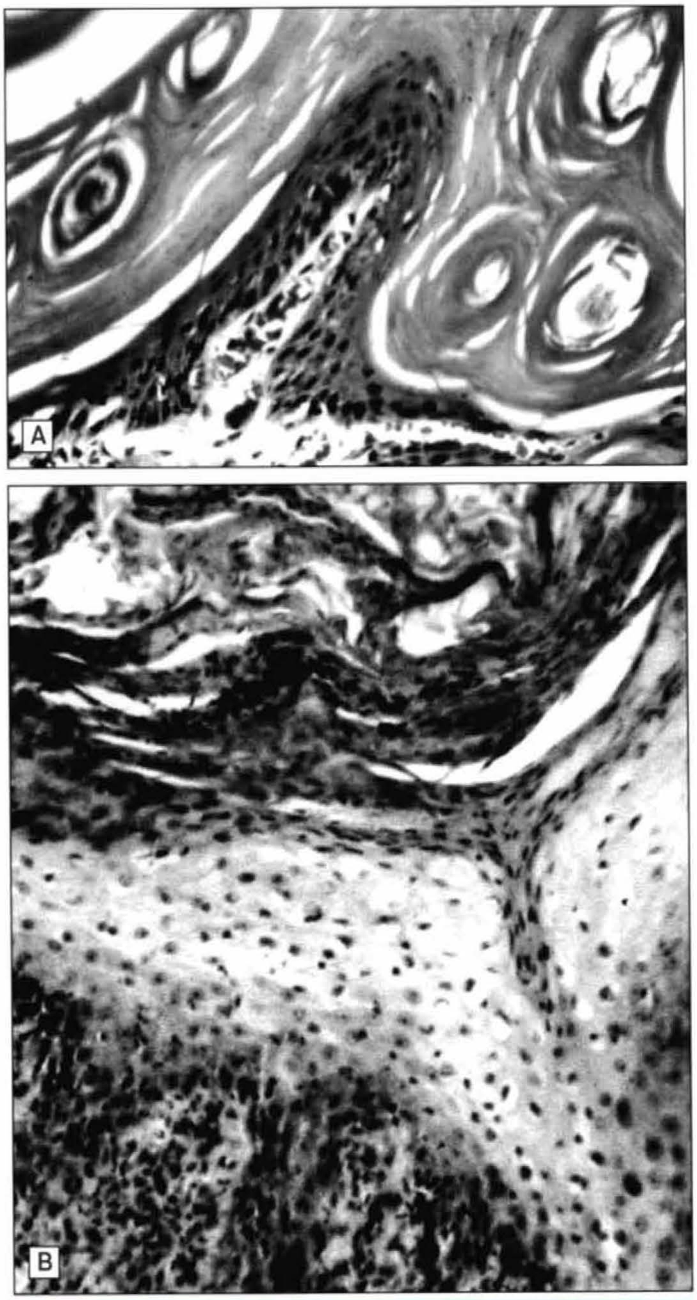

Figure 5.7 A. Orthokeratosis in ichthyosis. Laminated layers of compact anuclear keratin cover the epidermal surface. (Courtesy of B Dunstan.) **B. Parakeratosis** in zinc-responsive dermatosis. A thick layer of keratin with nucleated keratinocytes covers the epidermal surface.

retained) (Fig. 5.7B). *Hyperkeratosis and orthokeratosis are sometimes used synonymously.* Orthokeratosis can be divided into basket weave (the normal pattern in the stratum corneum), compact, and laminated. *Basket weave orthokeratosis* is the most common form, present not only in normal stratum corneum, but also in orthokeratotic disorders such as disorders of keratinization, endocrinopathies and hypersensitivities. *Compact orthokeratosis* can be seen in lichenoid dermatoses, cutaneous horns, and chronic trauma. *Laminated orthokeratosis* characterizes ichthyosis. Orthokeratosis and parakeratosis are not mutually exclusive and are often seen in the same section of hyperkeratotic skin. *Diffuse parakeratosis* can be seen in many chronic dermatoses, especially chronic ectoparasitism, zinc-responsive dermatosis, dermatophilosis, dermatophytosis, or thallotoxicosis. Multifocal parakeratotic caps over the shoulders of follicular ostia is a feature of idiopathic seborrheic dermatitis. Diffuse orthokeratotic hyperkeratosis suggests endocrinopathies, nutritional deficiencies, seborrhea, and ichthyosis. Marked orthokeratotic hyperkeratosis involving the hair follicles suggests vitamin A-responsive dermatosis, acne, Schnauzer comedo syndrome, or endocrine dermatopathies such as hyperadrenocorticism.

Hyperpigmentation refers to *increased melanin within the epidermis and, often, concurrently in dermal melanophages.* Hyperpigmentation may be focal or diffuse, and confined to the stratum basale or present throughout all epidermal layers. It is a common nondiagnostic finding in chronic inflammatory and hormonal dermatoses, as well as in some developmental and neoplastic disorders. Hyperpigmentation must always be cautiously assessed with regard to the animal's normal pigmentation.

Hyperplasia is an increase in the number of cells. In reference to the epidermis, it means an increased thickness due to an increased number of keratinocytes. *Epidermal hyperplasia is a common feature of almost all chronic inflammatory conditions. Acanthosis* is a term often used synonymously with epidermal hyperplasia. Epidermal hyperplasia may be further specified as *irregular* (in which the hyperplastic rete ridges are uneven in shape and height); *regular or psoriasiform* (in which the hyperplastic rete ridges are of even thickness and length); *papillated* (digitate projections of the epidermis above the skin surface); and *pseudocarcinomatous* (extreme, irregular hyperplasia that may

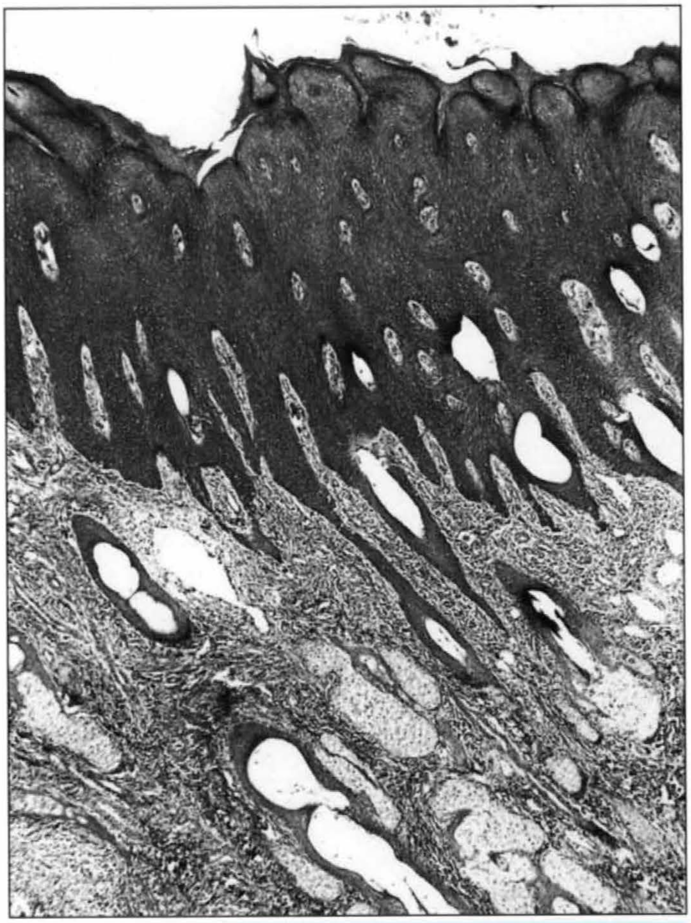

Figure 5.8 Pseudocarcinomatous epidermal hyperplasia. The epidermis has marked, irregular hyperplasia with branched or fused rete pegs. The basement membrane is intact and there is no cellular atypia.

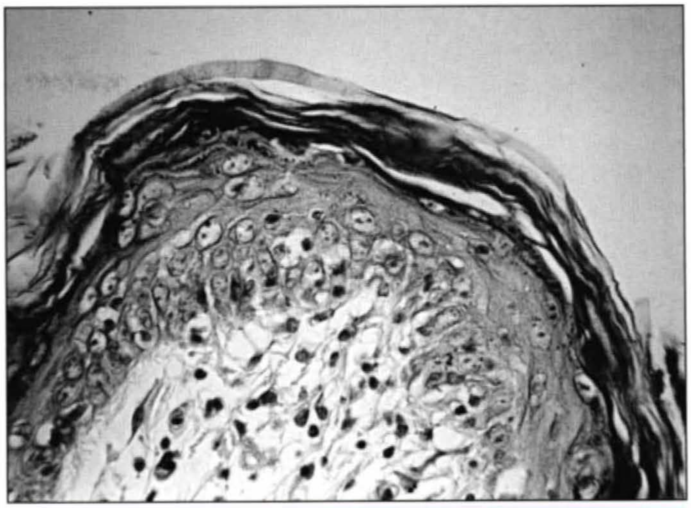

Figure 5.9 Hydropic degeneration. Clear vacuoles are present within and below basal keratinocytes.

demonstrate increased mitotic activity and branched or fused rete pegs) (Fig. 5.8). The process may resemble squamous cell carcinoma; however, there is no cellular atypia, and the basement membrane remains intact. *Irregular epidermal hyperplasia is nonspecific and is the most common type.* Regular epidermal hyperplasia is fairly uncommon and may indicate specific dermatoses, such as lichenoid psoriasiform dermatosis of the Springer Spaniel. Papillated hyperplasia is most commonly seen in seborrheic dermatitis, and in papillomas. Pseudocarcinomatous hyperplasia is most often seen at the margin of a chronic ulcer, or may be associated with underlying chronic dermal suppurative, granulomatous or neoplastic processes.

Hypopigmentation refers to *decreased melanin in the epidermis.* It may be associated with congenital or acquired idiopathic defects in melanization (leukoderma, vitiligo), toxic effects of certain chemicals on melanocytes (e.g., monobenzyl ether of dihydroquinone in rubbers and plastics), inflammatory disorders that affect melanization or destroy melanocytes, hormonal disorders, and dermatoses featuring hydropic degeneration of basal cells (e.g., lupus erythematosus). In those hypopigmented dermatoses associated with hydropic degeneration of basal cells, the underlying superficial dermis usually reveals pigmentary incontinence.

Intracellular edema of the epidermis is characterized by increased size, cytoplasmic pallor, and, sometimes, displacement of the nucleus to the periphery of the affected cell. Intracellular edema of the epidermis may affect cells in a laminar fashion, leading to horizontal layers of edematous keratinocytes. Severe intracellular edema may result in reticular degeneration and intraepidermal vesicles. *Intracellular edema is a common feature of any acute or subacute inflammatory dermatosis.* **Hydropic degeneration** is a specific type of intracellular edema restricted to the basal layer and sometimes the basal cells of the outer root sheath of hair follicles. Hydropic degeneration may result in intrabasal clefts or vesicles, or subepidermal clefts or vesicles due to dermoepidermal separation. It is characterized by clear vacuoles within basal keratinocytes, sometimes accompanied by individual keratinocyte necrosis (Fig. 5.9). **Vacuolar degeneration** is sometimes seen in conjunction with hydropic degeneration and refers to vacuoles above and below the basement membrane zone. Hydropic degeneration of basal cells can be seen in lichenoid dermatitides, drug eruptions, lupoid dermatoses, and dermatomyositis. Caution must be exercised not to confuse freezing artifact or delayed fixation artifact with intracellular edema.

Lymphoid nodules are well-circumscribed, rounded, dense, sometimes perivascular accumulations of predominantly mature lymphocytes in the deep dermis and/or subcutis. They are uncommon and *seen primarily in the cat.* They are seen most frequently in conjunction with immune-mediated dermatoses, dermatoses associated with tissue eosinophilia, and in panniculitis such as injection site panniculitis. They can also be seen in insect-bite granuloma (pseudolymphoma).

Mucinosis (myxedema, myxoid degeneration, mucoid degeneration) is characterized by increased amounts of an amorphous, granular, basophilic material that separates, thins or replaces dermal collagen fibers and surrounds blood vessels and appendages in hematoxylin and eosin-stained sections. Only small amounts of mucin are visible in normal skin, mostly around appendages and blood vessels. Mucin is more easily demonstrated with stains for acid mucopolysaccharides such as Alcian blue and colloidal iron. Mucinous degeneration may be seen as a focal process in numerous inflammatory, neoplastic and developmental dermatoses. Diffuse mucinosis is a feature of normal skin of the Chinese Shar-Pei dog, is occasionally seen in idiopathic mucinosis, and has rarely been reported in hypothyroidism and acromegaly.

Multinucleated keratinocyte. Keratinocytes with multiple nuclei can occasionally be seen in viral infections, such as herpesvirus and FeLV infections.

Munro's microabscess is a small, desiccated accumulation of *neutrophils* within the stratum corneum.

Necrosis is the death of cells or tissues. *Necrotic keratinocytes* are identified by loss of intercellular bridges with resultant rounding-up of the cell, and a normal-sized or swollen eosinophilic cytoplasm. The nucleus becomes pyknotic and cytoplasm becomes eosinophilic and homogeneous, and the cell loses its normal shape. Individual keratinocyte necrosis can occur in drug eruptions, graft-versus-host disease, and interface dermatoses. Necrosis of the epidermis or dermis may be more extensive due to physical and chemical injury, or to interference with vascular supply.

Nests (theques) are well-circumscribed clusters or groups of cells within the epidermis and/or the dermis. Nests are seen in some neoplastic and hamartomatous dermatoses such as melanocytic nevi and melanomas.

Nevus is a focal malformation of the skin, congenital or tardive in onset, consisting of *local excess of one or several of the normal mature constituents of the skin.* The term nevus should always be used with a modifier such as *melanocytic, epidermal, vascular, collagenous, organoid,* etc. The term nevus and hamartoma are often used interchangeably, as, although hamartomas are by definition congenital lesions, they are often not noticed until later in life.

Panniculitis (steatitis) refers to *inflammation of subcutaneous fat.* It can occur without significant involvement of the overlying dermis and epidermis (sterile nodular panniculitis, feline nutritional steatitis, bacterial or fungal panniculitis, lupus erythematosus panniculitis, subcutaneous fat sclerosis), or can be involved by extension of inflammation of the dermis. Fat micropseudocyst formation and lipocytes containing radially arranged needle-shaped clefts can be seen with subcutaneous fat sclerosis and idiopathic sterile panniculitis.

Papillomatosis refers to the projection of dermal papillae and epidermis above the surface of the skin resulting in an irregular undulating configuration of the epidermis. Papillomatosis is often associated with epidermal hyperplasia and is seen with chronic inflammatory and neoplastic dermatoses.

Pautrier's microabscess is a small, focal accumulation of *abnormal lymphoid cells* in the epidermis or follicular epithelium, typical of epitheliotropic lymphoma (Fig. 5.10).

Pigmentary incontinence *refers to the presence of melanin granules free within the subepidermal dermis and within dermal macrophages (melanophages).* It can result from any process that damages the stratum basale, especially hydropic degeneration of basal cells (lichenoid dermatoses, lupus erythematosus, dermatomyositis and erythema multiforme).

Pustules are cavities in the epidermis or follicular epithelium filled with inflammatory cells, usually neutrophils or eosinophils.

Reticular degeneration is caused by severe intracellular edema of epidermal cells. *These cells burst, resulting in multilocular intraepidermal vesicles whose septa are formed by resistant cell walls.* It may be seen with any acute or subacute inflammatory dermatosis, such as acute contact dermatitis.

Satellitosis *refers to individual necrotic keratinocytes in the epidermis surrounded by lymphoid cells (satellite cells)* (Fig. 5.11). It is a characteristic finding in erythema multiforme and occasionally is seen in other interface dermatoses.

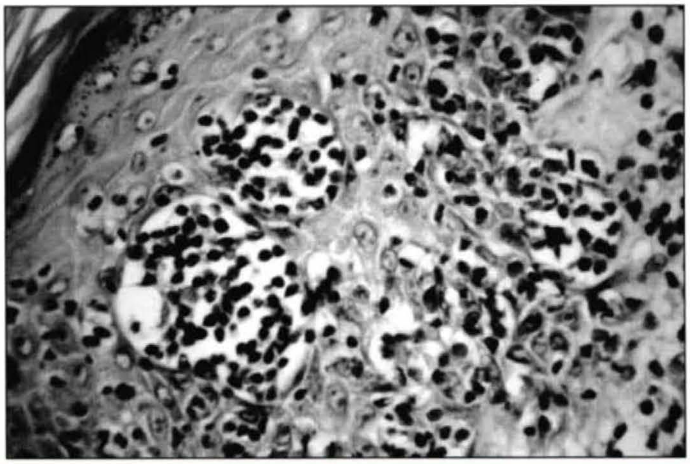

Figure 5.10 Pautrier's microabscess in epidermotropic lymphoma. Nests of neoplastic lymphocytes reside in clear spaces within the epidermis.

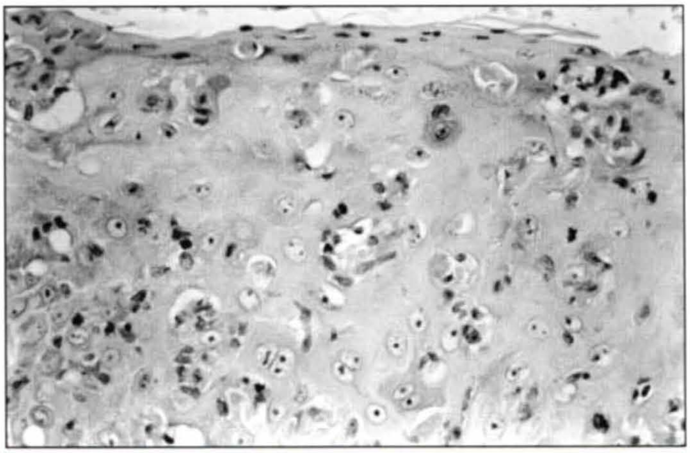

Figure 5.11 Satellitosis in erythema multiforme. Lymphocytes cluster around dyskeratotic, necrotic or apoptotic keratinocytes.

Sclerosis (scar) is the end point of fibrosis. *Increased numbers of collagen fibers* have a thick, eosinophilic, hyalinized appearance and the number of fibroblasts is greatly reduced.

Sebaceous gland hyperplasia refers to increased numbers of sebaceous glands and is common in chronic inflammatory conditions. Nodular aggregates of hyperplastic sebaceous glands are a common senile finding and are frequently multifocal.

Spongiform pustule of Kogoj is *multilocular accumulation of neutrophils within a sponge-like area of the stratum granulosum and stratum spinosum.*

Spongiosis (intercellular edema) of the epidermis is characterized by widening of the intercellular spaces with accentuation of the intercellular bridges, giving the involved epidermis a "spongy" appearance (Fig. 5.12A). Severe intercellular edema may lead to rupture of the intercellular bridges and the formation of *intraepidermal vesicles* (Fig. 5.12B). Severe spongiotic vesicle formation may disrupt the basement membrane zone in some areas, giving the appearance of subepidermal vesicles. Intercellular edema is a common feature of acute or subacute inflammatory dermatoses. Diffuse spongiosis, which also involves the hair follicle outer root sheath, may be seen in

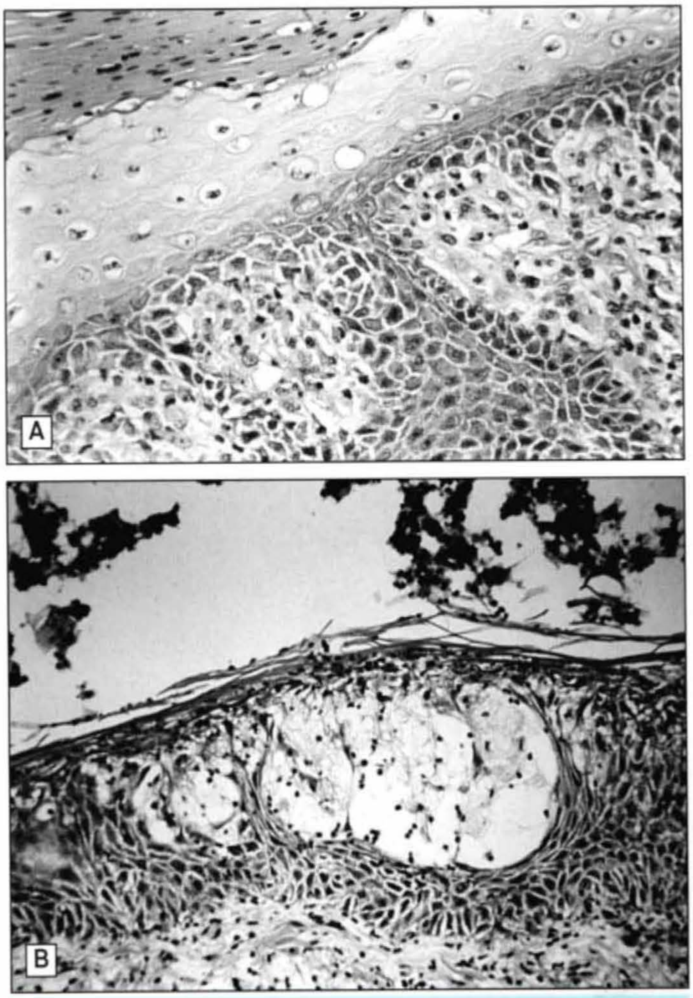

Figure 5.12 A. Spongiosis and laminar intracellular edema in superficial necrolytic dermatitis. Extracellular edema resulting in widening of intercellular spaces between keratinocytes of the deeper epidermis and a linear distribution of pale-staining keratinocytes affected by intracellular edema in the mid-epidermis. **B. Spongiosis with vesicle formation.** Marked intercellular edema has led to breakdown of intercellular bridges and vesicle formation. (Courtesy of B Dunstan.)

other inflammatory disorders including feline eosinophilic plaque or granuloma. Spongiosis of the upper one-half of the epidermis, which is overlaid by marked diffuse parakeratotic hyperkeratosis, is seen in superficial necrolytic dermatitis (hepatocutaneous syndrome).

Squamous eddies *are whorl-like patterns of squamous cells with no atypia, dyskeratosis or central keratinization.* Squamous eddies are features of numerous neoplastic and hyperplastic epidermal disorders.

Transepidermal elimination *is a mechanism by which foreign or altered constituents can be removed from the dermis.* This can be illustrated by the elimination of mineralized collagen across the epidermis and follicular epithelium in calcinosis cutis.

Vesicle is a *fluid filled blister less than 1.0 cm in diameter* in, or immediately below, the epidermis. They may be *subcorneal, suprabasilar, or subepidermal.* When these lesions contain large numbers of inflammatory cells, they may be referred to as **vesicopustules**.

Villus is a dermal papilla covered by one or two layers of epidermal cells that projects into the base of a vesicle or bulla. Villi are seen in pemphigus vulgaris and warty dyskeratoma.

Pattern analysis

The pattern of cell distribution in the skin and the cell types present are extremely important diagnostic clues to many dermatoses. *Pattern analysis is based on recognition of ten different non-neoplastic reaction patterns in the skin at scanning magnification.* At higher magnification, the predominant cell type can be identified and described as *lymphocytic, histiocytic, neutrophilic, eosinophilic, or plasmacytic.* Pattern analysis frequently allows a pathologist to generate a list of differential diagnoses. It is far more efficient to use pattern recognition, and then differentiate between the diseases that demonstrate that pattern, than to learn the histologic features of each disease. It is not unusual to see more than one pattern of inflammation in a biopsy. This can be due to the presence of more than one dermatosis, or due to the presence of both a primary and secondary condition, such as perivascular dermatitis due to a hypersensitivity with a secondary pustular pattern due to pyoderma. Another common combination of patterns would be an overall pattern of perivascular dermatitis (due to hypersensitivity reactions or ectoparasitism) or atrophic dermatosis (due to endocrinopathy) with a subordinate, focal pattern of folliculitis, furunculosis, or intraepidermal pustular dermatitis (due to secondary bacterial infection). It can be difficult to assess the importance of each pattern within the biopsy, and *it becomes very important to recognize which patterns are more specific than others in order to identify the primary condition.* An example would be an interface dermatitis, which is more specific for certain dermatoses than is a perivascular pattern (the least specific).

Perivascular dermatitis

Perivascular dermatitis is the *least specific of the patterns of inflammation,* and it is necessary to observe the type of leukocyte involved and the epidermal changes, in order to create a differential list. In perivascular dermatitis, *the predominant inflammatory reaction is centered around the superficial or deep dermal blood vessels, or both.* Most perivascular dermatitides involve predominantly the superficial dermal blood vessels. Concurrent involvement of the deep dermal blood vessels suggests a systemic disease (infection, immune-mediated). In the horse, most perivascular dermatitides are both superficial and deep. *The primary cause of superficial perivascular dermatitis is a hypersensitivity reaction,* although chronic bacterial infections, viral infections, diseases of altered keratinization, and nutritional deficiencies can all demonstrate this pattern at some point during evolution of the condition. Any perivascular dermatitis containing significant numbers of *eosinophils* should first be suspected of representing an allergic dermatitis such as ectoparasitism, food allergic dermatitis, or atopy. Focal areas of eosinophilic exocytosis and necrosis ("*epidermal nibbles*") are suggestive of ectoparasitism. Other perivascular dermatitides that may contain eosinophils include zinc-responsive dermatosis, equine multisystemic eosinophilic epitheliotropic disease, and chronic pyoderma. Perivascular dermatitis is subdivided on the basis of accompanying epidermal changes into four types:

- In **pure perivascular dermatitis**, there are few or no epidermal changes. The most common dermatoses in this category include acute hypersensitivity reactions and urticaria (Fig. 5.13).
- **Perivascular dermatitis with spongiosis** is characterized by various degrees of spongiosis and spongiotic vesicle formation. Severe spongiotic vesiculation may disrupt the basement

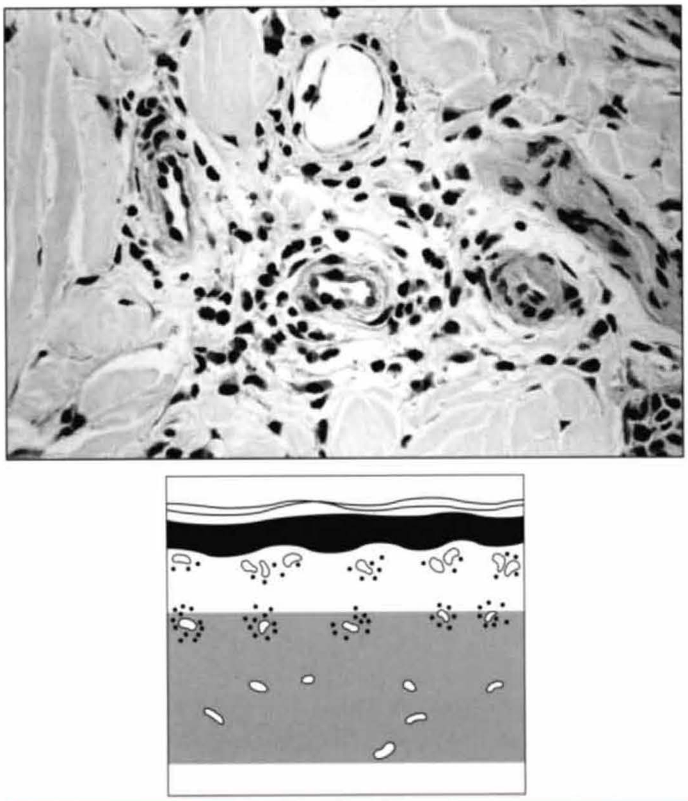

Figure 5.13 Histologic and schematic appearance of **superficial perivascular dermatitis**. *Culicoides* insect bite hypersensitivity. Note leukocytes, in this case eosinophils, surrounding dermal vessels.

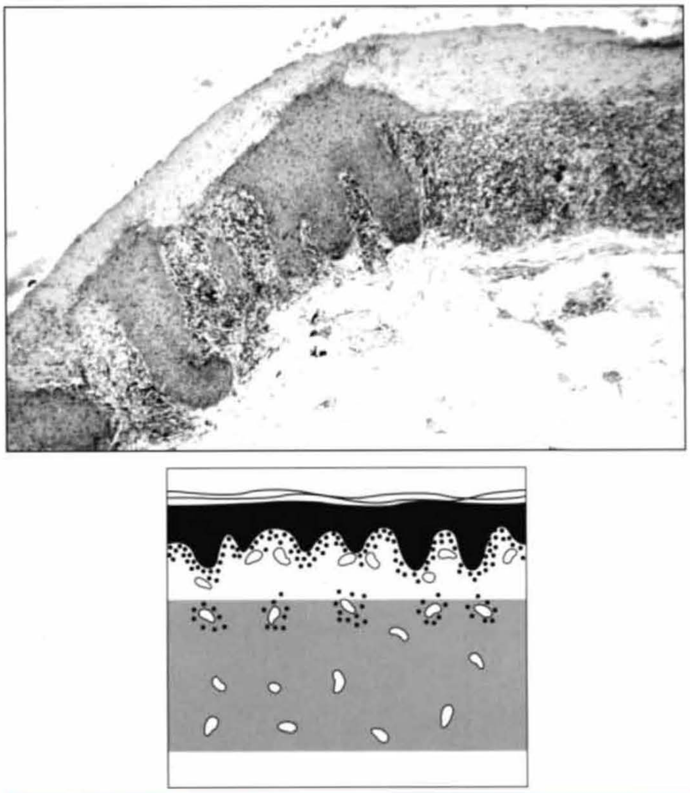

Figure 5.14 Histologic and schematic appearance of **lichenoid interface dermatitis** in discoid lupus erythematosus. Large numbers of lymphocytes and plasma cells abut the epidermal-dermal junction. The basal layer of the epidermis demonstrates apoptosis and vacuolar degeneration of keratinocytes.

membrane zone resulting in subepidermal vesicles. The epidermis usually shows various degrees of hyperkeratosis and hyperplasia. The most common dermatoses in this category include hypersensitivity reactions, acute contact or irritant dermatitis, ectoparasitism, feline eosinophilic plaque, feline miliary dermatitis, and viral infections. When the hair follicle outer root sheath is also involved, feline allergic dermatitides, such as feline eosinophilic plaque and feline eosinophilic granuloma, are suggested.

- **Perivascular dermatitis with epidermal hyperplasia** is characterized by various degrees of epidermal hyperplasia and hyperkeratosis with little or no spongiosis. This is a common, nondiagnostic, chronic reaction pattern. The most common dermatoses in this category are chronic hypersensitivity reactions, diseases of altered keratinization, acral lick dermatitis, and any dermatitis that has undergone chronic irritation and trauma.
- **Perivascular dermatitis with hyperkeratosis** is characterized by various degrees of either orthokeratosis or parakeratosis. The presence of orthokeratosis suggests diseases of altered keratinization (seborrhea) or ichthyosis, and the presence of parakeratosis suggests zinc-responsive dermatosis, chronic ectoparasite hypersensitivity, or *Malassezia* dermatitis.

Interface dermatitis

Interface dermatitis is characterized by damage to the basal layer of keratinocytes, such as basal cell degeneration or necrosis of keratinocytes, that obscures the dermoepidermal junction. This pattern can be divided into interface cell-poor (interface changes with minimal superficial dermal inflammation) or interface lichenoid (interface changes with a lichenoid band of mononuclear inflammation). Pigmentary incontinence and apoptotic bodies are commonly seen in both types.

- The **cell-poor interface pattern** can be seen in diseases such as dermatomyositis, systemic lupus erythematosus, erythema multiforme, drug eruptions, graft-versus-host reactions, bovine viral diarrhea, rinderpest, and bovine pseudo-lumpy skin disease.
- The **lichenoid interface pattern** can be seen with discoid lupus erythematosus, idiopathic lichenoid dermatoses, lichenoid keratoses, Vogt–Koyanagi–Harada-like syndrome (uveodermatologic syndrome), panepidermal pustular pemphigus, lichenoid psoriasiform dermatosis of Springer Spaniels, malignant catarrhal fever, and drug eruptions (Fig. 5.14). The lichenoid band of inflammation is usually lymphocytic and plasmacytic, except in VKH-like syndrome where it is primarily composed of lymphocytes and histiocytes that contain fine melanin granules.

Caution should be exercised in differentiating interface lichenoid inflammation from lichenoid inflammation. The latter refers to a lichenoid band of inflammation, commonly heavily plasmacytic, closely apposed to the dermoepidermal junction, that does not necessarily involve damage to the basal cell layer, such as chronic pyoderma, mucocutaneous pyoderma, and ectoparasitism (scabies or *Cheyletiella*) in dogs. In these cases, the lichenoid band of inflammation can also include neutrophils or eosinophils.

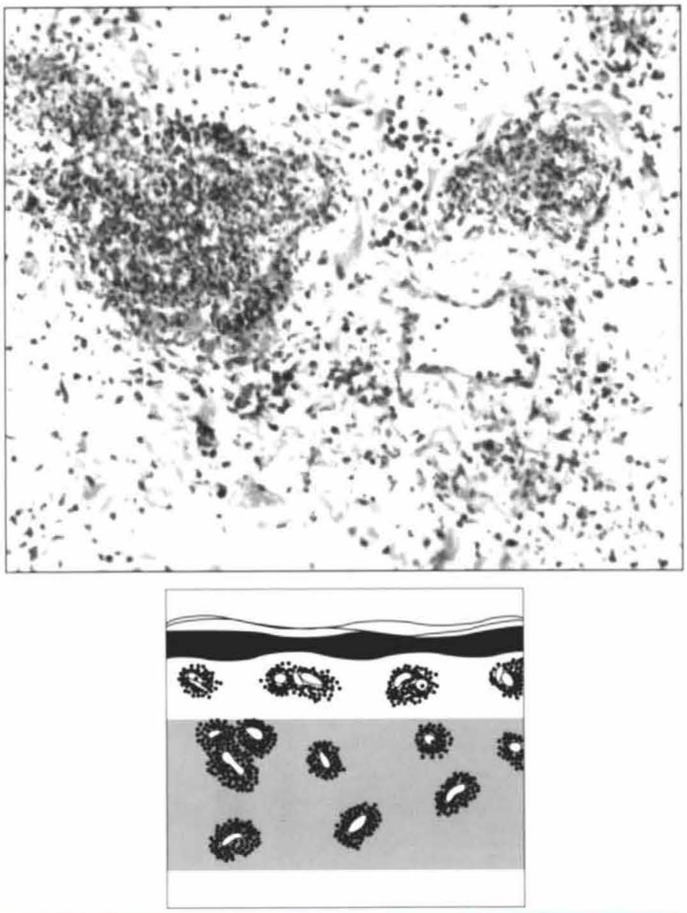

Figure 5.15 Histologic and schematic appearance of **vasculitis**. Leukocytes target vessel walls. Fibrin, erythrocytes and leukocytic debris are in the dermis and vessel walls.

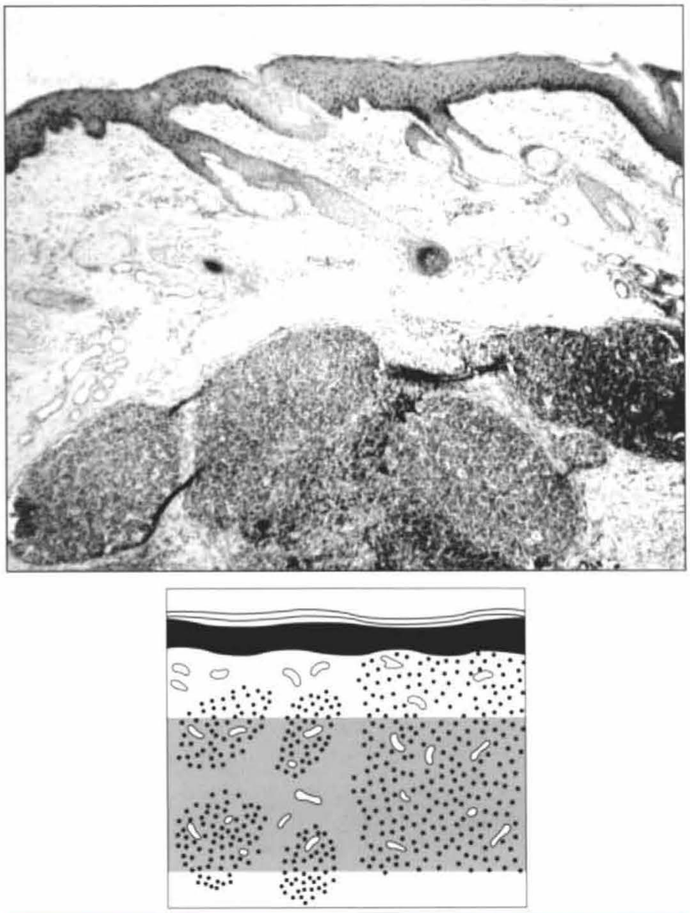

Figure 5.16 Histologic and schematic appearance of **nodular-to-diffuse dermatitis** in fungal dermatitis. Coalescing nodules of lymphocytes, plasma cells, and macrophages obscure the deep dermis.

Vasculitis

Vasculitis is characterized by *inflammation targeting the walls of venules or arterioles*, resulting in at least partial destruction of the vessel wall, sometimes with fibrin deposition (Fig. 5.15). It can be accompanied by fibrinoid necrosis, thrombosis, hemorrhage, and evidence of ischemia. Vasculitis can be immune mediated or septic. *Immune-mediated vasculitis* is due to type III hypersensitivity. The deposition of antigen–antibody complexes in vessel walls activates complement, which results in generation of factors chemotactic for neutrophils. Activation of neutrophils with release of reactive oxygen species and lysosomal enzymes then directly damages vessel walls. *Septic vasculitis* is caused by systemic infection with agents that have a predilection for endothelial cells, resulting in endothelial damage. Vasculitis can also be locally induced by bacterial antigens deposited in vessel walls.

Vasculitis can further be classified on the basis of the *dominant inflammatory cell* within vessel walls. There are neutrophilic, eosinophilic, lymphocytic and mixed types. It should be noted that the inflammatory cell involved often reflects the stage of the disease rather than characterizing a specific disease.

- **Neutrophilic vasculitis** is by far the most common type and may be *leukocytoclastic* (associated with karyorrhexis of neutrophils resulting in "nuclear dust") or *nonleukocytoclastic*. It is seen with connective tissue disorders, hypersensitivity reactions, septicemia, equine purpura hemorrhagica, Rocky Mountain spotted fever, classical swine fever, thrombophlebitis, and as an idiopathic disorder.
- **Lymphocytic vasculitis** may be seen with dermatomyositis, malignant catarrhal fever, vaccine-induced panniculitis, lymphomatoid granulomatosis, and rarely in cutaneous lymphoma. It can also reflect a chronic stage of a vasculitis that was originally neutrophilic.
- **Eosinophilic vasculitis** is rare. It is seen most commonly in lesions induced by arthropod insult, feline eosinophilic granulomas, and rarely in mast cell tumors.

Nodular and diffuse dermatitis

Nodular and diffuse dermatitis is characterized by nodules, or diffuse sheet-like infiltrates of inflammatory cells, in the dermis or subcutis (Fig. 5.16). Nodular and diffuse dermatitis may be characterized by the predominant cell type present (neutrophils, macrophages, lymphocytes, eosinophils, or mixed). The inciting antigen may be an infectious agent, noninfectious material, or the inflammation may be idiopathic. **Neutrophils** predominate in dermal abscesses associated with infectious agents such as bacteria, fungi, algae, and protozoa. They can also be present in sterile lesions, as in foreign body reactions and the sterile pyogranuloma syndrome. **Histiocytes** predominate in *granulomatous inflammation*, which is typically chronic. Granulomatous infiltrates containing large numbers of neutrophils are frequently called *pyogranulomas*. While all granulomatous dermatitis is nodular or diffuse in pattern, not all nodular and diffuse dermatitides are granulomatous.

Granulomas are nodular masses of granulomatous inflammation. They may be subclassified as "tuberculoid" (a central zone of neutrophils and necrosis surrounded by histiocytes, epithelioid macrophages, and giant cells, in turn surrounded by lymphocytes and an outer layer of fibroblasts) or "sarcoidal" (consisting of epithelioid macrophages). *Tuberculoid granulomas* may be seen in tuberculosis, feline leprosy, atypical mycobacterial infection, and *Corynebacterium pseudotuberculosis* infections. *Sarcoidal granulomas* may be seen in sterile sarcoidal granulomas and foreign body reactions. *"Palisading" granulomas* are characterized by the alignment of histiocytes like staves around a central focus of collagen degeneration (feline, canine, and equine eosinophilic granuloma, equine mastocytoma), parasite or fungus (habronemiasis, pythiosis, conidiobolomycosis, basidiobolomycosis, demodicosis), lipids (xanthoma), or other foreign material (e.g., calcium as in dystrophic calcinosis cutis and calcinosis circumscripta). Granulomas and pyogranulomas that track hair follicles resulting in large, vertically oriented ("sausage-shaped") lesions are seen in sterile granuloma/pyogranuloma syndrome of dogs and cats, or can be seen together with folliculitis due to the presence of intrafollicular antigens such as dermatophytes.

Nodular and diffuse dermatitis is often associated with certain unusual inflammatory cell types. **Foam cells** are histiocytes with vacuolated cytoplasm due to their contents (lipid, debris, microorganisms). **Epithelioid macrophages** are histiocytes with elongated or oval vesicular nuclei and abundant finely granular, eosinophilic cytoplasm with ill-defined cell borders. **Multinucleated giant cells** are histiocytic variants that assume three morphologic forms: *Langhans* (nuclei form a circle or semicircle at the periphery of the cell), *foreign-body* (nuclei are scattered throughout the cytoplasm), and *Touton* (nuclei form a wreath which surrounds a central, homogeneous, amphophilic core of cytoplasm that is, in turn, surrounded by abundant foamy cytoplasm). In general, these three forms of giant cells have little diagnostic specificity, although the Touton variety is strongly indicative of xanthomas, and the Langhans type suggests the need for an acid-fast stain. **Eosinophils** may predominate in feline, canine, and equine eosinophilic granuloma, in certain parasitic dermatoses (habronemiasis, elaeophoriasis, parafilariasis, dirofilariasis, dracunculiasis), furunculosis, and in hairy vetch toxicosis. Mixed cellular infiltrates are most commonly neutrophils and macrophages (pyogranuloma), or eosinophils and macrophages (eosinophilic granuloma), or a combination of the three cell types. **Plasma cells** are common components of nodular and diffuse dermatitis in domestic animals and are of no particular diagnostic significance. They may contain eosinophilic, intracytoplasmic inclusions, which are called *Russell bodies*. These accumulations of glycoprotein are largely globulin and may be large enough to displace the cell nucleus. Reactions to ruptured hair follicles are a common cause of nodular and diffuse pyogranulomatous dermatitis in domestic animals, and any such lesion should be examined for keratinous and epithelial debris. All other nodular and diffuse dermatitides should be cultured, examined in polarized light for foreign material and stained for bacteria and fungi. In general, microorganisms are most likely to be found near areas of suppuration and necrosis.

Intraepidermal vesicular and pustular dermatitis

Intraepidermal vesicles and pustules can be caused by intercellular edema which can be seen in any acute or subacute dermatosis, viral infections, hydropic degeneration of keratinocytes, and by acantholysis (Fig. 5.17). It can be useful to subdivide this category on the basis of the site of the vesicle or pustule within the epidermis.

- *Subcorneal pustules and vesicles* are most commonly seen in pemphigus foliaceus, pustules associated with superficial pyoderma, and eosinophilic pustules due to hypersensitivities.
- *Pustules and vesicles in the stratum spinosum* are most commonly seen in the pemphigus complex, viral diseases, and occasionally in hepatocutaneous syndrome.
- *Suprabasilar pustules and vesicles* are a feature of pemphigus vulgaris.

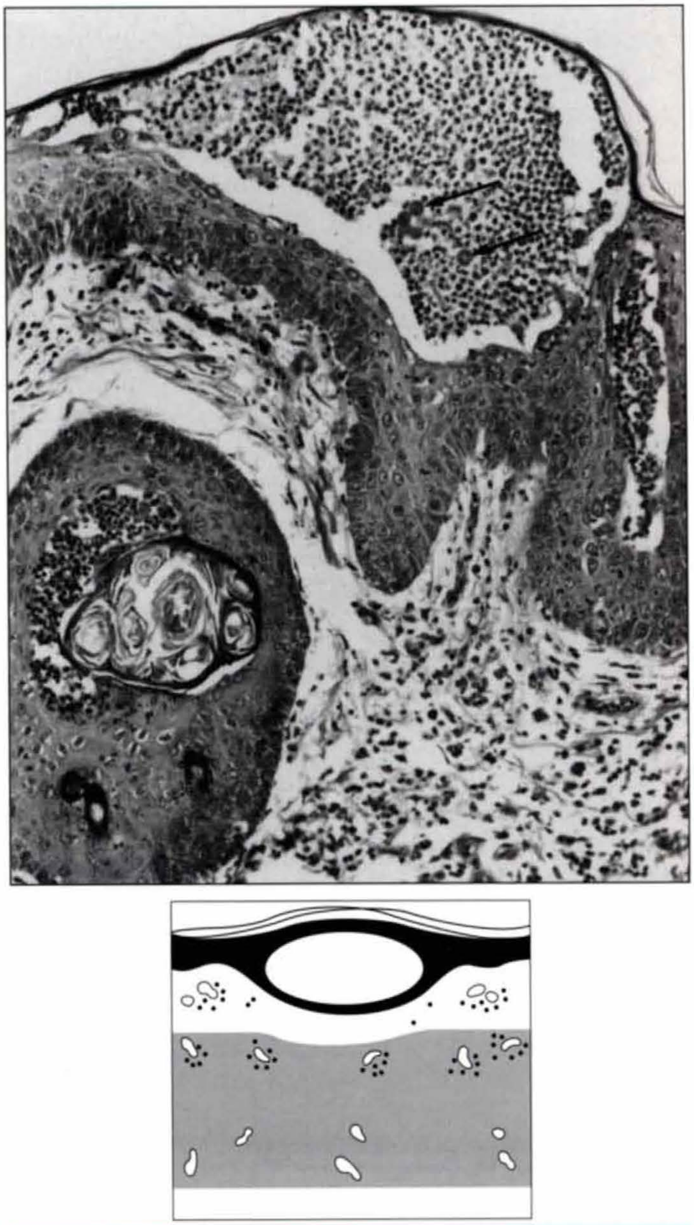

Figure 5.17 Histologic and schematic appearance of **intra-epidermal vesicular/pustular dermatitis** in pemphigus foliaceus. A collection of leukocytes and acantholytic keratinocytes (arrows) are within a subcorneal pustule. The follicular epithelium is also involved.

- *Intrabasilar vesicles* can be seen in lupus erythematosus, dermatomyositis, erythema multiforme, graft-versus-host disease, and toxic epidermal necrolysis.

Subepidermal vesicular and pustular dermatitis

This pattern is characterized by separation of the epidermis from the dermis (Fig. 5.18). Subepidermal vesicles and pustules may be formed through hydropic degeneration of basal cells, dermoepidermal separation, severe subepidermal edema and/or cellular infiltration, and severe intercellular edema with disruption of the basement membrane zone. Caution is warranted when examining older lesions, as re-epithelialization may result in subepidermal vesicles and pustules assuming an intraepidermal location as re-epithelialization forms a pseudo-base to a vesicle. Such re-epithelialization is usually recognized as a single layer of flattened, elongated basal epidermal cells at the base of the vesicle or pustule.

Perifolliculitis, folliculitis, and furunculosis

Perifolliculitis (see Fig. 5.5C) means accumulation of inflammatory cells around a hair follicle in which the inflammation does not significantly impinge on the follicular epithelium. It can be accompanied by mild follicular spongiosis. **Mural folliculitis** (see Fig. 5.5A) is characterized by inflammation which targets the wall of the follicle. **Luminal folliculitis** (see Fig. 5.5B) implies the accumulation of inflammatory cells within follicular lumina. **Furunculosis** (see Fig. 5.6) occurs when the hair follicle ruptures releasing the contents into the dermis. *Perifolliculitis, mural and luminal folliculitis, and furunculosis usually represent a pathologic continuum and all may be present in the same specimen.* Follicular inflammation is a common gross and microscopic finding in dogs, and is less common in other species. It can be caused by intrafollicular bacteria, dermatophytes, and parasites such as *Demodex* spp., *Pelodera strongyloides, and Stephanofilaria* spp. It can also be secondary to pruritus caused by atopy, food allergic dermatitis, ectoparasites, and keratinization disorders such as seborrhea. The folliculitides associated with bacteria, fungi and parasites are usually suppurative initially, whereas those associated with atopy, food allergy, and seborrheic dermatitis are usually predominantly initially spongiotic (small numbers of exocytosing mononuclear cells and/or neutrophils). Any chronic folliculitis, particularly where there is furunculosis, can become pyogranulomatous or granulomatous.

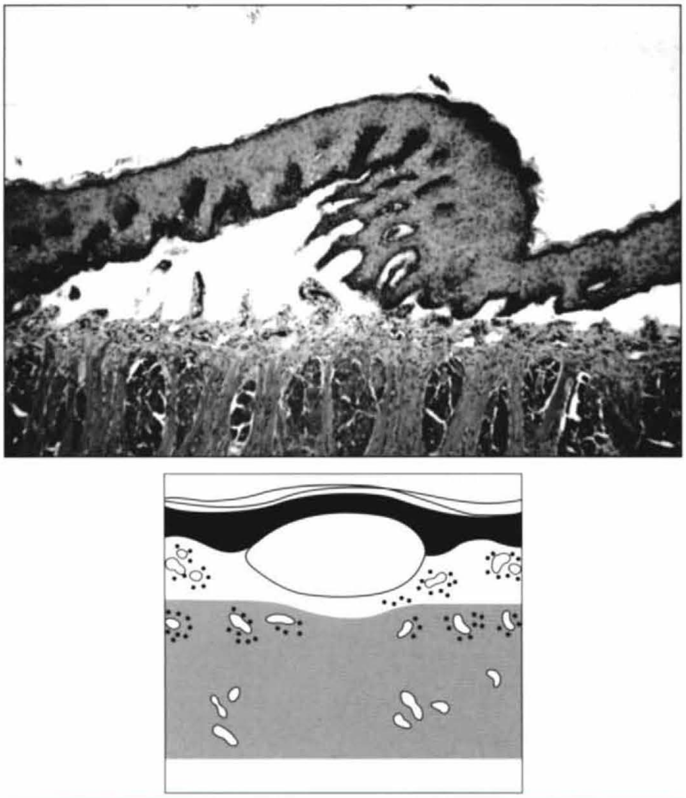

Figure 5.18 Histologic and schematic appearance of **sub-epidermal vesicular dermatitis** in epidermolysis bullosa. The epidermis is separated at the dermal–epidermal junction. (Courtesy of B Dunstan.)

Furunculosis, regardless of the initiating cause, is frequently associated with locally large numbers of eosinophils presumably due to a reaction to released keratin. Idiopathic sterile eosinophilic folliculitides may be seen in cattle and dogs (sterile eosinophilic pustulosis). Insect stings are postulated as the cause of eosinophilic folliculitides affecting the nose of dogs. In cats and horses, sterile eosinophilic folliculitis may be seen in conjunction with hypersensitivity reactions (mosquito bite hypersensitivity, atopy, food allergy, onchocerciasis, equine eosinophilic granuloma, *Culicoides* hypersensitivity, flea bite hypersensitivity). Feline herpesviral dermatitis can also result in eosinophilic folliculitis and furunculosis.

Mural folliculitis can be seen in the pemphigus complex, and these disorders should be considered if there is marked acantholysis. The hair follicle outer root sheath may be involved in hydropic degeneration and lichenoid cellular infiltrates of lupus erythematosus, drug eruptions, erythema multiforme and idiopathic lichenoid dermatoses.

Lymphocytic peribulbitis directed at the bulb of anagen hair follicles is characteristic of alopecia areata. Perifollicular fibrosis is commonly seen in chronic folliculitides, dermatomyositis and chronic granulomatous sebaceous adenitis.

Fibrosing dermatitis

Fibrosis marks the resolving stage of an intense, destructive inflammatory reaction or signifies an ongoing, more insidious, inflammatory process. Fibrosis which is recognizable histologically does not necessarily produce a visible clinical scar. Ulcers limited to the upper portion of the superficial dermis do not usually result in scarring, whereas virtually all ulcers that extend into the deep dermis result in fibrosis and clinical signs of scarring. *Fibrosing dermatitis follows many severe insults to the dermis and is often of minimal diagnostic value.* Common causes of fibrosing dermatitis include furunculosis, equine exuberant granulation tissue, actinic dermatitis, acral lick dermatitis, scleroderma, and morphea (localized scleroderma).

Panniculitis

Panniculitis is inflammation of subcutaneous fat (Fig. 5.19). This inflammation often also secondarily involves the deep dermis. Likewise, the panniculus can be secondarily involved in deep dermal inflammation. Panniculitis may be caused by infectious agents, foreign bodies, vitamin E deficiency, trauma, pancreatic disease, vasculitis, drug eruption, and lupus erythematosus. However, it is often sterile and idiopathic.

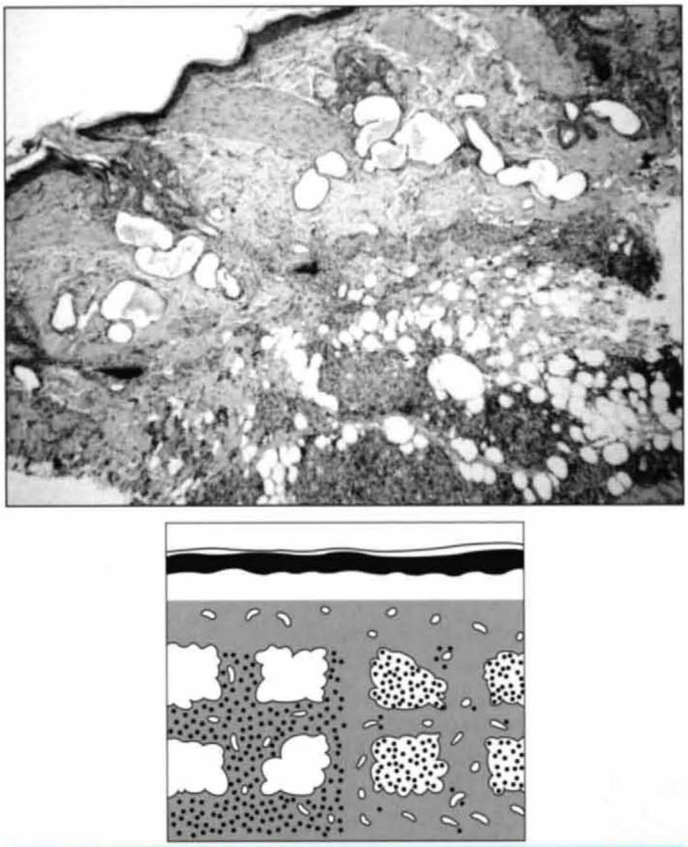

Figure 5.19 Histologic and schematic appearance of **panniculitis**. Inflammation targets the subcutaneous tissues. Note replacement of the adipose tissue with leukocytic aggregates.

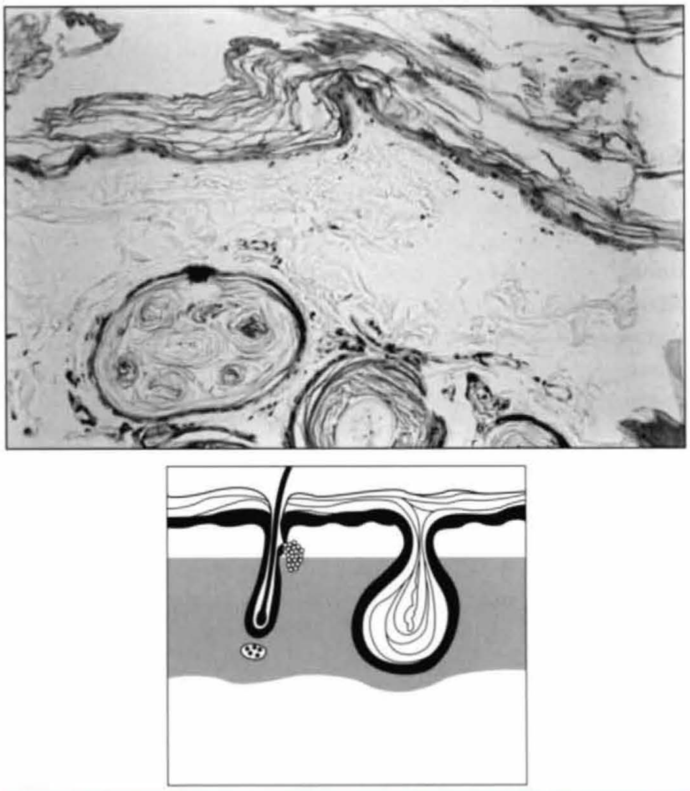

Figure 5.20 Histologic and schematic appearance of **atrophic dermatosis**. The epidermis is 1–2 cells thick, follicles are reduced to small epithelial cell clusters, the dermis has sparse collagen fibers, and sebaceous glands are inconspicuous. In the schematic, note the thin dermis, hyperkeratosis, pilosebaceous atrophy, follicular keratosis and plugging.

Panniculitis can be divided into **lobular** (fat lobules are primarily involved), **septal** (interlobular connective tissue septa are primarily involved), and **diffuse** (both anatomic areas involved) types. However, these anatomical divisions are rarely of diagnostic significance and, in fact, all three patterns may be seen in a single lesion from the same patient. *The majority of inflammatory conditions of the panniculus are granulomatous or pyogranulomatous*, and the histologic appearance of panniculitis due to an infectious agent can be very similar to sterile panniculitis.

In dogs, one form of panniculitis mimics a rare form of lupus erythematosus (lupus erythematosus panniculitis or lupus profundus). It is characterized by lobular hyaline degeneration of fat, lymphocytic vasculitis, lymphoid nodules, and sometimes mucinous degeneration. A similar microscopic lesion occurs in dogs at sites of previous rabies vaccination.

Atrophic dermatosis

Atrophic dermatosis is usually characterized by atrophic changes in the hair follicles and adnexal structures (Fig. 5.20). *It can also refer to atrophy of the epidermis or the dermis. Evaluation of atrophy of the epidermis and dermis should always take into account the site from which the biopsy was taken.* Epidermis is normally thicker on the dorsum than the ventrum, and hair follicles and shafts are larger and closer together on the dorsum than on the ventral or glabrous skin. In addition, familiarity with the various stages of the hair follicle cycle is essential if atrophy of the follicle is to be evaluated. Atrophic dermatosis is often accompanied by some, or all, of the following features: atrophic hair follicles (telogen and catagen follicles are usually predominant), orthokeratotic hyperkeratosis, follicular keratosis, decreased numbers of hair shafts in follicular infundibula, epidermal atrophy, sebaceous gland atrophy, and dermal atrophy (this can be difficult to assess without site-matched controls). Atrophic dermatosis is rarely diagnostic for a specific condition but can suggest a group of diseases such as the *endocrine dermatoses, the most common cause of atrophic dermatosis*. It will almost always be necessary to confirm the identity of the endocrinopathy with endocrinological function tests. Other less common causes of atrophic dermatoses include ischemia, heritable dysplasias such as dermal atrophy in cutaneous asthenia (dermatosparaxis), and paraneoplastic alopecia. Atrophic dermatosis is not an inflammatory pattern, but can be secondarily affected with inflammation, for example, pyoderma superimposed on an endocrine dermatopathy.

Follicular and adnexal atrophy can also be secondary, rather than the primary disease process. An example would be follicular atrophy as a result of a chronic inflammatory process, such as chronic allergic dermatitis, or sebaceous adenitis. In this case there would be histologic evidence of the chronic inflammation previously present, such as scarring.

CONGENITAL AND HEREDITARY DISEASES OF SKIN

Congenital diseases are those that are present at birth. They may be hereditary or result from other factors that were present during development in utero. Various environmental influences, such as infectious agents, nutrient imbalances, toxic chemicals and plants, and ambient temperature, present during gestation can bring about abnormalities in the skin and hair that are present at birth but are not hereditary. Some congenital diseases are incompatible with life and result in death at birth or shortly thereafter. Congenital abnormalities of the skin may be associated with abnormalities of other tissues or organs. In contrast, although they are genetically determined, some hereditary abnormalities of skin (*genodermatoses*) are not apparent at birth and may instead be manifested later in life, i.e., tardive onset. For example, color dilution alopecia may not be evident until early adulthood. These conditions will be covered elsewhere in the chapter under the appropriate section.

As developments in medical science have reduced the incidence of preventable diseases, an increasing awareness of genetic diseases has developed. New genetic disorders are being recognized at an increasing rate as the degree of diagnostic sophistication of veterinary medicine has grown. This is happening, at least in part, because knowledge from genetic disorders in humans often leads to recognition of similar diseases in animals. Once an analogous genetic disease is identified in animals, affected animals may be used to gain new knowledge regarding the genetics, pathogenesis, or treatment of the condition, thereby producing reciprocal benefits for both human and animal health.

Epitheliogenesis imperfecta

Epitheliogenesis imperfecta (EI) is a congenital condition in which localized or widespread areas of the squamous epithelium of the skin and mucous membranes are absent. It is an uncommon to rare anomaly of calves, piglets, foals, lambs, puppies, and kittens. Lesions consist of sharply demarcated, variably sized defects in the epidermis or mucosa, resulting in exposure of a glistening, red, moist, hairless dermis, or oral or esophageal submucosa (Fig. 5.21). Hooves and nails may be absent or poorly developed; teeth may be malformed; and pinnae may be absent. Congenital defects involving other systems are also present in some affected animals. Fetuses with extensive lesions are generally born dead. Affected animals born live may die in early postnatal life because of infection or septicemia, or secondary to dehydration and electrolyte abnormalities resulting from loss of large amounts of water from the nonepithelialized surfaces. Small lesions heal with cicatrization and may be compatible with life. In all species, *histologic lesions are an abrupt absence of epithelium and a lack of adnexal structures in the dermis or rare rudimentary hair follicles devoid of apocrine and sebaceous glands.*

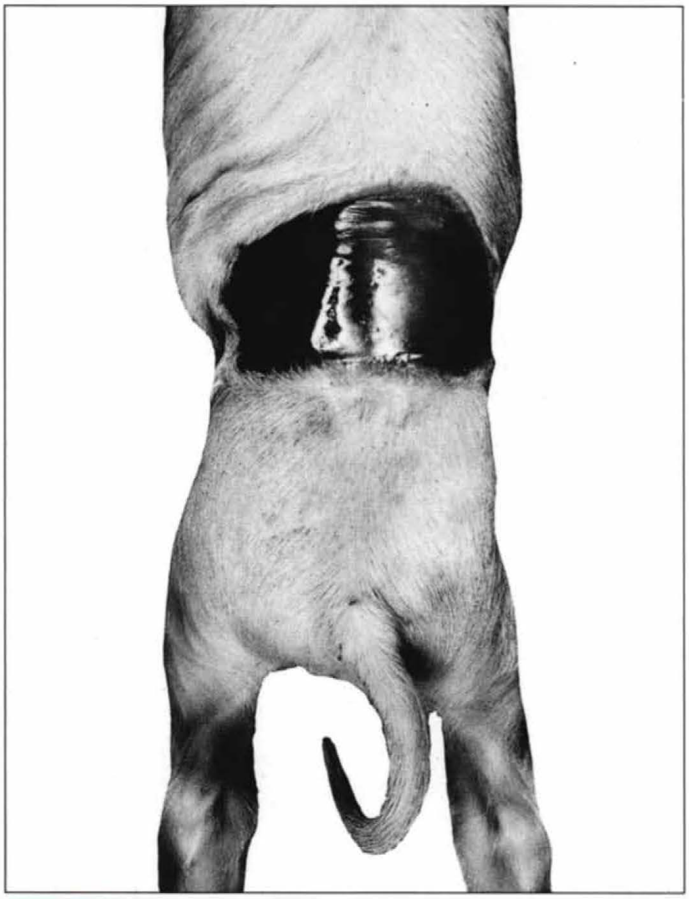

Figure 5.21 Epitheliogenesis imperfecta in a pig.

Epitheliogenesis imperfecta has been reported most often in **calves** and it occurs in many breeds. The condition appears to be an *autosomal recessive trait* and it is seen most often in herds in which there is extensive inbreeding. Both male and female calves are affected. Lesions are usually extensive and involve the extremities most commonly; however, any portion of the body may be affected as well as the squamous epithelium of the muzzle, lips, and oral cavity. Hooves and dewclaws may be missing or incompletely formed. Some affected calves also have deformed teeth and lack pinnae. Brachygnathia and atresia ani have accompanied the cutaneous abnormalities in some calves. Defects in collagen and lipid biosynthesis by dermal fibroblasts have been reported in a calf with epitheliogenesis imperfecta. However, the histologic abnormality seen in this calf was dermal–epidermal clefting; and ultrastructural examination indicated ballooning degeneration and confluent vacuole formation of the basal cells, changes suggestive of epidermolytic epidermolysis bullosa rather than of epitheliogenesis imperfecta.

Epitheliogenesis imperfecta appears to be a recessively inherited trait in **piglets.** Only male piglets were affected in one report and it was thus speculated that the condition is sex-linked. Most piglets have extensive lesions and die shortly after birth. Piglets with small focal lesions may survive but are smaller than normal littermates. At least some affected piglets also have hydroureter and hydronephrosis. Lesions in **foals** usually involve the legs and oral cavity. The proximal esophagus may also be affected and hooves may be lacking. In some instances, teeth are malformed. EI is hereditary in newborn American Saddlebred foals, and is linked to mutation in a gene coding for a laminin subunit protein on equine chromosome 8q. It is unknown, but likely, that EI is genetic in lambs, puppies, and kittens. In **lambs**, epitheliogenesis imperfecta is similar grossly to "red foot," a colloquial term for epidermolysis bullosa, with sloughing of hooves and ulceration of the tongue and hard palate. EI is very rare in **dogs.** In a closed colony of Beagle dogs in which 1500 puppies were born during a 4-year period, only one case occurred, suggesting a spontaneous mutation rather than an inherited anomaly. EI was reported in a litter of Siamese **kittens** with linear ulcers on the tongue.

Wattles

Wattles (tassels), similar to those seen in goats, occur occasionally in pigs and rarely in sheep. They occur in many breeds of **pigs** with no apparent sex predilection and are inherited as an autosomal dominant trait. Wattles are asymptomatic, cylindrical, teat-like structures that hang from the ventral mandibular region. They are 5–7 cm long and may be unilateral or bilateral. Histologically, they are composed of a core of fibrocartilage, surrounded by fibrous and adipose connective tissue, and covered by haired skin. Wattles have also been reported in Dorset Down, Merino, and Karakul **sheep**. The structures in sheep are smaller than those of pigs and they lack the fibrocartilaginous core seen in wattles of goats and pigs.

Ichthyosis (congenital disorders of cornification)

Ichthyosis is a heterogeneous group of disorders of cornification that are all characterized by hyperkeratosis and accumulations of scales (Fig. 5.22). The name is derived from the Greek word for fish because of the fish scale-like appearance of the hyperkeratotic skin. Ichthyosis in animals is a rare congenital condition that has been reported in cattle, dogs, pigs, chickens, laboratory mice, and a llama. The disease in humans is classified into four major and several minor forms based on clinical, histologic, cell kinetic, and genetic characteristics. Kinetic studies have shown that two of the major forms, lamellar ichthyosis and epidermolytic hyperkeratosis, are proliferation keratoses resulting from accelerated cell turnover causing abnormal cell maturation and excessive keratin. In contrast, icthyosis vulgaris and X-linked ichthyosis, the other two major forms, are retention hyperkeratoses related to increased cohesiveness between stratum corneum cells resulting in decreased loss of keratin. The biochemical defects in the various types of ichthyosis are still being investigated.

Ichthyosis vulgaris, the most common form in humans, is an autosomal dominant disease characterized histologically by orthokeratotic hyperkeratosis and a decreased or absent granular layer, and ultrastructurally by a delay in dissolution of desmosomes in the stratum corneum and small, abnormal keratohyaline granules. It is produced by a defect in synthesis of filaggrin. **X-linked ichthyosis**, a recessive form in which males have more severe disease than female heterozygotes, is caused by an absence of steroid sulfatase activity. Steroid sulfatase acts on cholesteryl sulfate, a product of lamellar granules or Odland bodies, which is discharged into the intercellular space and is involved in cell cohesion in the lower stratum

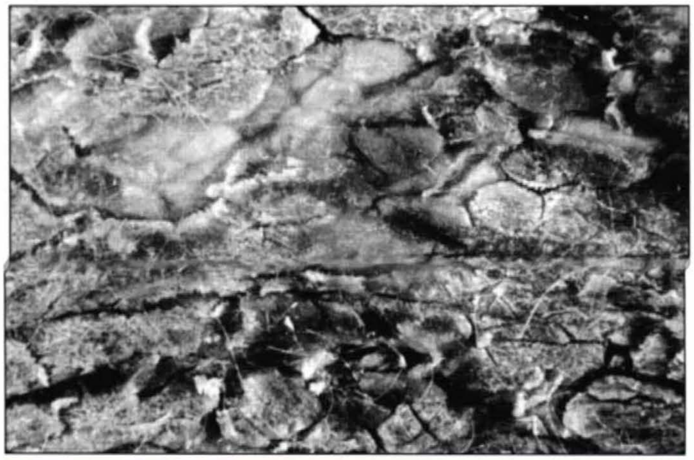

Figure 5.22 Ichthyosis. Note adherent plaques of keratin. (Courtesy of B Dunstan.)

corneum. Failure of the enzyme to inactivate cholesteryl sulfate results in persistent cell cohesion and interferes with the normal process of desquamation. The histologic features of X-linked recessive ichthyosis are orthokeratotic hyperkeratosis with a normal or hyperplastic granular layer. Keratohyaline granules are ultrastructurally normal. **Epidermolytic hyperkeratosis**, also called bullous congenital ichthyosiform erythroderma or bullous ichthyosis, is an autosomal dominant form characterized histologically by orthokeratotic and parakeratotic hyperkeratosis, vacuolation of keratinocytes in the upper stratum spinosum and stratum granulosum, and a markedly thickened granular layer with increased numbers of irregularly shaped keratohyaline granules. Ultrastructural changes consist of increased numbers and clumping of tonofilaments, premature formation of keratohyaline granules, and abnormal association of desmosomes and tonofilaments resulting in acantholysis. The biochemical basis is a defect in the K1 and K10 genes. **Lamellar ichthyosis** is an autosomal recessive ichthyosis characterized histologically by compact orthokeratotic hyperkeratosis and mild acanthosis. It is thought to be caused by a defect of keratinocyte transglutaminase which results in decreased cross-linking of loricrin and involucrin and thus interferes with formation of the cornified cell envelope. **Harlequin ichthyosis** is a rare autosomal recessive, usually fatal form to which some cases of ichthyosis in calves have been compared. In this form of ichthyosis, there is a thick compact stratum corneum with follicular hyperkeratosis and variable appearance of the stratum granulosum. The exact biochemical defect is uncertain but abnormal lamellar granule formation and secretion and a defect in protein phosphatase, which may be involved in processing of filaggrin, have been demonstrated. The majority of cases of ichthyosis in animals have been compared to lamellar ichthyosis of humans based on the clinical and light microscopic features (Fig. 5.23). However, *cases that have been characterized more completely do not correlate well with the human classification system*. The biochemical defect has not been determined in any of the cases of ichthyosis reported in animals thus far.

Ichthyosis has been reported in many breeds of **cattle** and the mode of inheritance appears to be *autosomal recessive*. Both males and females are affected. Two forms of ichthyosis have been described in cattle, *ichthyosis fetalis* and *ichthyosis congenita*. However, the underlying molecular defect(s) is unknown, and it is uncertain whether the forms are distinct diseases or merely represent variations in expression of a single abnormality. *Ichthyosis fetalis* is the more severe form and it has been compared to the harlequin fetus form of ichthyosis in humans. Affected calves are dead at birth or die shortly after birth. The skin is hairless and covered by thick scales divided into plates by deep fissures which represent normal cleavage planes of the skin. The tight, inelastic skin is everted at the mucocutaneous junctions and the ears are usually smaller than normal. *Ichthyosis congenita* is a less severe form compatible with life in which the limbs, abdomen, and muzzle are primarily involved. The skin is dry, hard, and inflexible like old leather and may be prominently folded. There are flat plates of hyperkeratosis in which dense mats of hairs are entrapped. The keratin plaques are separated by shallow hyperemic fissures. The condition is characterized histologically by *prominent laminated orthokeratotic hyperkeratosis of the epidermis and superficial portion of hair follicles*. The epidermal surface is wrinkled or folded and acanthosis is variable.

Ichthyosis has been reported rarely in various purebred and mixed-breed **dogs**. In all cases, parents of affected animals have been clinically normal and thus a *recessive mode of inheritance was suspected*; however, the pattern of inheritance has not been documented by breeding studies. The biochemical abnormality has not been identified in any of the cases, but ultrastructural findings and cell kinetic studies performed in a few dogs with ichthyosis suggested a *proliferative mechanism* for the condition. Lesions are evident at birth; and both male and female pups are affected. The entire body is usually involved but in some cases lesions are limited to the sparsely haired portions of the body. Tightly adherent light tan-gray or parchment-like scales or thick plaques are frequently widely distributed. The skin is variably thickened and may be greasy; and the hair is thin and dull or absent in patches. Some affected dogs are smaller than their normal littermates. Footpads are frequently also hyperkeratotic and appear to be painful. Histologically, there is *marked orthokeratotic hyperkeratosis that includes the infundibular portion of hair follicles*. The epidermal surface is frequently irregular and the epidermis is mildly to moderately hyperplastic. In many of the cases, the granular layer contains an increased number of enlarged and irregular keratohyaline granules and many cells are vacuolated and degenerated leading to microvesicle formation. The dermis is usually normal or has nonspecific inflammation.

Several familial disorders of cornification have been described in dogs. An unusual hereditary condition has been reported in five related *female*

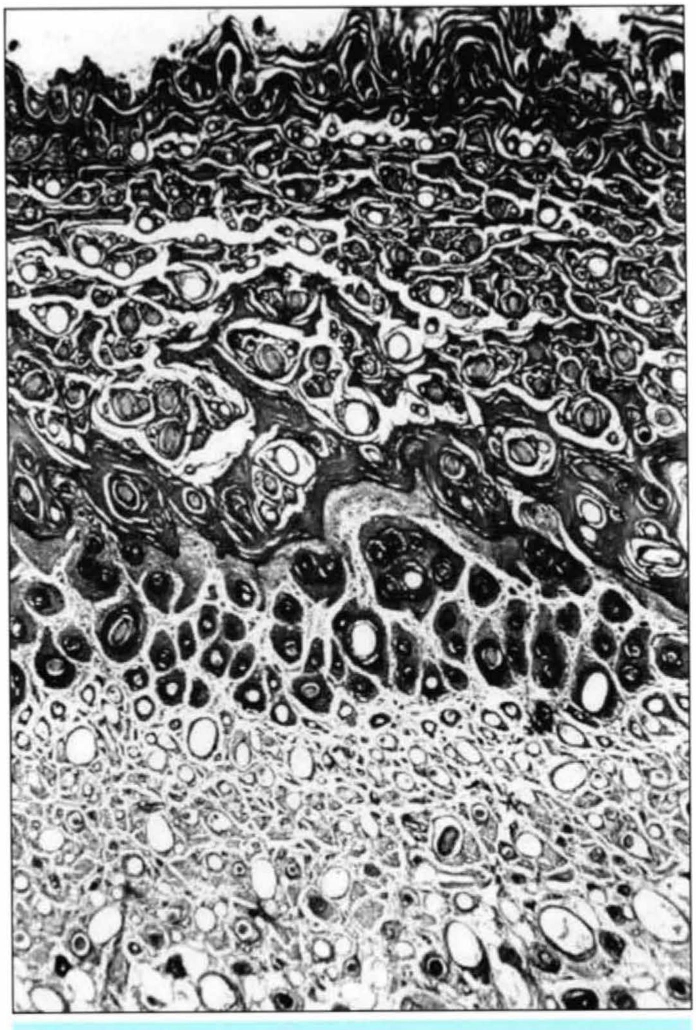

Figure 5.23 Ichthyosis. Note the thick layer of excess keratin adherent to the epidermal surface. (Courtesy of B Dunstan.)

Rottweiler dogs. Since no related males were affected, an X-linked mode of inheritance was suspected. Cutaneous lesions consisted of generalized scaling and hyperkeratotic pigmented plaques. Three dogs also had multiple noncutaneous congenital anomalies. Histologic findings in these dogs included intracellular keratinocyte edema, epidermal vacuoles, and primarily parakeratotic hyperkeratosis of the surface and follicular epidermis. Ultrastructural changes in two of the dogs included large keratohyaline granules, tonofilament clumps, and numerous lipid vacuoles in the stratum corneum and granulosum. The clinical, histologic, and ultrastructural features of this disorder cannot be classified into any single disorder of cornification in humans. *Hereditary footpad hyperkeratosis* has been reported in Irish Terriers and in a family of Dogues de Bordeaux. All footpads become progressively hyperkeratotic, fissured, and painful. Both males and females are affected and lesions are evident by six months of age. The mode of inheritance has not been determined. The histologic features are mild to moderate papillated epidermal hyperplasia and diffuse orthokeratotic hyperkeratosis.

Hereditary zinc deficiency

Hereditary zinc deficiency occurs in cattle and Bull Terrier dogs and results in multisystemic disease that includes skin lesions. Animals are normal at birth and usually begin developing skin lesions at approximately one to two months of age at which time growth retardation also becomes evident. Skin lesions consist of crusting which is most prominent on the face and distal extremities, dry flaky skin, and hair color fading. A decrease in serum zinc concentration precedes clinical signs; and alkaline phosphatase, a zinc-dependent enzyme, frequently decreases in parallel with the zinc concentration. Affected animals also commonly have diarrhea. Animals with hereditary zinc deficiency have a hypoplastic thymus; and, consequently, secondary infections are common because of associated immune system dysfunction involving both humoral and cell-mediated immunity. The condition is an *autosomal recessive trait* in both cattle and dogs; and it is considered analogous to acrodermatitis enteropathica of humans. *The characteristic histologic lesion is marked diffuse parakeratotic hyperkeratosis*.

Hereditary zinc deficiency in cattle is also called *lethal trait A 46, hereditary parakeratosis, hereditary thymic aplasia*, and *Adema disease*. It affects Friesian cattle and Black Pied Danish cattle of Friesian descent in Europe, and has been reported in Shorthorn cattle in the United States. The condition normally begins with depression, diarrhea, and skin lesions when calves are 4–8 weeks of age. The skin becomes dry and flaky and the hair coat is rough. Patches of erythema, scaling, oozing, crusting, and alopecia begin on the muzzle and then appear around the eyes, ears, and intermandibular space. Similar lesions develop later on the legs; and the skin around the stifles, fetlocks, and coronary bands becomes particularly crusty, fissured, and painful. The flanks, perianal area, and ventral abdomen may also be affected. The hair may lighten in color, a change that may be especially prominent around the eyes and resemble the spectacle lesion of copper deficiency. Affected calves are lethargic, drool, and may have difficulty suckling. They are smaller than unaffected calves of the same age. Conjunctivitis, rhinitis, bronchopneumonia, and other infections are common because of *immune dysfunction*. Untreated calves usually die 4–8 weeks after the onset of clinical disease.

Oral zinc supplementation effects a complete reversal of clinical signs and may restore thymic morphology if instituted early enough. *Intestinal malabsorption of zinc is the cause of the disorder in cattle*. Zinc is absorbed from the intestine by two separate pathways, i.e., a transporter-dependent active system and passive diffusion, and it is the zinc-binding ligand system which is suspected to be defective. A cysteine-rich intestinal protein (CRIP) has been identified in the ligand-dependent pathway and has been suggested as being defective in this condition.

The most striking and consistent gross abnormality is *marked thymic hypoplasia*. Histologic abnormalities include *depletion of small lymphocytes* of the thymus, especially in the cortical region, and hypoplasia of the spleen, lymph nodes, and Peyer's patches. The skin lesions are characterized histologically by *perivascular dermatitis, acanthosis, pallor and vacuolation of the upper spinous and granular layers, and marked diffuse parakeratosis*. Neutrophilic exocytosis and superficial bacterial cocci may be prominent.

Lethal acrodermatitis of Bull Terrier dogs is also thought to be caused by an abnormality in zinc absorption or metabolism; however, zinc supplementation fails to produce clinical improvement. The concentrations of both serum zinc and copper have been found to be lower in affected bull terriers as compared to control dogs, raising the question of the role of copper deficiency in the pathogenesis of the canine disease. The condition is characterized by growth retardation, progressive skin lesions, paronychia, diarrhea, abnormal behavior, bronchopneumonia, and death usually by 18 months. Some affected puppies have lighter pigmentation than their normal littermates and this difference becomes more pronounced with age. By 2 months of age, they are obviously smaller than their normal littermates. Skin lesions usually begin by 6–8 weeks of age and consist of crusty exfoliative lesions involving the distal extremities, footpads, and mucocutaneous junctions, particularly around the eyes and mouth. Digits are prominently splayed and footpads develop cracks and frond-like masses of keratin. The skin is erythematous and moist under the crusts. Interdigital pyoderma and paronychia are common. Many affected dogs also have diarrhea and exhibit abnormal behavior consisting of increased aggressiveness initially, and lethargy and decreased responsiveness later in the course of disease. Respiratory tract infections are common and bronchopneumonia is a common cause of death.

Extracutaneous necropsy lesions consist of a *small or absent thymus* and may also include a high, arched palate and brachygnathia inferior. Histologic changes in the skin are *mild to moderate perivascular dermatitis, moderate to marked acanthosis which may be accompanied by pallor of the superficial epidermis, and marked diffuse parakeratotic hyperkeratosis.* There may also be neutrophilic exocytosis, intraepidermal neutrophilic pustules, and serocellular crusts containing bacterial cocci and/or yeasts. Diagnosis is straightforward if signalment and clinical history are known. If this information is not available, differential diagnoses include superficial necrolytic dermatitis, zinc-responsive dermatosis, and generic dog food dermatosis. However, parakeratosis is less severe in these diseases and superficial epidermal necrolysis is not a feature of lethal acrodermatitis.

Epidermolysis bullosa

Epidermolysis bullosa is a heterogeneous group of mechanobullous genodermatoses which are all characterized by skin and mucous membrane blistering and ulceration in response to minor mechanical trauma (Fig. 5.24). Lesions are a result of insufficient coherence of the dermal–epidermal junction because of structural defects in the basement membrane zone. The molecular bases for the various forms of epidermolysis bullosa have been discovered only in recent years. The condition is divided into three broad groups based on the ultrastructural level of the skin cleavage, i.e., epidermolysis bullosa simplex (epidermolytic epidermolysis bullosa), junctional epidermolysis bullosa, and dystrophic epidermolysis bullosa (dermolytic epidermolysis bullosa). Epidermolysis bullosa is further classified into more than 20 subtypes in humans based on clinical manifestations of skin lesions, mode of inheritance, and presence or absence of extracutaneous abnormalities, as well as ultrastructural features. The clinical presentation may range from minimal localized involvement of hands and feet to severe, life-threatening generalized blistering with extracutaneous involvement. Corneal erosions, tooth, nail, and hair abnormalities, and tracheal, gastrointestinal, genitourinary, and musculoskeletal involvement occur in various subtypes of epidermolysis bullosa in humans. In animals, epidermolysis bullosa has been reported rarely and, in most instances, has led to the death of affected individuals.

Epidermolysis bullosa simplex is characterized by *cytolysis of the basal keratinocytes,* which produces intraepidermal clefting. This form of the disease is caused by fragility of the epidermal basal cells because of mutations in basal cell-specific keratins 5 and 14. These mutations result in disruption of the assembly, structure, and/or function of the keratin intermediate filaments that act as the skeleton of basal keratinocytes. Ultrastructurally, cytolysis of the basal cells is seen as intra-epidermal clefting. In some forms, cytolysis is preceded by aggregation and clumping of the keratin tonofilaments which are attached to hemidesmosomes. In **junctional epidermolysis bullosa**, clefting occurs within the lamina lucida because of abnormalities of the anchoring filament-hemidesmosome complexes, which may be reduced in number and poorly formed or may be completely absent. Most cases of junctional epidermolysis bullosa are due to a deficiency or abnormality in one of the hemidesmosome-associated proteins laminin-5, collagen XVII (also called BPAG 2 and BP180), or integrin $\alpha6\beta4$, or the extracellular protein LAD-1, which is secreted by epidermal cells and localizes to the upper aspect of the anchoring filaments. **Dystrophic epidermolysis bullosa** is characterized by a split in the superficial dermis below the lamina densa in the region of the anchoring fibrils, which are fewer in number and distorted or completely absent. The molecular cause of dystrophic epidermolysis bullosa is a mutation in the anchoring fibril protein, type VII collagen.

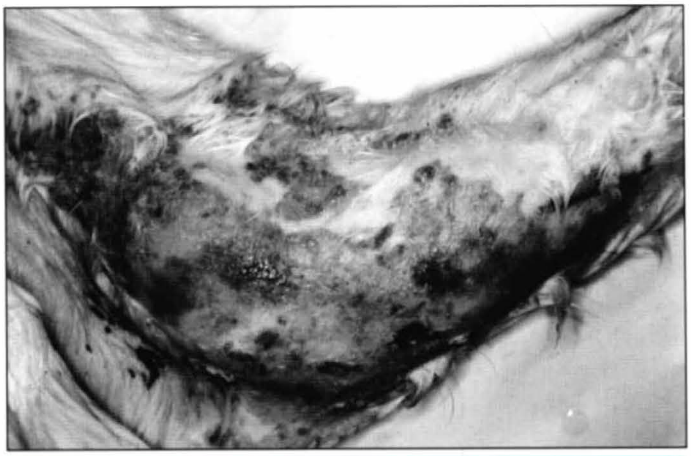

Figure 5.24 Epidermolysis bullosa. An easily detached epidermis led to extensive ulceration in areas exposed to minor mechanical trauma. (Courtesy of B Dunstan.)

Affected animals usually develop lesions shortly after birth; however, in some cases, the disease is not evident until the animal is several months old. *Initial lesions consist of vesicles and bullae, but they quickly rupture and only ulcers may be evident clinically.* Lesions are located in areas of the skin and mucous membranes which are most prone to frictional trauma such as *over bony prominences of the distal extremities, foot pads, lips, tongue, palate, and gingiva.* Hoof sloughing and nail dystrophy and shedding accompany skin lesions in some forms of the disease. Lesions may be induced accidentally by rough handling of an affected animal or intentionally for diagnostic purposes by gentle frictional trauma.

Histologically, most forms of epidermolysis bullosa are characterized by subepidermal clefts and vesicles with minimal inflammation (see Fig. 5.18), changes which are indistinguishable from bullous pemphigoid. Even in the epidermolytic form of epidermolysis bullosa, the cleavage is usually so low in the epidermis that the vesicle appears subepidermal in routine sections. PAS staining to visualize the basement membrane zone may be helpful in determining the level of cleavage, but definitive diagnosis requires ultrastructural examination. Basement membrane antigen mapping by immunofluorescence or immunohistochemistry may be a diagnostic adjunct or alternative to electron microscopy to establish the diagnosis. In epidermolysis bullosa simplex, the PAS-positive basement membrane is at the base of the blister as are type IV collagen, laminin, and BP (bullous pemphigoid) antigen. In junctional epidermolysis bullosa, the PAS-positive basement membrane, type IV collagen, and laminin are at the base of the blister, whereas the BP antigen is primarily on the blister roof. The PAS-positive basement membrane as well as all three basement membrane proteins, i.e., type IV collagen, laminin, and BP antigen, are at the roof of the blister in dystrophic epidermolysis bullosa.

Cattle

A congenital mechanobullous disease, identified as *epidermolysis bullosa simplex*, was described in 25 of 72 calves sired by a single Simmental bull. The condition appeared to be inherited as an *autosomal dominant trait* with high mortality. Lesions were evident in newborn calves and consisted of ulcers of the muzzle, lips, gingiva, dorsum of the tongue, and around joints of distal limbs. Calves were unthrifty, became emaciated after weaning, and developed areas of alopecia, hyperkeratosis, ulcers, and exfoliative dermatitis. Three animals kept under laboratory conditions showed a gradual improvement in severity of lesions but rough handling could still elicit lesions. Histologic changes were typical of epidermolysis bullosa and consisted of *dermal-epidermal separation unassociated with any significant inflammation*. PAS-positive basement membrane was evident on the dermal side of the cleft. In thin sections of skin, cytolysis of the basal keratinocytes was seen but no ultrastructural examination was done to confirm the diagnosis.

A mechanobullous disease suspected to be *dystrophic epidermolysis bullosa* has been reported in Texas Brangus calves with a common bull in their pedigree. The calves developed ulceration of distal limbs and oral mucosa, nasolabial mucosal sloughing, and sloughing of hooves within the first few days of life. The mode of inheritance was suspected to be recessive because of extensive inbreeding. Histologically, the lesions were dermal-epidermal clefts with the PAS-positive basement membrane remaining attached to the basal cell layer, i.e., forming the roof of the bullae. Ultrastructural examination revealed that the lamina densa was attached to the basal layer of the epidermis; inadequate fixation prevented accurate evaluation of the anchoring fibrils.

A *congenital mechanobullous dermatosis of uncertain type* has been described in Angus calves in New Zealand and Murrah buffalo (*Bubalus bubalis*) calves in Brazil. In both reports, skin lesions developed in newborn calves in sites prone to trauma or were induced by trauma. Hoof separation and sloughing were also observed; and in buffalo calves, horns were frequently deformed and partially or completely separated from the underlying corium. Mucous membrane and mucocutaneous involvement was seen in the Angus calves but not in the buffalo calves. The histologic changes seen in the Angus calves were separation of prickle cells and basal cells from each other and sometimes basal cells from the underlying dermis, resulting in *suprabasilar to sub-basilar vesicles* and subsequent shedding of the epithelium. Many basal and prickle cells contained large eosinophilic cytoplasmic bodies. In the Murrah buffalo calves, the characteristic histologic alteration was *suprabasilar clefting* with detachment of the stratum spinosum from the underlying basal layer. Ultrastructural changes in affected areas of skin in the buffalo calves consisted of a loss of desmosomal adhesion between the basal and prickle cell layers. The basal lamina, hemidesmosomes, anchoring fibrils, and anchoring filaments appeared normal. In the Angus calves, desmosomes were lacking or fewer than normal, and many keratinocytes contained a mass of tonofilaments arranged in whorls. Hemidesmosomes were normal. Although the clinical presentation of these cases was typical of epidermolysis bullosa, the histologic and ultrastructural features were unlike those of the common forms of epidermolysis bullosa. However, some variants of epidermolysis bullosa simplex in humans are characterized by cleft formation with acantholysis in the middle or upper epidermis, and in some instances cells contain round clumps within their cytoplasm produced by aggregation of tonofilaments. In both reports, the condition in the calves was suspected to be inherited as an *autosomal recessive* trait.

Sheep

A congenital bullous disease suggestive of *dystrophic epidermolysis bullosa* has been described in Suffolk and South Dorset Down lambs in New Zealand, Scottish Blackface lambs, and Weisses Alpenschaf lambs in Switzerland. Blisters which evolved into ulcers were seen at birth or within the first few weeks of life. Lesions occurred in areas with sparse hair and those prone to frictional trauma such as the muzzle, ears, groin, coronary band, lips, tongue, gums, dental pad, and palate. Lameness and hoof separation and sloughing were common and gave rise to the colloquial name "red foot disease" in Scotland. The lambs grew poorly and were underdeveloped, changes attributed to oral ulceration and reluctance to nurse. Histologic changes were typical of epidermolysis bullosa and consisted of *dermal–epidermal separation with minimal inflammation*. The PAS-positive basement membrane zone remained attached to the epithelium and formed the roof of the vesicle, suggestive of dystrophic epidermolysis bullosa. Only in the Swiss Weisses Alpenschaf has the condition been characterized. Ultrastructural examination of skin from the Swiss lambs indicated that the splitting was below the lamina densa and that anchoring fibrils were absent or rare and rudimentary. Antigen mapping of the lesion identified laminin and type IV collagen at the roof of the cleft, which *confirms sub-lamina densa blistering*; and no type VII collagen, the major structural component of anchoring fibrils, could be identified. These findings are consistent with the dystrophic form of epidermolysis bullosa. The disease was found to have a *recessive mode of inheritance*.

Horses

Junctional epidermolysis bullosa (JEB) has been described in both male and female Belgian foals within the first week or two of life, corresponding to the severe Herlitz form of JEB in humans. Lesions consist of skin and oral mucosal ulceration, most often of the carpi, stifles, hocks, fetlocks, tongue, gingiva, and hard palate. Hoof separation and sloughing (exungulation) are common features. Extracutaneous lesions are rare, and included ocular lesions in one foal and dental dysplasia in another. The histologic lesions consist of *subepidermal clefting with minimal inflammation and PAS-positive basement membrane material evident at the base of the cleft*. Ultrastructurally, the separation is located within the lamina lucida, indicating that hemidesmosomes are underdeveloped. The trait is inherited as an autosomal recessive. The mutation responsible – a cytosine insertion in exon 10 of the LAMC2 gene – has also been identified in JEB phenotype horses in two French draft breeds, the Breton and Comtois.

Dogs

All three forms of epidermolysis bullosa have been reported in dogs. However, the initial cases reported as epidermolysis bullosa simplex in young collies are now thought to represent a mild form of dermatomyositis with unrecognized myositis. *Junctional epidermolysis bullosa* has been described in a newborn Toy Poodle and in three puppies less than 1 month of age from a litter of seven German Shorthaired Pointers. Vesicles, bullae, and ulcers were present on multiple foot pads, in haired skin of frictional sites, and the oral cavity. The lateral hocks, elbows, stifles, and carpi were most commonly involved. No onychodystrophy or dental enamel dysplasia were evident. All of the puppies were euthanized because of the severity of the lesions. A case of *nonlethal junctional epidermolysis bullosa* has been reported in a 4-year-old female mixed-breed dog with a history of vesicles, erosions, crusts, and alopecia since birth. Lesions initially occurred on the lips and ventral abdomen and eventually progressed to involve the face, trunk, tail, and acral regions. Cutaneous atrophy and hyperpigmentation, alopecia, and nail dystrophy developed later. Histologic changes in all affected dogs consisted of subepidermal clefts and vesicles with minimal inflammation and no basal keratinocyte degeneration. The earliest changes seen in sections from the newborn poodle puppy were individual vacuoles in the basement membrane zone. Coalescence of vacuoles led to formation of subepidermal clefts. PAS staining demonstrated the basement membrane at the base of the cleft. Ultrastructural examination in all dogs revealed the separation to be within the lamina lucida. However, changes in hemidesmosomes were variable in the three reports. In the poodle, hemidesmosomes appeared rudimentary in comparison to a normal dog; whereas in the adult mixed-breed dog, hemidesmosomal attachment plaques were hypoplastic and no sub-basal dense plate was apparent. No hemidesmosomal abnormalities were evident in skin sections from the German Shorthaired Pointers. Immunostaining for hemidesmosomal-anchoring filament proteins in the German Shorthaired Pointer puppies indicated that expression of laminin-5 and integrin $\alpha 6\beta 4$ was normal but collagen XVII (BPAG2, BP180) was undetectable. In skin sections from the adult mixed-breed dog, expression of laminin-5, BPAG2, the $\alpha 6$ subunit of integrin $\alpha 6\beta 4$, and type VII collagen was similar to that of normal canine skin.

Dystrophic epidermolysis bullosa has been reported in a 4-year-old female Akita with a life-long history of trauma-induced ulcers and scars over pressure points of limbs and on foot pads. Nail dystrophy was apparent from 1 year of age. The lesions had periodic exacerbations and remissions. The histologic changes were *dermal–epidermal clefting* with minimal inflammation and PAS-positive basement membrane visible at the roof of the cleft. Ultrastructural examination indicated that the separation was beneath the lamina densa and anchoring fibrils were in reduced numbers. Expression of type VII collagen, the major structural protein of anchoring fibrils, was normal. A *dominant mode of inheritance* was speculated in this nonlethal case of epidermolysis bullosa because the dominant form of dystrophic epidermolysis bullosa in humans is typically relatively mild.

Cats

Epidermolysis bullosa appears to be *very rare in cats*. Two cases of dystrophic epidermolysis bullosa have been reported in unrelated cats. The cats were a male domestic shorthair and a Persian female cat. Skin lesions were evident in both cats by the age of 3 months. Lesions consisted of ulceration of multiple foot pads, the palate, oropharynx, gums, tongue, and dorsal spinous skin. Most claws had sloughed and suppurative, ulcerative paronychia affected all four feet. Histologic examination of skin biopsies showed dermal–epidermal separation progressing to ulceration. Type IV collagen was shown by immunohistochemistry to be present at the roof of the blisters. *Sub-lamina densa clefting* was confirmed by electron microscopic examination; and anchoring fibrils were markedly reduced in number and appeared rudimentary and filamentous in skin sections from the Persian cat. Immunofluorescent staining for collagen VII, the primary component of anchoring fibrils, was markedly reduced. *A mutation in the collagen VII encoding gene, COL7A1, was suggested as the cause,* since this gene is mutated in all subsets of dystrophic epidermolysis bullosa in affected human patients.

An undetermined type of epidermolysis bullosa was reported in a 3-year-old male domestic longhaired cat in the United Kingdom. The skin condition had been evident since the cat was 3 months old; a female littermate obtained at the same time showed no skin abnormalities. The affected cat had widespread skin lesions that consisted of scarring, alopecia, crusting, seborrhea, blistering, and ulceration. Several nails had been shed and very few whiskers were present. No lesions were evident in the oral cavity. Histologically, lesions were characterized by dermal–epidermal separation. Ultrastructural examination indicated the cleavage to be above the lamina densa and that hemidesmosomes and anchoring fibrils were fewer and less distinct when compared to skin from a normal cat.

Canine inherited epidermal acantholysis

A dominantly inherited epidermal acantholytic disease resembling human Hailey–Hailey disease/benign familial chronic pemphigus has been described in English Setters. Hailey–Hailey disease is an autosomal dominant hereditary skin disorder of cellular cohesion characterized by dissociation of epidermal keratinocytes that are subjected to frictional trauma. Lesions in people consist of vesicles and bullae usually located in large skin folds and regions exposed to chronic frictional trauma; mucosal involvement is rare. The histologic characteristics of the condition include *suprabasal clefting and extensive separation of keratinocytes which remain loosely in place*, giving the appearance of a "dilapidated brick wall." Because of the resemblance to autoimmune pemphigus, Hailey–Hailey disease is also called benign familial chronic pemphigus. A widespread intrinsic weakness in keratinocyte adhesion appears to be present but the molecular defect responsible for the disorder is unknown. Desmosomes appear normal in intact skin; structural proteins of desmosomes, adherens junctions, and gap junctions studied so far appear to be expressed normally.

The condition was seen in a 7-month-old male dog and in two of his female offspring, at the ages of 1 and 2 months. Lesions consisted of well-demarcated, alopecic, erythematous, markedly hyperplastic plaques with a rough surface, occasional serous crusting, and peripheral scaling. They occurred on the ventral thorax, head, and stifle. The clinical appearance of the lesions and their location were not typical of the human disease, but the *histologic and ultrastructural features were similar to benign familial chronic pemphigus*. Microscopically, the epidermis was markedly hyperplastic and suprabasal keratinocytes were much larger than those in the perilesional epidermis. Extensive acantholysis resulted in lacuna formation in the suprabasal and upper epidermis and the follicular epithelium. Ultrastructural changes included increased intercellular spaces, perinuclear tonofilament aggregation, and intact desmosome-tonofilament complexes and actin filament in early lesions. Immunohistochemical examination of various desmosomal proteins failed to demonstrate any abnormalities and the molecular defect in these dogs was not identified.

Congenital hypotrichosis

Congenital hypotrichosis has been described in all domestic species but it occurs most frequently in calves. The hairlessness may be associated with congenital anomalies of other systems such as brachygnathism, dental defects, and thymic or genital abnormalities. Many affected animals are otherwise completely healthy, but some forms of congenital hypotrichosis are associated with ill-thrift and early death. Deliberate propagation of spontaneous mutations producing hairlessness has resulted in development of *specific hairless breeds* such as the Chinese Crested dog, Mexican Hairless dog, American Hairless Terrier, Sphinx cat, and Mexican Hairless pig, among others. The hair coat is an important protective barrier for animals and when it is compromised, as in congenital hypotrichosis, *affected animals are predisposed to sunburn, less tolerant to temperature extremes, and more susceptible to bacterial and fungal infection.*

Hairlessness varies from partial to complete. Partial hypotrichosis is frequently bilaterally symmetrical and the hair that is present is frequently abnormal. It is usually sparse, short and fine, or coarse and wiry, brittle, and easily broken or epilated. Histologic changes are variable, likely a reflection of the different mutations responsible for the hypotrichosis. Some affected animals have only follicular disease; while others have involvement of other skin appendages, in which case the condition is called ectodermal dysplasia.

Genetic hypotrichosis must be differentiated from various causes of non-genetic hypotrichosis. Iodine deficiency can cause goiter and hypotrichosis in piglets, lambs, and calves. Adenohypophyseal hypoplasia in Guernseys and Jerseys, and maternal ingestion of *Veratrum album* by Japanese cattle, have been associated with hairlessness in calves. In addition, alopecia of various degrees has been associated with intrauterine infection with *Bovine viral diarrhea virus* in calves and *Classical swine fever virus* in piglets.

Cattle

Various types of inherited hypotrichosis occur in cattle. Many breeds of cattle are affected and the mode of inheritance varies with the particular form of hypotrichosis. Histologic features are not well characterized for all forms of hypotrichosis in cattle.

A form of **lethal hypotrichosis** occurs in Holstein-Friesian and Japanese native cattle. Calves are born almost hairless and have only small amounts of hair on the muzzle, eyelids, ears, tail, and pasterns. The condition is inherited as a simple autosomal recessive trait, and homozygous calves die within hours after birth. Histologically the skin contains normal numbers of follicles but they are shallow, rudimentary in appearance and do not form hairs. Sebaceous glands and arrector pili muscles appear normal while sweat glands undergo cystic degeneration.

A condition called **semihairlessness** has been reported in polled and horned Hereford calves. Calves have a thin coat of short fine, curly hair at birth and progressively develop a patchy sparse coat of coarse wiry hair which is thicker and longer on legs than elsewhere. The skin is wrinkled and scaly. Animals may not grow well and may have a wild temperament. The condition is a simple autosomal recessive trait. The histologic changes described are dysplastic hair follicles that do not produce hairs. Similar histologic features have been described in **viable hypotrichosis** reported in various breeds of cattle, including Guernseys, Jerseys, Holsteins, Ayrshires, and Herefords. Calves are born with variable degrees of hairlessness. The condition appears to be inherited as a simple autosomal recessive trait in all breeds affected.

Hypotrichosis and anodontia (hypotrichosis anodontia defect, HAD) has been described in male mixed Maine-Anjou-Normandy cross calves and suspected to be a sex-linked recessive trait. Calves are born hairless and toothless and develop a fine, downy hair coat and partial dentition after several months. Affected calves also have a thick protruding tongue, defective horns, and hypoplastic testicles, and they usually do not survive beyond 6 months of age. Histologic changes include small, inactive hair follicles, deformed dermal papillae lacking a vascular network, and degenerative sweat glands. An HAD syndrome, with hypotrichosis, almost complete lack of teeth, and complete absence of eccrine nasolabial glands, has been observed in a family of German Holsteins; similar anomalies in humans are known as X-linked anhidrotic ectodermal dysplasia (ED1). This Holstein phenotype was inherited as a monogenic X-linked recessive trait, and was caused by a deletion in the bovine *ED1* gene.

Hypotrichosis and incisor anodontia (hypotrichosis incisor defect, HID) has been described in Holstein-Friesian cross calves, and inheritance is suspected to be an X-linked incompletely dominant gene. Affected calves have variable areas of thin coat of fine short silky hairs usually involving the face, neck, ears, back, and inner thighs. Eyelashes, vibrissae, and tail brush are usually normal. Calves may become normal with age. Histologically, there are numerous small hairs but large medullated hairs are absent and only telogen follicles are evident in severely affected HID calves.

Inherited epidermal dysplasia, also called **baldy calf syndrome**, is a lethal disease of Holstein- Friesian calves that is likely inherited as a single autosomal recessive trait. The disease causes loss of condition and skin, horn, and hoof lesions that can be confused with inherited zinc deficiency. Calves appear normal at birth; but at one to two months they begin to lose condition despite normal appetite, and develop generalized hair loss and patchy areas of scaly, wrinkled, thickened skin over the neck, shoulders, flanks, and on pressure points. Hooves are elongated, narrow, and pointed and frequently have horizontal rippling. Horns fail to develop and ear tips are curled backwards. Calves have fine slender limbs and drool. They become emaciated and usually die at 6–8 months of age. Histologic examination indicates variable atrophy of adnexa, remnants of hair follicles and sebaceous glands incorporated into the basal layer, and scattered atrophic remnants of apocrine sweat glands.

Congenital hypotrichosis of Hereford cattle is thought to be due to a simple autosomal dominant gene. Alopecia is variable and nonprogressive. Calves have thin, pliable skin, extremely curly facial hair, and may have sparse pellage of thin soft curly, easily broken and epilated hairs, or they may be completely hairless. Some calves also have impaired hoof development. The condition is characterized histologically by hypoplastic or degenerate hair follicles with vacuolation and necrosis of Huxley's and Henle's layers and abnormally large trichohyaline granules in Huxley's layer. Most follicles contain fragmented hair shafts. Arrector pili muscles are reduced in number and frequently not associated with hair shafts. Ultrastructural examination indicates that the giant trichohyaline granules lack normal micro- and macrofilament structures.

A condition consisting of **congenital anemia, dyskeratosis, and progressive alopecia** has also been described in polled Hereford calves in Canada and the USA. Affected calves are often small at birth and have a prominent forehead. They have a hyperkeratotic muzzle with a dirty-faced appearance, and their hair is wiry and kinked or tightly curled and easily epilated. Alopecia is evident initially on the bridge of the nose and ears and it becomes generalized but is most severe on the head, lateral neck, shoulders, and back. The skin of the face and neck is wrinkled and hairless skin is hyperkeratotic. Affected calves also have nonregenerative anemia and fail to grow despite a normal appetite. Histologic abnormalities in the skin consist of orthokeratotic hyperkeratosis and hypergranulosis extending into the infundibular portion of hair follicles and prominent dyskeratosis (apoptosis) of individual epidermal and follicular keratinocytes. Hair follicles are in normal number but many follicles are in telogen phase. There is degeneration of the internal root sheath and atrophy of sebaceous glands. The bone marrow is hyperplastic and characterized by ineffective erythropoiesis with maturation arrest in the late rubricyte stage.

The "**rat-tail syndrome**" is a form of hereditary congenital hypotrichosis that occurs in a small percentage of calves produced by crossing some Continental cattle breeds, e.g., Simmental, with black Angus or Holsteins. The calves have short, curly, malformed, sometimes sparse hair and a lack of normal tail switch development.

Dogs

Congenital hypotrichosis has been reported in *many breeds of dogs*. In most cases, a single puppy of a litter is affected but in some reports several puppies in a litter have been affected. The majority of cases of hypotrichosis in dogs have been in males, and may be referred to as *X-linked ectodermal dysplasia*. Hairlessness may be virtually complete or involve discrete areas that are typically distributed symmetrically. In such cases, areas most commonly affected include the top of the head, ears, ventrum, medial aspect of the legs, and the lumbosacral area. The skin is initially normal but frequently becomes hyperpigmented, hyperkeratotic, and greasy as affected dogs age. Some affected dogs also have sparse, short, wiry whiskers or they may be altogether absent. Eyelashes may also be absent. Some dogs also have missing or misshapen teeth or conjunctivitis. Most cases of hypotrichosis in a single puppy are assumed to be a spontaneous mutation; but X-linked recessive mode of inheritance has been confirmed in a family of Miniature Poodles and German Shepherd Dogs with hypotrichosis. *Histologic changes are variable*, no doubt reflecting differences in underlying abnormalities. In some cases, there are decreased numbers of hair follicles that contain poorly formed or no hair shafts but with normal sebaceous and sweat glands. In other cases, all follicles and associated appendages are absent. These dogs usually also have dental abnormalities and are considered to have a more general abnormality termed a *congenital ectodermal defect*. Footpad biopsies of such dogs also demonstrate a lack of eccrine sweat glands. The underlying molecular defect is unknown in all cases but an abnormality in the epidermal growth factor (EGF) signaling pathway was speculated in the German Shepherd Dogs with hypotrichosis since fibroblasts from these dogs had decreased expression of EGF receptor on their plasma membranes.

Cats

An autosomal recessive form of congenital hypotrichosis has been described in *Siamese and Birman kittens*. The Birman kittens were born virtually hairless and had short fragile wrinkled whiskers or lacked whiskers altogether. Both males and females were affected. Although initially healthy, all affected kittens in one report died by 13 weeks of age from various infections. Necropsy examination of some of the affected Birman kittens revealed *thymic aplasia and lymphoid depletion* of paracortical regions of lymph nodes, spleen, and Peyer's patches, suggesting an immunologic deficiency. Histologic examination of skin indicated reduced numbers of primary hair follicles, which were hypoplastic and devoid of hairs. Sebaceous glands were normal but sweat glands were hypoplastic and in decreased number, and arrector pili muscles were rare.

Hereditary hypotrichosis is recognized in **piglets** and there may be both dominant and recessive forms. The dominant form is thought to be lethal in homozygotes; it is characterized histologically by a decreased number of hair follicles and most appear atrophic. Congenital hypotrichosis is thought to be a simple autosomal recessive trait in polled Dorset **sheep**. Alopecia is most pronounced on the face and legs. Histologic abnormalities consist of hypoplastic hair follicles containing keratosebaceous material but no hairs. Congenital hypotrichosis has been described in a Percheron, but is rare in **horses**. Congenital hypotrichosis is rare in **goats**.

Hypotrichosis associated with pigmentary alterations

Generalized or regional alopecia attributed to follicular dysplasias that include histologic evidence of pigment abnormalities have been frequently described in dogs and less frequently in other species. They have arbitrarily been divided into two categories.

The first of these two categories is **color-dilution alopecia** described in color-dilute animals of breeds such as the Doberman Pinscher, Irish Setter, Dachshund, Chow Chow, Poodle, Whippet, Italian Greyhound, Boston Terrier, Chihuahua, Saluki, Yorkshire Terriers, and mongrels in which the onset of alopecia can be tardive, generally ranging from four months to three years. Puppies are born with normal hair, but develop slowly progressive alopecia (Fig. 5.25). Pedigree analysis in color-dilute Dachshunds suggests this disorder may be inherited as an autosomal recessive trait. The histologic lesions include *misshapen, fragmented anagen hair follicles with pigment clumping in follicular epithelium, hair bulb matrix cells, hair shafts, infundibular keratin, and epidermis* (Fig. 5.26). *Melanin-containing macrophages are frequently present in the dermis around hair bulbs.* There can be some hair follicle atrophy in chronic cases, however this is a secondary change. A condition similar to color dilution-alopecia in dogs has been described in cattle as **cross-related congenital hypotrichosis.** This has been reported in crosses involving Simmental, Gelbvieh and Charolais cattle, most common in the Simmental-Angus and Simmental-Holstein crosses. The condition appears in calves that have color-dilute (gray or chocolate) coats. The affected hair is short, curly and sparsely haired leaving the white haired areas of the coat unaffected. The histologic lesions are virtually identical to canine color-dilution alopecia. **Coat-color-linked hair follicle dysplasia** has also been described in buckskin Holstein cows (color-dilute tan-and-white Holsteins). These animals have short and clinically abnormal hair in the tan areas of the coat.

The second traditional category is **black hair follicular dysplasia**, seen in bi- or tri-color black and white dogs, such as Bassett Hounds, Beagles, Bearded Collies, and mongrels, and in Holstein cattle, in which the alopecia affects only the black-haired areas of the coat, and in which onset is generally in the first few weeks or

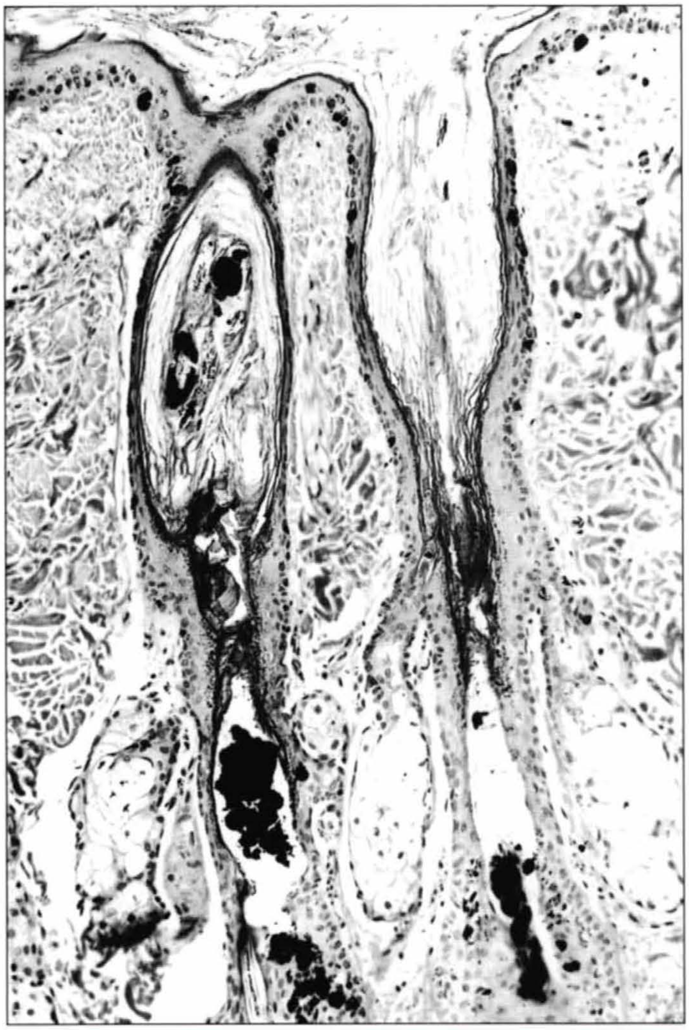

Figure 5.26 Color dilution alopecia in a dog. Note the clumped melanin in the fractured, misshapen hair shafts, follicular hyperkeratosis, and prominent melanocytes in the overlying epidermis.

months of life. Black hair follicular dysplasia is thought to be an autosomal inherited disorder in mongrel puppies, and is thought to have a genetic component in some purebred animals such as Bearded Collies. *The histologic lesions in black hair follicular dysplasias are virtually identical to those of color-dilution alopecia.* A difference in the appearance of the melanin clumps in whole mounts of hair shafts has been suggested.

There are *other follicular dysplasias associated with pigment abnormalities* that do not fall easily into these two categories, but have similar histologic changes. These include follicular dysplasia in the **Portuguese Water Dog** which occurs in the black or red color phase of this breed. These are not color-dilute dogs and the onset can be tardive, generally between 3 months and 5 years. **Black-and-red Doberman Pinschers** that are not phenotypically color dilute, are also reported to have a follicular dysplasia that is generally confined to the caudal dorsum and that has an adult onset. Follicular dysplasia has been described in **Weimaraners**, in which affected young adults had progressive alopecia of the trunk with recurrent folliculitis/furunculosis. In **cattle**, follicular dysplasia has been reported in black Angus and black Angus-Brahman cross; the histologic changes are similar to those in dogs. These cattle are all black animals that are not phenotypically color dilute, however there is adult onset of alopecia that is more commonly associated with color-dilution alopecia. In view of the dysplasias in Portuguese Water Dogs, black-and-red Doberman Pinschers, and black Angus and their crosses that occur in animals not phenotypically color dilute but that can have adult onset, *it is quite possible that separation of follicular dysplasias with pigmentary alteration into color-dilution alopecia and black-hair follicular dysplasia is artificial.* It is likely that these histologically similar follicular dysplasias are subtypes of a single process, however until the mechanism underlying follicular dysplasia is characterized the classification is somewhat arbitrary.

Hypertrichosis

Congenital hypertrichosis, a condition characterized by an *excessive amount of hair*, is rare. In some instances, the abnormality involves a change in the character of the hair rather than an absolute increase in amount. Excessively long hair is inherited as an autosomal dominant trait in **Friesian cattle** in Europe. The condition results in discomfort during hot weather and decreased productivity. High environmental temperature during gestation has been associated with an unusual hairy appearance of newborn **lambs**. The lambs are small and most do not survive to weaning; the histologic appearance of this abnormality has not been described. *Border disease* is a congenital pestiviral infection of sheep in which lambs are born weak and small, have an abnormal haircoat, and exhibit tonic-clonic spasms (*hairy shaker disease*). Instead of the normal short, fine, closely crimped birthcoat, affected lambs have a long straight coarse coat. The coat abnormality is due to aberrant differentiation of hair follicles that develops only when infection occurs prior to 80 days of gestation. The histologic changes include enlargement of primary hair follicles with an increased degree of medullation and a decreased number and retarded development of secondary follicles.

Canine dermatomyositis

Dermatomyositis is an idiopathic inflammatory condition of skin, muscle, and occasionally blood vessels of humans and dogs. A familial pattern of occurrence has been found in Collies, Shetland Sheepdogs (Shelties), and their crosses. Dermatomyositis in collies is an autosomal dominant trait with variable expressivity; and it appears to be widespread in Collies in the USA. The disease in Collies has been proposed as a model for a nonfatal form of childhood dermatomyositis, although familial cases are uncommon in humans. The condition in Shelties is assumed to be inherited in a similar manner but the mode of inheritance has not been confirmed by breeding studies. Dermatomyositis has been identified in Shelties in the United Kingdom. The disease has not been characterized as well in this breed; but it appears that myositis is a less prominent feature of the disease in Shelties. Occasional cases of dermatomyositis have been reported in other breeds of dogs; nothing is known regarding the nature of inheritance of the disease in these dogs.

The cause and pathogenesis of dermatomyositis are unknown. Variation in expression of dermatomyositis in dogs suggests that factors other than simple autosomal dominant inheritance are involved in the etiopathogenesis of the disease. Immunologic mechanisms are thought to be involved in this disease in humans and both cell-mediated and humoral immunity have been implicated in the pathogenesis. In Collies with dermatomyositis, serum levels of circulating immune complexes were found to be increased above normal before clinical disease was evident, the onset and severity of dermatitis and myositis correlated with the serum levels of circulating immune complexes and IgG, and circulating immune complex levels decreased to normal as disease resolved. These findings suggest that the immune complexes initiated inflammation rather than resulted from it. IgG was identified as the immunoglobulin component of the immune complexes but the identity of the antigen component was not determined. Dermatomyositis has been associated with viral, bacterial, and *Toxoplasma* infections but infectious agents are generally not isolated from tissues of affected people. Crystalline structures, suggestive of picornaviruses, have been seen in endothelial cells of muscle from severely affected collies. Cases in humans have also occurred following immunization, therapy with various drugs, during pregnancy, and in association with neoplasia.

Skin lesions usually develop in juvenile dogs 7 weeks to 6 months of age. *Earliest lesions consist of small pustules, vesicles, papules, and nodules which evolve into erythematous, crusty, ulcerated, alopecic areas with hypo- or hyperpigmentation* (Fig. 5.27). Lesions are most common on the pinnae, bridge of the nose, lips, periocular skin, over bony prominences of the distal extremities, sternum, and tip of the tail. Mucous membranes and mucocutaneous junctions may be transiently involved early in the course of disease. Footpad ulceration is rare. The disease exhibits a *waxing and waning course* over weeks to months with a variable outcome. In mildly to moderately affected dogs, lesions may resolve spontaneously in 6–12 months; while in severely affected dogs, lesions may regress but do not usually resolve completely and disease may be lifelong and extensive. Lesions heal with no residual scarring in mildly affected dogs; permanent alopecic, hypo- or hyperpigmented disfiguring scars develop, especially on the face, in severely affected dogs. Lesions may be exacerbated by estrus, parturition, or exposure to sunlight. Although cases of adult-onset dermatomyositis have been reported, it is likely that at least some of these dogs had mild transient lesions that were overlooked when they were pups and subsequently developed more obvious disease as adults.

Myositis usually develops several weeks after dermatitis and is proportional in severity to the dermatitis. It is usually first recognized as a bilaterally symmetrical decrease in temporal muscle mass. However, because of the dolichocephalic shape of the collie head, mild temporal or masseter muscle atrophy may be missed. *Myositis principally involves muscles of mastication and extremities below the elbow and stifle*, but it is more generalized in more severely affected dogs. Over time, active myositis is succeeded by muscle atrophy and fibrosis. Generalized symmetrical muscle atrophy, weakness, and exercise intolerance may develop in moderately and severely affected dogs.

Various additional abnormalities may accompany skin and muscle lesions in more severely affected dogs. Peripheral lymph nodes are

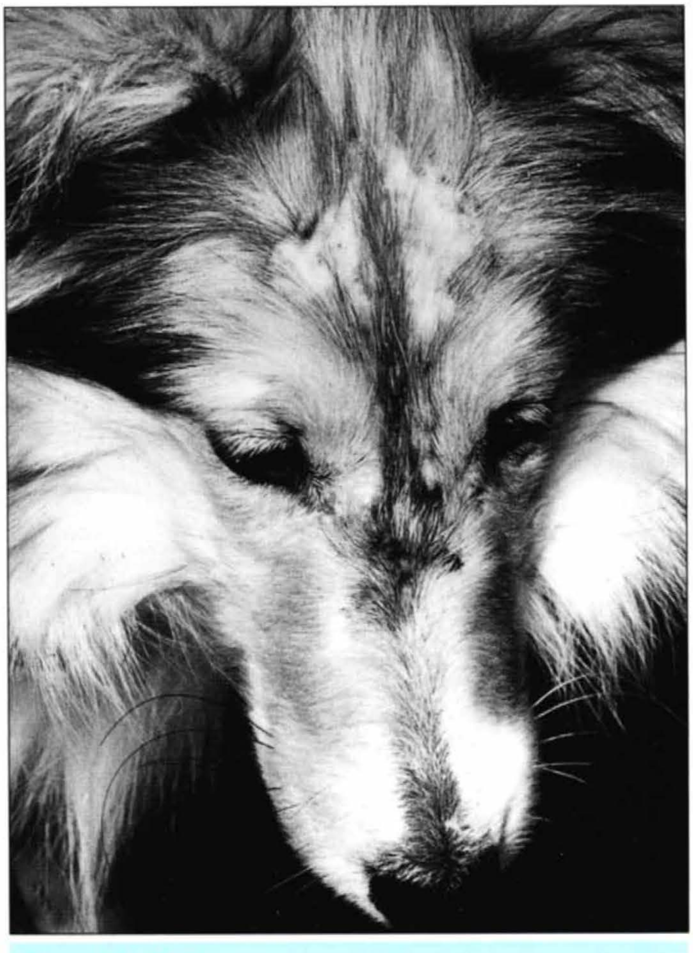

Figure 5.27 Familial canine dermatomyositis in a puppy. Alopecia and crusting of the face.

enlarged because of reactive hyperplasia. Conjunctivitis may develop in dogs with severe periocular skin lesions or because of facial palsy and inability to blink. More severely affected dogs are small and unthrifty in comparison to normal or mildly affected dogs. Fever and joint swelling are noted in some dogs. Secondary bacterial pyoderma, septicemia, or megaesophagus with secondary aspiration pneumonia may develop in more severely affected dogs. Demodicosis may also be present and complicate diagnosis. Severe secondary amyloidosis with resultant renal failure has been described in one affected Collie.

Affected dogs have variable and usually nonspecific *clinicopathologic abnormalities*. Moderately and severely affected dogs commonly have inflammatory leukogram changes which include neutrophilia, with or without a left shift, and monocytosis. Nonregenerative anemia typical of chronic inflammation may develop in severely affected dogs. Serum creatine kinase levels in collies with dermatomyositis were normal or only slightly increased; however, most serum muscle enzyme determinations were done in later stages of disease when active myositis may have been waning. Mild to moderate elevations in serum creatine kinase concentrations were present in several young Shelties with the disease. Occasionally, dogs have positive Coombs' tests, and rarely rheumatoid factor (RF) tests are positive.

The histologic changes in the skin are variable and may be quite subtle or nonspecific. Early lesions consist of scattered individual vacuolated or shrunken, brightly eosinophilic necrotic keratinocytes in the epidermis and infundibular portion of hair follicles. Hydropic degeneration of basal keratinocytes is often present and leads to *dermal-epidermal clefts* that develop into vesicles that contain proteinaceous fluid, erythrocytes, and inflammatory cells. Diagnostically useful artifactual dermal-epidermal separation may be induced at the margins of the section by the shearing action of the punch biopsy. Ulceration and crusting result from lesions with extensive dermal-epidermal separation. Intra-epidermal pustules are uncommon. Hyperkeratosis and acanthosis are variable. In the absence of ulceration, dermal inflammation tends to be mild and consists of mixed cells either surrounding superficial dermal vessels, hair follicles, and glands or distributed in an interface pattern or in some cases diffusely distributed. The infiltrate includes mononuclear cells primarily, fewer neutrophils, and occasional eosinophils and mast cells. *The most consistently present histologic abnormalities are follicular atrophy and perifollicular inflammation that may be accompanied by perifollicular fibrosis* (Fig. 5.28A, B). Variable

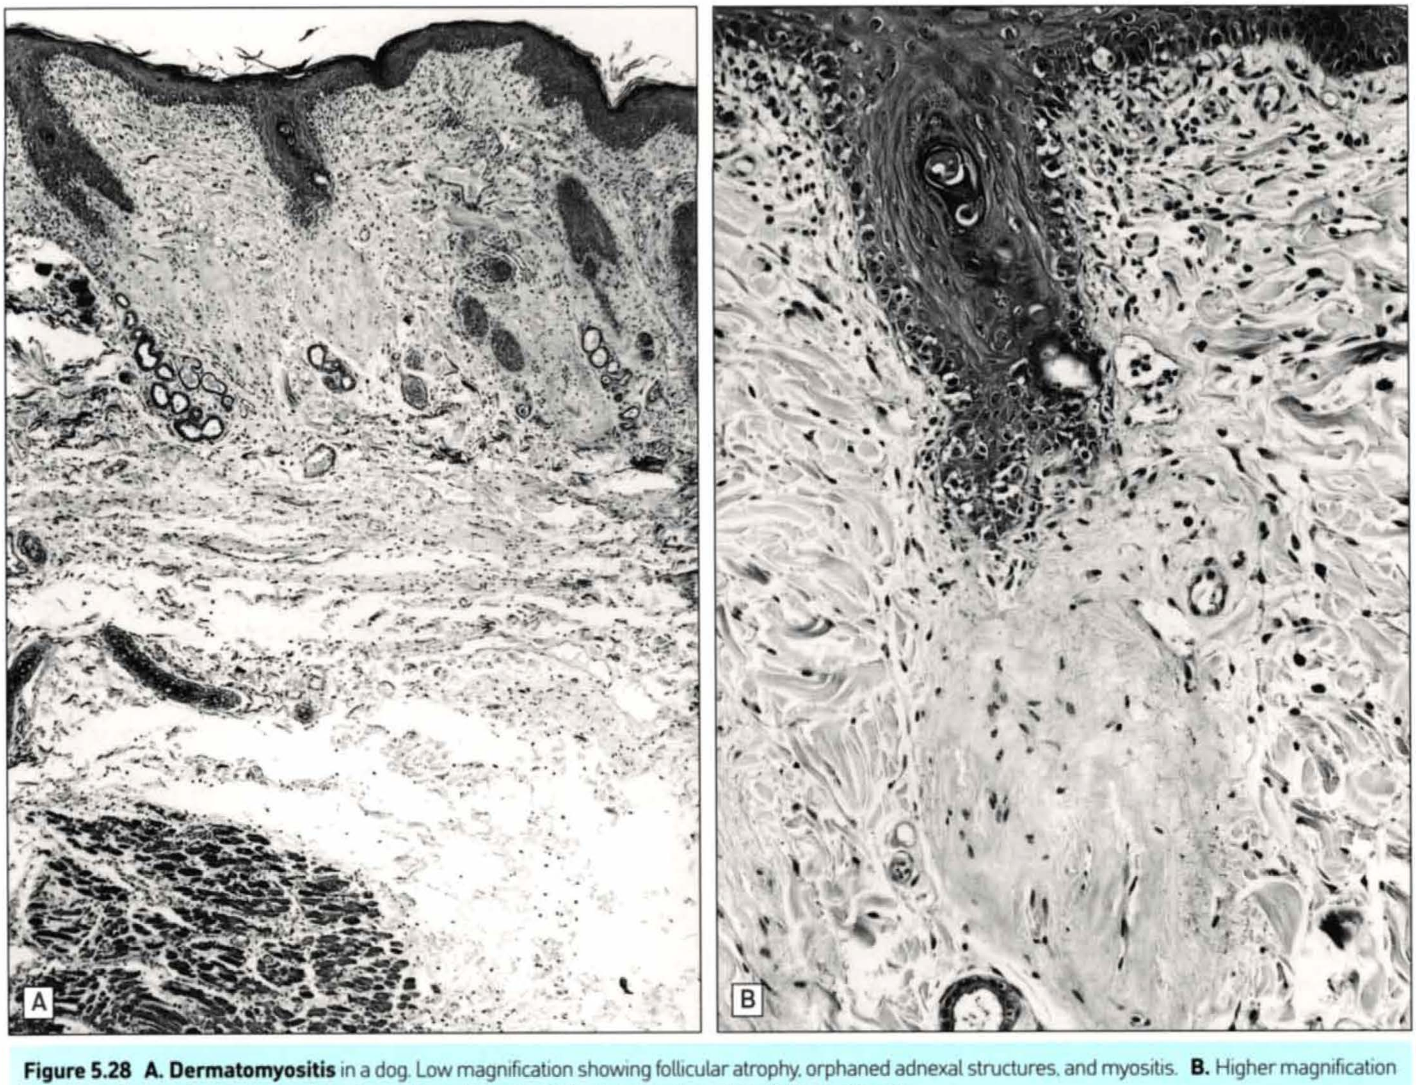

Figure 5.28 A. Dermatomyositis in a dog. Low magnification showing follicular atrophy, orphaned adnexal structures, and myositis. **B.** Higher magnification showing cell-poor hydropic, interface dermatitis and marked follicular atrophy and perifollicular fibrosis.

dermal fibrosis is usually evident in biopsies from dogs older than 6 months. *Muscle lesions* include multifocal interstitial and perivascular infiltrations with mixed cells; myofiber degeneration, regeneration, and atrophy; and fibrosis. *Vasculitis* is an infrequent and subtle finding in the skin, muscle, and occasionally in other tissues.

The principal differential diagnosis is lupus erythematosus and the two diseases may be indistinguishable on individual biopsies. However, lichenoid dermal inflammation is usually prominent in discoid and some cases of systemic lupus erythematosus but is not characteristic of dermatomyositis. Follicular atrophy, a common feature of dermatomyositis, is not usually present in lupus erythematosus. Lupus erythematosus is not typically a disease of young dogs. In some cases, immunologic tests may be required to differentiate the two diseases. Direct immunofluorescent antibody examination, antinuclear antibody test (ANA), and lupus erythematosus test (LE) are frequently positive in lupus erythematosus but negative in dermatomyositis.

Hereditary connective tissue disorders

The connective tissue components of the skin include collagen (primarily types I and III), elastic fibers, and ground substance composed of glycoproteins and proteoglycans. A defect in any one of these skin molecules can result in structural and functional abnormalities of the entire tissue. Inherited connective tissue disorders of skin may consist of abnormalities involving only one of these components or there may be concurrent alterations in several components. Hereditary collagen dysplasia, the most commonly recognized connective tissue disease, is a complex group of disorders of collagen that results in decreased tensile strength of the skin and may also affect other connective tissues. Alterations in elastic fibers and ground substance may accompany some forms of collagen dysplasia but there are also diseases in which an abnormality of the elastic fibers or ground substance appears to be primary. *Diagnosis of many of these conditions requires ultrastructural examination and biochemical analysis to confirm the presence of structural abnormalities and to identify the molecular defect.*

Hereditary collagen dysplasia

Collagen dysplasia (dermatosparaxis, Ehlers–Danlos syndrome, cutaneous asthenia, cutis hyperelastica) has been reported in humans, cattle, sheep, horses, dogs, cats, mink, and rabbits. Collagen is the major structural protein in skin and other connective tissues and abnormalities in its structure result in skin that is fragile, easily torn, and frequently hyperextensible and loose. In humans, Ehlers–Danlos syndrome (EDS) is divided into at least ten types based on clinical, biochemical, and molecular genetic studies. The natural history of clinical disease and mode of inheritance vary among the different types of EDS. Joint laxity, vascular abnormalities, bowel or uterine rupture, bone abnormalities, ocular abnormalities, and periodontal disease occur in addition to the fragile skin in the various forms of human EDS. Inheritance may be autosomal dominant, autosomal recessive, or X-linked recessive. In animals, clinical disease has been restricted almost exclusively to skin abnormalities and has been characterized in only a few breeding colonies or herd outbreaks. Most instances of collagen dysplasia occur in single animals and the molecular defect and mode of inheritance are usually not determined.

Individuals with inherited collagen dysplasia typically have a *history of frequent skin lacerations following routine handling*, such as shearing or manual restraint, normal activities such as scratching or playing with littermates, or minor trauma. The skin wounds commonly *develop into wide gaping wounds with minimal hemorrhage.* Healing usually proceeds normally but results in *characteristic thin, pale wrinkled scars* resembling cigarette or tissue paper. Extracutaneous signs, such as joint laxity and ocular abnormalities, have been reported in animals only rarely. The skin is usually soft and velvety, hyperextensible, and may hang in loose folds. In some affected animals, the skin laxity becomes progressively more pronounced with age. Severity of clinical signs is variable, even among animals with the same biochemical abnormality. This variability in clinical severity is most pronounced in sheep. One form of the disease described in sheep exhibits such severe manifestations that all lambs die or require euthanasia within the first day or two of life. A second milder form of collagen dysplasia is usually not recognized until later in life when sheep are handled for shearing. *In general, the disease tends to be most severe in sheep, less severe in cattle, followed by dogs and cats, and least severe in horses.*

Diagnosis of collagen dysplasia is based on typical clinical signs and demonstration of morphologic or biochemical abnormalities of the dermal collagen. In some cases, abnormalities are evident at the light microscopic level but frequently none are found or the differences are subtle and difficult to determine except by comparison to a breed- and age-matched control. The dermis may be normal, thinner than normal, or thicker than normal because of an increased amount of ground substance. Collagen fibers may be widely separated, finer and paler than normal, and haphazardly arranged. Rarely, increased numbers of elastic fibers are seen with elastic stains. Fibroblasts are in increased numbers in the dermis of some affected animals. Abnormal collagen fibers may stain unevenly with collagen stains such as Masson's trichrome. Instead of the uniform blue staining of normal collagen, the abnormal collagen may have a red core. This staining feature is not unique to collagen dysplasia, however, as uneven collagen staining also occurs with degenerative disorders of collagen.

In most cases, ultrastructural examination is required to confirm the collagen abnormality. A variety of alterations of collagen fibrils have been found. In longitudinal sections, collagen fibrils may be loosely wound and flat or helical. In cross-section, they may have several irregular thin projecting arms that give them a "hieroglyphic" appearance. This appearance is typical of dermatosparaxis of sheep and cattle and has also been described in a Himalayan cat and a dog. In other forms of the disease, the collagen fibrils are shaped normally but vary markedly in diameter from the normal range. They may all be uniformly larger or smaller or there is a mixed population of fibrils that extend beyond the range of normal minimum and maximum diameter sizes. The fibrils frequently are loose and disorganized rather than being arranged in uniform, compact bundles.

The ultrastructural abnormalities are not specific and biochemical analysis is necessary to determine the particular molecular defect. Collagen synthesis is a multi-step process that includes extensive post-translational processing involving multiple intracellular and extracellular enzymes. Abnormalities in several of these enzymes as well as structural mutations involving the collagen chains have been identified in the various forms of collagen dysplasia in humans and animals. For unknown reasons, the same biochemical defect may produce different clinical abnormalities in different individuals and in different species.

Cattle

Collagen dysplasia in cattle is usually referred to as *dermatosparaxis,* which means "torn skin." The condition is *caused by a mutation in the gene for procollagen I N-proteinase* (also called procollagen aminopeptidase), the enzyme that excises the amino-propeptide of type I and type II procollagens. Each of the three polypeptide chains making up a collagen molecule have short extensions at the amino and carboxy termini. These additional propeptides make the molecules soluble to aid in their transport out of the cell. Subsequent extracellular conversion of the procollagen to collagen requires two enzymes to cleave the amino and carboxy terminal extensions. Following cleavage of the procollagen peptides, the collagen molecules spontaneously assemble into collagen fibrils. *The defect in processing of type I procollagen to collagen results in abnormal precursor molecules with peptide extensions which inhibit formation of uniform fibers and fibers capable of producing normal cross-links.* They assemble instead into abnormal ribbon-shaped collagen fibrils lacking normal tensile strength. Dermatosparaxis in cattle is recessively inherited as is the biochemically analogous condition in humans, EDS type VII C, although clinical signs are not identical.

Most affected calves have thick, wet skin that tears easily and sometimes hangs in loose folds. Associated joint laxity and soft bones have been reported rarely. Light microscopic changes consist of a thicker than normal dermis composed of sparse bundles of fine pale collagen distributed in abundant Alcian-blue-positive ground substance (proteoglycans). Individual collagen fibers are smaller in diameter than in normal skin and their arrangement appears disorganized. There may be an increase in dermal elastin and number of fibroblasts. Ultrastructural examination reveals the collagen to be arranged in loose, twisted flat or helical ribbons rather than being organized in compact parallel arrays. In cross-section, these fibrils have irregular projecting arms which confer a "hieroglyphic" appearance.

Sheep

At least two forms of collagen dysplasia, called *dermatosparaxis,* have been described in sheep, i.e., a *severe form in lambs* noted shortly after birth, and a *milder form* not apparent until sheep are handled as adults. The severe form has been described in Norwegian Dala sheep, Border-Leicester-Southdown crossbred sheep in Australia, and white Dorper sheep in South Africa. The condition is inherited as a simple autosomal recessive trait. Only in the Dala breed has the biochemical defect been identified and it consists of a deficiency in procollagen aminopeptidase activity, as in bovine dermatosparaxis. In Border-Leicester-Southdown crossbred lambs the biochemical abnormality was not determined but it did not appear to be a procollagen peptidase deficiency since there was no increase in dermal procollagen detected. Affected lambs develop skin lacerations during birth or shortly thereafter. The skin is soft and edematous. Lambs frequently die within a few days as a consequence of wound infection and septicemia. Gross examination of the skin indicates that the dermis is moist and thicker than normal with a jelly-like consistency. In some instances, increased friability of internal organs and joint capsules was observed. The histologic and ultrastructural abnormalities are similar to those in cattle with dermatosparaxis.

The *less severe form of dermatosparaxis* has been found in Merino sheep in Australia when adult sheep were handled for shearing. No skin hyperelasticity or joint hypermobility are associated with the skin fragility. The skin lacerations predispose affected individuals to infections and fly-strike. This form is also caused by a deficiency of procollagen aminopeptidase activity. Light microscopic examination reveals a loose, more open appearance to the dermis and a significant increase in the number of dermal fibroblasts in comparison to normal skin. Most collagen fiber bundles are smaller and more lightly stained than those in normal skin. The collagen in some areas is arranged in prominent layers. Transmission electron microscopic examination shows a combination of distorted, hieroglyphic-type fibrils mixed with normal collagen fibrils.

Horses

Collagen dysplasia has been reported in Quarter Horses, a Thoroughbred gelding, and an Arabian-cross filly. An *autosomal recessive* mode of inheritance has been suggested but not proven in the Quarter Horses; *the biochemical defect has not been identified in any of the equine cases.* The condition is not usually recognized until the animal is 6–12 months old and develops frequent skin wounds and scarring on the legs, shoulders, and saddle area. The skin is hyperextensible; but in some cases, the abnormal skin involves sharply delineated areas interspersed among large areas of normal skin. This unusual feature has not been described in other species.

Histologic examination of affected skin may not indicate any dermal abnormalities or the dermis may be thinner than normal and collagen fibers may appear smaller than normal when compared to a control. In some cases, the collagen fibers have abnormal red cores when stained with Masson's trichrome. Ultrastructural changes in two Quarter Horses included disorganized and nonparallel collagen fibril arrangement, increased space between collagen fibrils, and irregular outlines and increased variation in the diameter of collagen fibrils. In contrast, ultrastructural changes in an Arabian-cross filly were suggestive of collagen degeneration. Collagen fibrils were uniform and densely packed in parallel arrays in unaffected areas of skin from this horse; but in sections from abnormal, fragile skin, collagen fibrils were fragmented, widely separated by granular material, disorganized, and associated with phagocytic fibroblasts. These ultrastructural abnormalities are unlike those described in other horses or species.

Dogs

Collagen dysplasia has been described in many purebred and mixed-breed dogs. Affected dogs typically have *soft, easily torn, hyperextensible skin* (Fig. 5.29). In some cases, the skin hangs in loose pendulous folds, a feature that frequently becomes more prominent with age. Thin, white scars are typically the sequelae to skin wounds. Ocular

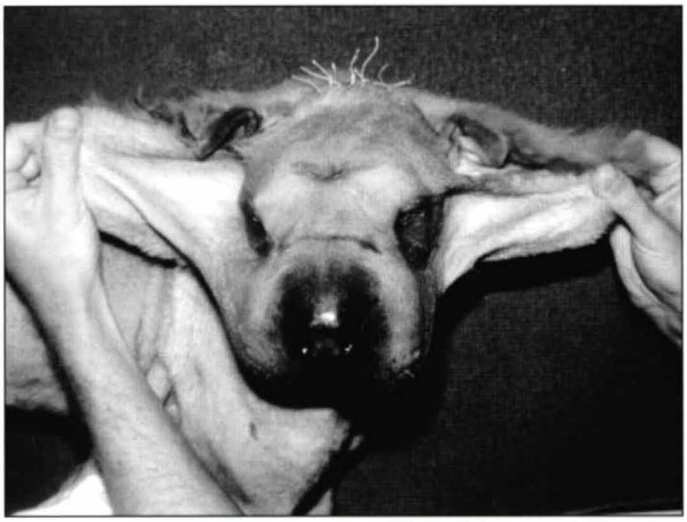

Figure 5.29 Collagen dysplasia in a dog. Note hyperextensible facial skin. (Courtesy of B Dunstan.)

abnormalities and joint laxity, associated problems commonly seen in humans with EDS, have been reported infrequently in dogs, and bone abnormalities are rare. Several breeding studies have shown collagen dysplasia to be inherited in a simple autosomal dominant manner with complete penetrance. *The biochemical abnormality has not been identified in any cases of collagen dysplasia in dogs*; but the skin of Springer Spaniels with collagen dysplasia has been found to have more uncross-linked α-chains than collagen from normal dogs.

Histologic changes may be subtle and consist of dermal thinning evident only in comparison to a section from a normal control. In other cases, a decreased amount of dermal collagen, collagen disorganization, variation in collagen staining, increased number of elastic fibers, or increased amount of extracellular matrix may be seen. The abnormal collagen fibers may stain red with trichrome stain. Ultrastructural abnormalities of the collagen consist of variation in the fibril diameter, shape abnormalities, fibril disorganization, and loose fibril packing. A mixture of normal and abnormal collagen fibers may be present.

Cats

Collagen dysplasia in cats is usually referred to as *cutaneous asthenia*, although in early cases reported it was called dermatosparaxis. The condition has been reported in a number of breeds; *in the majority of the cases, neither the biochemical defect nor the mode of inheritance has been identified*. In a single Himalayan cat with collagen dysplasia, the abnormality was determined to be a defect of the amino-terminal procollagen peptidase, as in dermatosparaxis of cattle and sheep. This cat could not be bred, however, and the mode of inheritance was not determined. A breeding study based on an affected male domestic shorthair cat indicated that the condition is inherited as an autosomal dominant trait and heterozygous individuals synthesize both normal and abnormal collagen molecules.

Cats with cutaneous asthenia have thin, soft, velvety skin that tears easily but with minimal hemorrhage (Fig. 5.30). Lacerations heal to form typical white, tissue paper-like scars. In some cats, loose folds of skin develop as the cats age. No joint laxity has been described in cats with cutaneous asthenia. Histologic examination of the skin yields variable results. No dermal changes are evident in some cases; while in others, the dermis is thinner and collagen fibers are finer and separated by an increased amount of ground substance when compared to skin from an unaffected cat. Normal collagen fibers stain uniformly blue with Masson's trichrome stain while abnormal fibers exhibit segmental red staining areas that are birefringent under polarized light. Ultrastructural examination indicates that normal and abnormal collagen fibers may be present in varying proportions. Abnormal fibers are characterized by disorganized, tangled, nonparallel packing of fibrils. Abnormal "hieroglyphic" fibrils were a feature of the affected Himalayan cat.

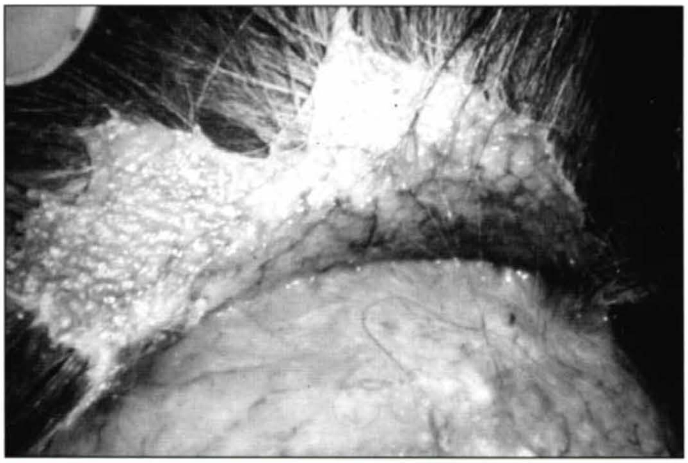

Figure 5.30 Feline cutaneous asthenia. Note tearing of fragile skin with minimal hemorrhage. (Courtesy of R Rosychuk.)

Skin fragility in cats has also been reported as an acquired condition associated with a number of conditions including spontaneous and iatrogenic hyperglucocorticism, diabetes mellitus, hepatic lipidosis, cholangiocarcinoma, and administration of various drugs. The histologic and ultrastructural changes of collagen in cats with acquired skin fragility may be similar or indistinguishable from those seen in cats with cutaneous asthenia.

Abnormalities of elastic fibers

An *excess of elastic fibers* was reported in several piglets of a litter of Large White X Essex pigs with multiple circular to oval shallow depressed skin lesions. The skin was abnormally elastic in these areas and seemed to be bound less tightly to the underlying subcutis. The increase in thick elastic fibers was present only in those areas in which the skin was hyperextensible and the condition was termed **cutis hyperelastica**.

Congenital abnormalities of ground substance

Proteoglycan deficiency

An abnormality of dermal proteoglycan is a rarely documented cause of fragile skin in humans and animals. Proteoglycan is composed of a core protein and glycosaminoglycan (mucopolysaccharide) side chains, and it is the major component of the extracellular ground substance of the dermis. A 4-month-old female Holstein calf with skin fragility, soft and hyperextensible skin, and poor wound healing typical of dermatosparaxis was found to have normal collagen fibers. However, levels of dermatan sulfate proteoglycan in the dermal connective tissue were undetectable. The defect was identified as a mutation involving the gene that codes for the proteoglycan core protein. The mode of inheritance was not determined.

Cutaneous mucinosis of Chinese Shar-Pei dogs

Cutaneous mucinosis is a dermal connective tissue disorder in which *excessive mucin accumulates in the skin.* Mucin is a gel-like substance comprised primarily of acid glycosaminoglycan, hyaluronic acid, and water. *The inherited form of cutaneous mucinosis is considered normal in the Chinese Shar-Pei dog* and is responsible for the thick, wrinkled skin characteristic of the breed. The degree of mucin accumulation is variable. In some dogs, large lakes of mucin form nodules or cysts that may rupture and drip clear, stringy fluid.

Histologically, cutaneous mucinosis is characterized by a variable increase in dermal thickness because of excessive mucin separating collagen fibers. Mucin has great water-binding capacity and thus contains a substantial amount of water, the majority of which is removed during processing of the tissue. What remains in HE-stained tissue sections is fine basophilic granular to fibrillar material separating dermal collagen fibers. Special stains can be used to better visualize the mucin; these include Alcian blue at pH 2.5, which stains mucin blue-green, and mucicarmine, which stains it red. Mucin stains metachromatically with toluidine blue and methylene blue. PAS stain, which stains neutral mucopolysaccharides, does not stain dermal mucin.

Dermatosis vegetans

Dermatosis vegetans is an inherited disorder of young pigs characterized by vegetating skin lesions, hoof malformation, and giant cell pneumonia. The condition is a simple autosomal recessive trait of Landrace swine in Europe, Canada, and Australia. Clinically affected pigs grow slowly, become emaciated and unkempt, and usually die by 2 months of life. The economic impact of the disease may be considerable since virtually all homozygotes die before reaching slaughter age.

Skin lesions may be present at birth, but more commonly they develop during the first 3 weeks of life, and in rare cases may not arise until 2–3 months of age. *Lesions begin as erythematous papules*, 0.5–2.0 cm in diameter, usually on the ventral abdomen and medial aspect of the thighs. They may extend up the sides and back but do not affect the head. The papules enlarge peripherally over the course of 2 or 3 days and the center becomes depressed. At this stage, the lesions are clinically similar to pityriasis rosea. The papules enlarge to form *plaques* with a depressed center filled with characteristic gray to brown-black granular brittle material. Over a period of weeks, the lesions continue to expand and develop a dry, horny, papilloma-like appearance. They become dark brown to black and *each crusty plaque is surrounded by a hyperemic raised border that sharply demarcates the lesions from the surrounding normal skin* (Fig. 5.31A). As lesions spread peripherally, they coalesce to form extensive areas covered by black crusts. Affected piglets frequently die when lesions reach the typical papilloma-like appearance at 5–8 weeks of age. Skin lesions then begin to resolve if the pig survives.

When they occur, *foot and hoof lesions* are always present at birth (Fig. 5.31B). Usually more than 1 limb is affected and typically all digits, including accessory digits, of an affected foot are involved. The coronary region is markedly swollen and erythematous; and the skin is covered by yellow-brown greasy material. The wall of the hoof is thickened by ridges and furrows parallel to the coronary band. Affected hooves become progressively enlarged, wider, and flatter than normal if pigs survive to 5 or 6 months. Coronary band changes, however, diminish as the pig ages.

At birth, affected piglets seem otherwise normal but over a period of weeks they gradually decline in growth and vitality. Except for animals that die perinatally, virtually all affected pigs show signs of *respiratory dysfunction*, typically increased respiratory rate and labored respiration, several days prior to death. Affected pigs commonly develop anemia and secondary infections, especially bacterial pneumonia.

The *histologic lesions* in the skin vary according to the stage of the condition. Initially, there is superficial dermal edema, vascular congestion, and dermal infiltration with numerous granulocytes, many

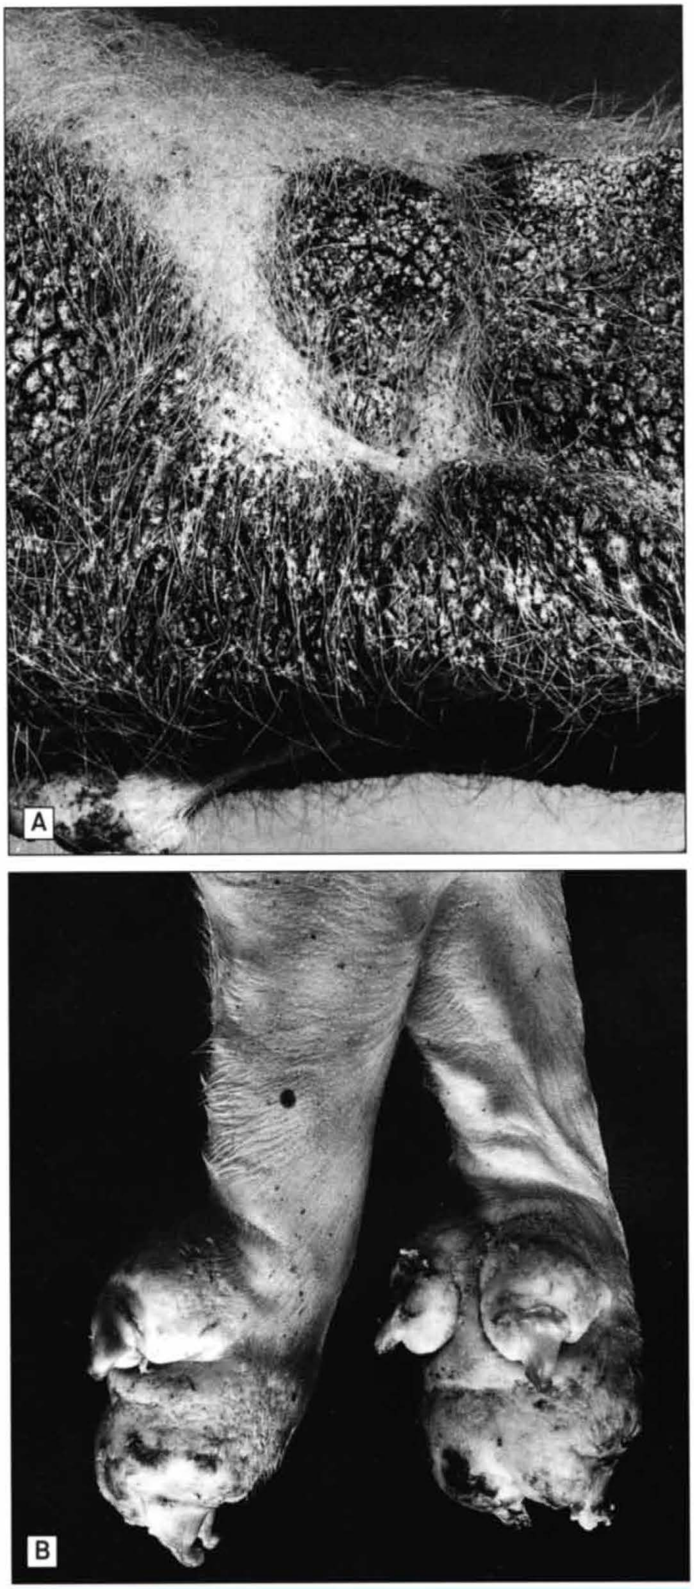

Figure 5.31. Dermatosis vegetans in a pig. **A.** Coalesced, crusted lesions on the abdominal wall. (Courtesy of DH Percy.) **B.** Congenital lesions of the feet. (Courtesy of JA Flatla.)

of which are eosinophils. Fully developed lesions are characterized by *marked orthokeratotic and parakeratotic hyperkeratosis, prominent irregular epidermal hyperplasia, intercellular edema, and intraepidermal pustules and microabscesses containing eosinophils and neutrophils.* The characteristic histologic lesion in the lung is *giant cells in alveoli.* The giant cells have been identified immunohistochemically as originating from monocytes/macrophages. In chronic cases, epithelialization and interstitial fibrosis are evident and multinucleated giant cells may be infrequent when the condition has lasted several months. Typical pulmonary changes may be obscured by secondary infections.

Dermoid cyst

The dermoid cyst (dermoid sinus) is an uncommon developmental anomaly that has been reported in dogs, cats, horses, and cattle. It is caused by defective epidermal closure along embryonic fissures, which isolates an island of ectoderm in the dermis or subcutis. The majority of dermoid cysts occur on the dorsal midline because of incomplete separation of skin and neural tube during embryonic development; but they also occur in other locations. Although present at birth, dermoid cysts are usually asymptomatic and may not be noticed until they become distended or infected in an older animal. The cyst usually *contains hair, keratin, and sebum* and this material may produce progressive enlargement of the structure so that it becomes clinically apparent. Cysts frequently become infected, producing clinical signs such as purulent discharge, local swelling from cellulitis, or neurologic signs secondary to meningomyelitis.

In **dogs**, dermoid cysts have been reported most commonly in the *Rhodesian Ridgeback*, a breed in which the lesion appears to be inherited as a simple recessive trait. Dermoid cysts have also been reported in a Siberian Husky, Yorkshire Terrier, Shih Tzu, and Boxer. It is unknown whether the lesion is an inherited condition in other breeds of dogs. Dermoid cysts have been associated with multiple vertebral and spinal malformations and hindlimb neurologic deficits in several dogs. The rare condition of *nasal dermoid sinus cyst* results in a discharging sinus over the external nares in dogs; the cyst may extend into the cranial vault and cause cerebral abscessation or recurrent meningitis. In one survey, all cases in *horses* were in Thoroughbreds. Several cases reported in *cattle* all involved Angus. Dermoid cysts are rare in *cats*, and both cases reported were in domestic shorthairs.

Dermoid cysts may be single or multiple. They consist of a well-circumscribed circular or tubular structure in the skin or subcutis and frequently connect to the skin surface by a small pore. A tuft of hair may protrude through this pore and it may be surrounded by a whorl of hair. The cyst may end blindly in the subcutis, it may connect to the dorsal spinous process of vertebrae directly or by a fibrous cord, or rarely it extends down to be continuous with the dura mater of the spinal cord. *Microscopically*, the dermoid cyst is a circular or tubular structure lined by a wall of well differentiated, keratinizing squamous epithelium with associated small but well developed hair follicles, sebaceous glands, and occasional apocrine sweat glands. The hair shafts project into the cyst cavity which also contains keratin and variable amounts of sebum. Bacterial infection results in neutrophilic infiltration into the cyst. Pyogranulomatous dermatitis or cellulitis ensues when the cyst ruptures because of infection, trauma, or obstruction of the pore.

DISORDERS OF EPIDERMAL DIFFERENTIATION

The epidermis is stratified squamous epithelium that forms a continuously regenerating protective sheet around the body. Basal keratinocytes proliferate, then differentiate, become keratinized and are then sloughed. *In normal canine skin, the migration from the basal to the cornified layer requires 22 days*, as measured by tritiated thymidine incorporation studies. This turnover rate is shortened in some skin diseases; for example, in seborrheic skin disease it is 7–8 days. The basement membrane separates the epidermis from the dermis and basal keratinocytes rest on this membrane anchored by hemidesmosomes and focal adhesions. Basal keratinocytes are the only cells in the epidermis that can undergo mitosis, and once mitosis occurs, the basal cell proceeds to undergo terminal differentiation. These postmitotic cells enter the stratum spinosum, develop intercellular attachments, desmosomes and adherens junctions, and change the keratin composition of the cytoplasmic keratin filaments. In the basal layer, keratins K5 and K14 are expressed, whereas in the suprabasal cells, K1 and K10 are expressed. The intercellular and cell substrate adhesions are complex. *Hemidesmosomes* and *desmosomes* are stable junctions that associate with cytoplasmic keratin filaments, whereas *focal adhesions* and *adherens junctions* connect to actin filaments and are transitory adhesions. *Integrins* are receptors that mediate cell–substrate adhesion, whereas *cadherins* mediate cell–cell adhesion. As the cells are pushed outwards they move into the stratum granulosum. Here they start to make proteins that make up *keratohyaline granules*. As the cells move into the stratum corneum, the cytoplasmic organelles are lost and they become metabolically inactive. These flattened inactive keratinocytes are compacted into a keratin layer that eventually exfoliates. In this way, *the epidermis is continuously regenerating and degenerating by proliferation, differentiation, and keratinization.*

While the cells are moving outward, keratin polypeptides form and polymerize into *keratin intermediate filaments* that are epithelial specific and the major component of the cytoskeleton of epithelial cells. The keratin intermediate filaments aggregate into *tonofilaments* which connect with desmosomes, and therefore indirectly with adjacent cells. The molecular structure of keratin is very important, and genetic mutation can affect keratin filament formation. There are at least 30 keratins in epithelium; K9–20 are acidic (type I), and K1–8 are basic (type II). Two different keratins (one acidic and one basic) pair to form *heterodimers*, for example K1 and K10 in suprabasal cells, and K5 and K14 in basal cells. Hyperproliferative epidermis in skin diseases expresses keratins K6 and K16, not seen in normal skin.

When the cells reach the stratum granulosum they start to synthesize proteins, stored in keratohyaline granules, necessary to form the mechanically strong *macrokeratins* in the stratum corneum. One of these, profilaggrin, dephosphorylates to form *filaggrin*, the major molecule responsible for the glue-like aggregation of intermediate filaments. *Loricrin* is also stored in keratohyaline granules, and this polypeptide contributes to the cell envelope; an insoluble intracytoplasmic barrier. *Other proteins* involved in cell envelope formation include involucrin, cystatin A, CREP (cystine-rich envelope protein), trichohyaline, SPRR (small proline-rich proteins), sciellin, and filaggrin. All of these serve as substrates for *transglutaminases* that polymerize and crosslink these proteins in the formation of the cell envelope. Three different transglutaminases have been identified in the skin. The granular layer also contains small lipid-rich granules – *submembranous lamellar bodies* (Odland bodies, membrane-coating granules) – that contain lipids necessary to form a permeability barrier between cells when they are secreted into the intercellular space. Keratinocytes forming the stratum corneum are dead and can be sloughed when desmosomes are broken down. Hydrolytic enzymes such as cathepsin B-like, carboxypeptidase, and acid phosphatase are thought to be responsible for this desmosomal degradation and subsequent keratinocyte desquamation.

In various epidermal diseases, this orderly epidermal turnover is altered. For instance, increased proliferation and/or decreased dyshesion of epithelial cells will lead to thickening of the epidermis. Nutritional factors such as amino acids, vitamins A or B, zinc, fatty acids, and copper influence proper differentiation and maintenance of the epidermis. Altered expression of different molecules and keratin mutations are the focus of much research.

Seborrhea

Seborrhea is a term used to describe a broad range of conditions ranging from dry flaky skin to severe oily or scaling, crusty lesions with alopecia. Seborrhea literally means "abnormal flow of sebum," however, the major clinical abnormality in seborrheic skin diseases is *altered keratinization.* Current terminology favors the use of the term *cornification defect* to cover all hyperkeratotic conditions from ichthyosis to flaky skin. The seborrheas can be divided into *primary idiopathic seborrhea* or *secondary seborrhea* where there is an underlying primary dermatosis.

The majority of seborrheic skin diseases are secondary. They can be secondary to disorders such as hormonal imbalances (especially hypothyroidism, hyperadrenocorticism and sex hormone imbalances), ectoparasitism (especially cheyletiellosis, pediculosis and demodicosis), endoparasitism, dermatophytosis, hypersensitivities (inhalant, dietary, drug), abnormal lipid metabolism (malabsorption, liver or pancreatic disease, diabetes mellitus), dietary deficiencies (fatty acids, protein, vitamin A, zinc), chronic catabolic states, environmental factors (especially hot, dry conditions), autoimmune disease (systemic lupus erythematosus, pemphigus foliaceus), and neoplasia (epitheliotropic lymphoma and internal malignancy).

Whatever the underlying cause, seborrheic skin is characterized by certain abnormalities. The first is *altered keratinization with or without altered glandular function.* This is reflected grossly by various degrees of scaling and crusting, with or without greasiness. Second, the surface lipids, whether the seborrheic skin is dry or greasy, have an *increased percentage of free fatty acids and cholesterol, and a decreased percentage of diester waxes.* Third, the altered keratinization and lipid film are accompanied by *a marked increase in the number of surface bacteria per unit of skin.* In addition, the bacterial flora usually switches from the normally nonpathogenic resident micrococci, corynebacteria and coagulase-negative and coagulase-positive staphylococci to a pure, heavy potentially pathogenic population of *coagulase-positive staphylococci.* Thus seborrheic skin, regardless of the underlying cause, is *often complicated by secondary bacterial disease.*

Clinically, seborrheic skin disease is often separated into three morphologic types:

- **Seborrhea sicca** is characterized by dry skin with focal or diffuse flaking and accumulations of white-to-gray nonadherent scales.
- **Seborrhea oleosa** is characterized by focal or diffuse scaling associated with excessive lipid production that produces yellowish to brownish material that adheres to the skin and hair.
- **Seborrheic dermatitis** is characterized by scaling and greasiness with gross evidence of local or diffuse inflammation. Pruritus and/or secondary bacterial infection is often present with all three forms. This clinical categorization has little significance in terms of differential diagnosis, and animals may be dry in one area of the body and greasy in another.

Seborrheic skin disease is reported most commonly in the dog, but also occurs in horses, cats, goats, sheep, cattle, rodents, and primates.

Primary idiopathic seborrhea

Seborrheic skin disease is common in **dogs**. Primary idiopathic seborrheic skin disease occurs in many breeds. The association with particular breeds and also an early age of onset suggest that primary canine seborrhea *may have an inherited basis.* Cocker Spaniels and Springer Spaniels tend to have a greasy, inflammatory form of seborrhea with numerous hyperkeratotic plaques, comedones and follicular casts. *Inflammatory ceruminous otitis externa* is also a constant finding. In Cocker Spaniels, cell proliferation kinetics indicate that seborrheic individuals have increased epithelial cell proliferation of the epidermis, hair follicle infundibulum and sebaceous gland. In addition, recombinant grafting studies have shown that the hyperproliferative epidermis from seborrheic Cocker Spaniels remains hyperproliferative, suggesting that the abnormality may be in the keratinocyte itself. *Other breeds with primary, greasy seborrhea* include the Basset Hound, West Highland White Terrier, German Shepherd, Dachshund, and Chinese Shar-Pei. Breeds having a *dry form of primary seborrhea* include the Irish Setter, Doberman Pinscher, Dachshund, and West Highland White Terrier. Primary seborrhea in German Shepherds, West Highland White Terriers, and Labrador Retrievers is often very inflammatory, lichenified, and pruritic. Seborrheic skin disease is typically more pronounced on the face, pinnae, trunk, pressure points, intertriginous areas, mucocutaneous areas, and paws. In Labrador Retrievers, the distribution is often strikingly ventral ("water-line disease").

Primary seborrhea is uncommon in cats and horses. Primary seborrhea oleosa, presumably of autosomal recessive inheritance, has been described in Persian **cats**. Severely affected kittens show lesions at 3–4 days of age, and develop progressively severe, generalized greasiness, matting of the haircoat, rancid odor, comedones, alopecia, and ceruminous otitis externa. Pruritus is absent. A milder form of the disease is recognized in 6–8-week-old kittens, with mild to moderate greasiness of the skin and haircoat. Primary seborrhea in the **horse** occurs in both dry and greasy forms, and tends to be restricted to the mane and tail. Pruritus is absent. Generalized primary seborrhea is rare in the horse.

Primary idiopathic seborrhea is usually characterized histologically by *superficial perivascular dermatitis. Epidermal hyperplasia* is usually mild to moderate and papillated in configuration. A pronounced keratinization defect is present, typified by *alternating vertical tiers of orthokeratotic and parakeratotic hyperkeratosis.* The parakeratosis is typically found overlying the shoulders of follicular ostia (*parakeratotic "caps"*). The underlying dermal papillae are often edematous, leading to spongiosis and *leukocytic exocytosis of the overlying epidermis ("papillary squirting")* (Fig. 5.32). Spongiform or Munro's microabscesses may be seen in conjunction with the parakeratosis. The perivascular inflammatory cells include variable combinations of lymphocytes, neutrophils, plasma cells, macrophages, and mast cells. Since *secondary bacterial infection is common*, subordinate patterns of suppurative folliculitis, furunculosis, perifolliculitis and intraepidermal pustular dermatitis are frequently seen.

Secondary seborrhea

Secondary seborrheic skin disease is also characterized by a *pronounced keratinization defect, orthokeratotic and/or parakeratotic in nature.* The overlying histologic reaction pattern, however, reflects the underlying disease process (hypersensitivity, ectoparasitism, endocrinopathy, etc.). Occasionally, in predisposed breeds, it is necessary to attempt to eliminate coexisting dermatoses to determine if a primary seborrhea is also present.

Acne

Acne is seen in *short-coated breeds of* **dogs**, especially English Bulldogs, Boxers, German Shorthaired Pointers, Great Danes, and Doberman Pinschers. It usually occurs between 3–12 months of age with no sex predilection and occasionally persists into adult life. The *etiology and pathogenesis are unknown*, but, since this is a disease seen in association with puberty in dogs, may be similar to that in humans, involving increased circulating levels of androgens and "acne-prone" skin. The lesions of canine acne are *asymptomatic papules and pustules, which arise from comedones*. Typically, the *chin and lips* are involved. Secondary bacterial folliculitis and furunculosis may occur. Histologically, there is marked orthokeratotic hyperkeratosis, dilation and plugging of hair follicles, and variable inflammation.

Acne is common in **cats** and has no sex or breed predilections. It usually occurs in mature cats, is asymptomatic, and persists for life. It is therefore unlike acne in the dog or humans as it is not associated with puberty. The cause is unknown. The lesions of feline acne are *asymptomatic comedones on the chin and lips*. Occasionally, secondary bacterial folliculitis and furunculosis develop. Histologically, marked orthokeratotic hyperkeratosis, dilation and plugging of hair follicles with variable inflammation are seen.

Schnauzer comedo syndrome

This condition occurs only in the Miniature Schnauzer breed. Either sex may be affected, and the condition usually develops early in life. The exclusive occurrence in Schnauzers and the early onset suggest that this syndrome *may be a developmental dysplasia of hair follicles with an inherited basis*. Clinically, the condition is characterized by multiple asymptomatic comedones over the *dorsal midline*. Occasionally, secondary bacterial folliculitis and furunculosis may develop. Histologically, there is marked orthokeratotic hyperkeratosis, dilation and plugging of hair follicles (comedones), and variable inflammation.

Tail gland hyperplasia

Many **dogs** have an oval area of skin on the dorsal surface of the tail above the fifth to seventh coccygeal vertebrae referred to as the *tail (supracaudal, preen) gland*. Microscopically, large, densely packed *perianal ("hepatoid") and sebaceous glands* characterize this area. In some dogs, especially adult to aged males, this area enlarges. The enlargement is usually firm to slightly spongy, and associated with partial alopecia, scaling and greasiness. At this stage, the lesion is asymptomatic. Occasionally, the lesions become cystic and/or secondarily infected, or neoplastic.

In most instances, canine tail gland hyperplasia is associated with *hormonal imbalances*, especially elevated levels of blood testosterone. Histologically, the lesions are characterized by *marked hyperplasia of the perianal gland component, with a variable inflammatory response*.

The entire dorsal surface of the tail in **cats** is replete with large, densely packed sebaceous glands, recently proposed to be embryonal hepatoid glands. In some cats, especially sexually active males of the Persian, Siamese and Rex breeds, this area becomes clinically seborrheic, whereupon a brown to black, greasy keratosebaceous material accumulates on the hairs of the skin surface. Unless secondarily infected, the condition is asymptomatic. The cause of feline tail gland hyperplasia is unknown, and the colloquialism "stud tail" is misleading, as the condition is also seen in intact females and neutered males and females. Histologically, the condition is characterized by *marked hyperplasia of sebaceous glands, with variable orthokeratotic hyperkeratosis and inflammation*.

Canine nasodigital hyperkeratosis

Canine nasodigital hyperkeratosis is characterized by *increased amounts of horny keratin on the nasal planum and/or footpads*. This disorder may be seen in association with canine distemper (hard pad disease), pemphigus foliaceus, pemphigus erythematosus, systemic or discoid lupus erythematosus, zinc-responsive dermatoses, superficial necrolytic dermatitis, and as an idiopathic senile change. Digital hyperkeratosis occurs as an hereditary disorder in Irish Terriers and dogues de Bordeaux; nasal hyperkeratosis may occur as a hereditary disorder in young Labrador Retrievers. Histologically, *marked orthokeratotic and/or parakeratotic hyperkeratosis and irregular to papillated epidermal hyperplasia* characterize nasodigital hyperkeratosis. Age, breed, and other histopathologic findings reflect those of the underlying diseases.

Keratoses

Keratoses are firm, elevated, circumscribed areas of excessive keratin production. In humans, keratoses are common and of numerous types. *Keratoses are uncommonly reported in domestic animals.* Actinic keratoses are discussed elsewhere.

Equine linear alopecia (linear keratosis) is a characteristic clinical entity. It occurs in many breeds, however Quarter Horses seem to be predisposed. The age of onset is usually at 1–5 years. The clinical lesions are characterized by one or more *vertically oriented linear areas of alopecia, with variable crusting and scaling.* They are usually unilateral and occur most commonly on the *neck, shoulder and lateral thorax.* The lesions are usually asymptomatic, and may be persistent or permanent. The *etiology of the condition is unknown* but may involve an immune-mediated attack on the wall of the hair follicle. The reason for the linearity is unknown. Histologically the lesion is characterized by *lymphocytic or lymphohistiocytic mural folliculitis*, sometimes with follicular destruction (Fig. 5.33A, B). Multinucleated giant cells are variably present. Sebaceous glands can be secondarily effaced, and there is a variable amount of orthokeratotic or parakeratotic hyperkeratosis, with or without superficial perivascular nonsuppurative inflammation. Linear keratoses with a similar gross and histologic appearance have also been described in *cattle.*

Equine cannon keratosis is a clinically recognizable disease of the horse. It represents a localized form of seborrheic dermatosis, can occur at any age, and has no breed predilection. The colloquial term, "stud crud," is inappropriate as it also occurs in mares. The lesions consist of *vertically oriented, moderately well demarcated areas of alopecia, scaling and crusting on the cranial surface of the rear cannon bones.* The lesions are usually bilateral and persist for life. Pruritus and pain are absent. Histopathologic findings include orthokeratotic and/or parakeratotic hyperkeratosis, irregular to papillated epidermal hyperplasia, and mild superficial perivascular dermatitis featuring lymphocytes and macrophages.

Seborrheic keratoses have been recognized in dogs. They are of unknown cause, and have nothing to do with seborrhea. They may be single or multiple and have no apparent age, breed, sex or site predilections. The lesions are elevated plaques or nodules with a hyperkeratotic, often greasy surface. They are frequently hyperpigmented. Pruritus and pain are usually absent. Histologically, seborrheic keratoses are characterized by orthokeratotic hyperkeratosis, epidermal hyperplasia (basaloid and squamoid), and papillomatosis. In humans, the sudden appearance or enlargement of multiple lesions can be associated with an internal malignancy. This association has not been made in domestic animals.

Lichenoid keratoses have been reported as single or occasionally multiple wart-like papules or hyperkeratotic plaques that may be hyperpigmented on the *inner surface of the pinna in dogs.* Age, breed and sex predilections have not been noted. Histologically, irregular to papillated epidermal hyperplasia, moderate to marked orthokeratotic and/or parakeratotic hyperkeratosis, and a lichenoid inflammatory infiltrate predominantly consisting of lymphocytes and plasma cells characterizes lichenoid keratosis.

Lichenoid dermatoses are rare skin disorders of dogs and cats. There is no apparent age, breed, or sex predilection. The dermatoses are characterized by the usually asymptomatic, *symmetric, grouped, flat-topped papules and plaques that are variably distributed, and that develop a scaly to markedly hyperkeratotic surface.* The lesions are *self-limiting* although resolution may take several years. Histologically these dermatoses are characterized by lichenoid interface dermatitis composed of plasma cells and lymphocytes, marked orthokeratotic hyperkeratosis and follicular keratosis, and moderate epidermal hyperplasia. Apoptotic keratinocytes can be seen primarily, although not exclusively, in the basal layer and there is often hydropic degeneration of basal keratinocytes. If focal areas of suppurative epidermitis and/or suppurative folliculitis are present, a lichenoid tissue reaction in response to staphylococcal infection should be suspected.

Cutaneous horns are recognized occasionally in all domestic species. Some are of unknown cause; *others originate from papillomas, basal cell tumors, squamous cell carcinomas or other keratoses.* In cattle, sheep, and goats, cutaneous horns may arise in lesions of dermatophilosis. In the cat, multiple cutaneous horns on the footpads have been reported in association with *Feline leukemia virus* (FeLV) infection; FeLV was

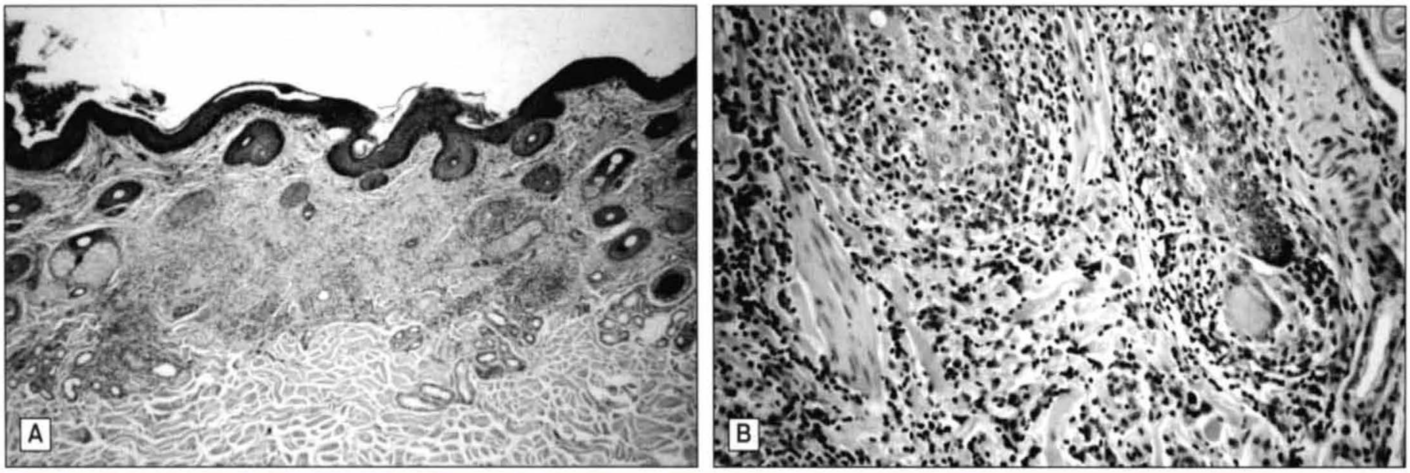

Figure 5.33 Equine linear alopecia A. Low magnification showing a follicular orientation of the inflammatory infiltrate. **B.** Lymphohistiocytic to granulomatous mural folliculitis disrupts hair follicles.

cultured from the horns, and type C viral particles were seen in the lesions with the electron microscope.

Cutaneous horns may be single or multiple, and have no apparent age, breed, sex or site predilections. The lesions are *firm, well-circumscribed horn-like projections from the skin.* They may be small (1 mm diameter × 5 mm length) or quite large (3 cm diameter × 12 cm length). Histologically, cutaneous horns are characterized by *extensive, compact, laminated, orthokeratotic, and/or parakeratotic hyperkeratosis.* The base of the horn must be inspected for the possible underlying cause.

Linear epidermal nevi are characterized histologically by *linear hyperkeratosis with epidermal hyperplasia.* They have been reported in several species. These include linear epidermal nevi in Belgian horses, inflammatory linear verrucous epidermal nevus in dogs, and a hereditary disorder of cornification in Rottweiler dogs (see Congenital and hereditary diseases of skin). The term nevus implies a lesion present at birth and composed of mature elements, and therefore since these linear hyperkeratotic lesions have in common an early age of onset, *they may represent linear epidermal nevi that have tardive onset.* Equine cannon keratosis is grossly and histologically similar to linear epidermal nevi but differs from the linear epidermal nevi of Belgian horses as it can occur at any age and is restricted to the skin of the cannon area.

Sebaceous adenitis

Sebaceous adenitis is an *uncommon skin disease of dogs* that has also been reported in the cat and rabbit. The condition has been reported in numerous breeds of dog and in mongrels, however there *is breed predilection* for Standard Poodles, Akitas, Samoyeds, and Vizslas, suggesting a genetic basis. In Standard Poodles and Akitas, an autosomal recessive trait is proposed. Onset of the disorder is usually in young adults to middle-aged animals and there is no sex predilection.

The early lesions consist of patches of scaling and alopecia that tend to appear on the *ears and dorsum.* In short-coated dogs, these progress to annular areas of alopecia and scaling on the trunk and head. Longer-coated animals initially develop a thin coat due to loss of the undercoat, and then develop symmetrical multifocal to generalized areas of patchy alopecia and brittle to broken hairs encircled by yellow to brown follicular casts. Secondary bacterial infection is common. Early histopathologic changes are characterized by *granulomatous or pyogranulomatous inflammation targeted on the sebaceous glands and eventually destroying the gland* (Fig. 5.34A). Inflammation can occasionally impinge secondarily on the follicular epithelium causing folliculitis. Orthokeratotic and/or parakeratotic hyperkeratosis together with follicular keratosis can be marked. In the chronic stages, both active inflammation and sebaceous glands may be absent, and there may be perifollicular fibrosis (Fig. 5.34B). After the disappearance of the glands, the hair follicles frequently assume a "stretched out" configuration and are keratin filled. Regeneration of sebaceous glands after variable amounts of time has been reported in occasional cases.

The pathogenesis of this disease has not been fully characterized. Several possibilities include: (1) destruction of the gland due to immune-mediated mechanisms leading to secondary hyperkeratosis; (2) a

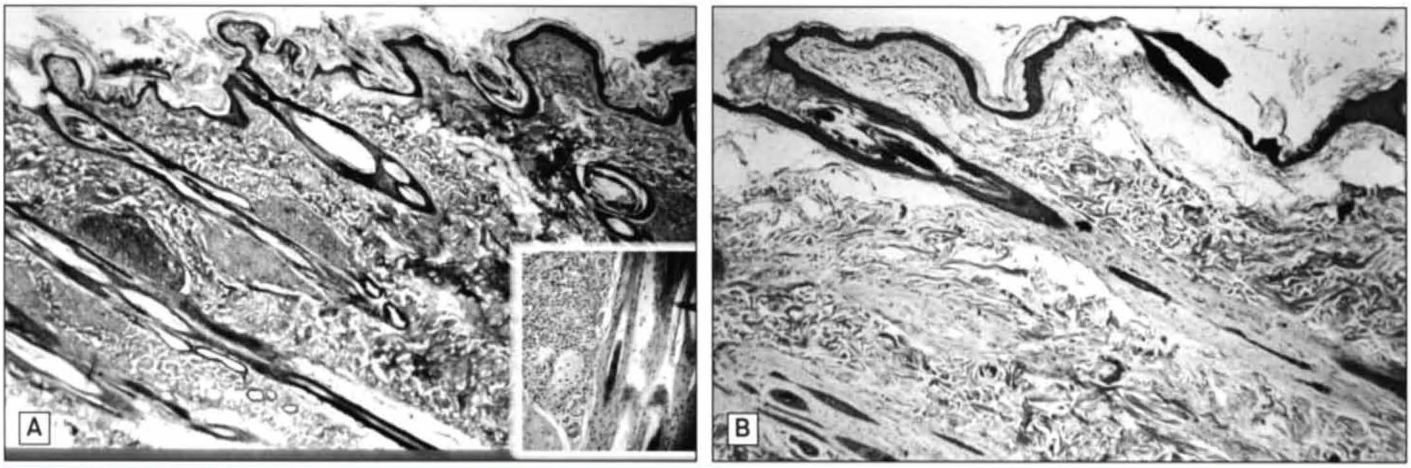

Figure 5.34 Sebaceous adenitis in a dog. **A.** Early lesions. Mononuclear leukocytes target sebaceous glands. Sebocytes are destroyed by the inflammation (see inset). **B.** Late lesions. Inflammation is minimal and areas of fibrosis have replaced sebaceous glands. There is epidermal and follicular hyperkeratosis. (Courtesy of B Dunstan.)

primary keratinization defect resulting in increased amounts of follicular keratin blocking the sebaceous duct and causing inflammation of the gland; or (3) a defect in the structure of the sebaceous duct or gland resulting in inflammation directed at free sebum. In the predisposed breeds such as Standard Poodles and Akita, a genetic basis seems probable together with other factors that would explain the variation in onset and progression of the disease.

Vitamin A-responsive dermatosis

Vitamin A-responsive seborrheic dermatoses occur most commonly in Cocker Spaniels, but can occur in other breeds (see Nutritional diseases of skin). There is, however, no clinicopathologic evidence to suggest that these animals have vitamin A deficiency.

Lichenoid-psoriasiform dermatosis of Springer Spaniels

This is an uncommon dermatosis that affects young English Springer Spaniels of either sex. Asymptomatic, generally symmetric, hyperkeratotic, erythematous papules usually begin on the pinnae and groin, coalesce to plaques, and progressively involve large areas of the body, especially the ventral abdomen and prepuce. Secondary bacterial infection is common.

Histopathologic findings include *lichenoid dermatitis* composed predominantly of plasma cells, with areas of *psoriasiform epidermal hyperplasia*, occasional apoptotic basal keratinocytes, intraepidermal microabscesses (containing eosinophils and neutrophils), and Munro's microabscesses. Chronic lesions frequently show papillated epidermal hyperplasia, papillomatosis, and moderate to marked orthokeratotic and/or parakeratotic hyperkeratosis. *The histologic findings are very similar to lichenoid keratosis and must be differentiated clinically by knowledge of distribution of lesions and knowledge of the breed.*

Ear margin dermatosis

This is an idiopathic seborrheic disorder that is localized to the margins of the pinnae. It occurs primarily in the Dachshund, although it can be seen in other breeds with pendulous ears. It may represent a localized primary seborrhea. There is no sex predilection, and the disorder usually begins in young adults. Waxy keratosebaceous accumulations and alopecia follow initial scaling of the ear margins. The disease is symmetrical and asymptomatic. The dermatosis may be complicated by secondary bacterial infection and fissures, at which point ulceration, oozing, crusting, pain and pruritus may be seen. Histopathologic findings are characterized by *marked orthokeratotic and/or parakeratotic hyperkeratosis with follicular keratosis and variable mild superficial perivascular dermatitis.*

Exfoliative dermatoses (exfoliative erythroderma)

This refers to a cutaneous reaction pattern that can be associated with many diseases. Clinically it is characterized by scaling and erythema that can be localized or generalized. Most cases of exfoliative dermatosis have been reported *in association with thymoma, cutaneous lymphoma, visceral malignant neoplasms, drug reactions, or are idiopathic.* Histopathologic findings can reflect the underlying condition and can include parakeratosis, epidermal acanthosis, variable psoriasiform epidermal hyperplasia, variable lymphocytic exocytosis, and perivascular to lichenoid dermal inflammation.

Exfoliative dermatosis resembling human large plaque parapsoriasis has been reported in a dog and a cat. The human disease, to which these cases were compared, is frequently a precursor to mycosis fungoides.

Hyperplastic dermatosis of West Highland White Terriers

This is a *severe chronic seborrheic disorder* in which there is a marked breed association with West Highland White Terriers. It was previously referred to as "epidermal dysplasia of West Highland White Terriers;" however epidermal hyperplasia is a more common finding. Epidermal disorganization or keratinocyte abnormalities characteristic of dysplasia are not present. Clinical signs begin at <1 year to middle age, with severely affected dogs tending to have an earlier age of onset.

Erythema and scaling with pruritus develop on the trunk, especially axillary and inguinal regions, and progress to involve the whole body. In chronic cases, the skin becomes lichenified, alopecic, hyperpigmented, and greasy. This combination of gross lesions has led to this condition being referred to as the "armadillo Westie syndrome." Histologic epidermal lesions are characterized by *acanthosis with mild to marked orthokeratosis or parakeratosis*. The base of the hyperplastic epithelium can have a scalloped appearance, and there is multifocal spongiosis with lymphocytic exocytosis. *There is commonly secondary* *pyoderma and/or infection with Malassezia.* The absence of *Malassezia* organisms in histologic sections does not necessarily exclude their presence as the organisms may be lost in tissue processing. Cytological evaluation for yeasts is a more reliable indicator of the presence and numbers of yeasts. *The lesions of hyperplastic dermatosis of West Highland White Terriers can be very similar histologically to lesions of chronic allergic dermatitis,* and the two conditions can frequently coexist in this breed. The condition may actually be a tissue reaction secondary to an allergic dermatitis or infectious condition and not a primary disease entity.

Equine coronary band dystrophy

Equine coronary band dystrophy is a condition of *unknown etiology and pathogenesis.* The condition affects adult horses of any breed, but draft breeds are considered predisposed. Equine coronary band dystrophy is characterized by *marked proliferation and hyperkeratosis of the epidermis of the coronary band and in some cases the chestnuts and ergots.* Usually all four limbs are affected; however the lesion may not encompass the entire coronary band. Clinically, the coronary band is thickened, crusty and scaly. Cracks and fissures may develop and lead to lameness. The chestnuts and ergots are similarly affected and may be ulcerated. Histologically, the epidermis of affected areas is characterized by marked papillary hyperplasia and marked ortho- to parakeratotic hyperkeratosis. In some areas, there is ballooning degeneration of keratinocytes. Dermal inflammation is minimal unless secondary infection is present. *The diagnosis is made by ruling out other differential diagnoses that include pemphigus foliaceus, the hepatocutaneous syndrome, bacterial or fungal infection, selenium toxicosis, and eosinophilic exfoliative dermatitis.* The condition is chronic and treatment palliative.

Ichthyosis

The ichthyoses are rare disorders of cornification that result in severe generalized scaling. These disorders are congenital and heritable (see Congenital and hereditary diseases of skin).

DISORDERS OF PIGMENTATION

Melanin pigments are responsible for the coloration of the hair, skin, and eyes, and also play an important role in photoprotection. Melanin is synthesized by melanocytes, which are dendritic cells originating as melanoblasts in the neural crest. Melanoblasts develop in the neural crest, migrate to peripheral sites such as skin, hair follicles, and dermis, differentiate into melanocytes, and synthesize melanosomes and melanin. Genetic mutations affecting any of these steps can lead to hereditary hypopigmentation. Many such mutations have been characterized in the murine model but this area has been little studied in domestic animals. Many types of exogenous influences, such as inflammation, UV radiation, endocrinopathies, autoimmune diseases, and nutritional status can affect melanocytes in the skin resulting in acquired hypopigmentation or hyperpigmentation.

Melanin synthesis in melanocytes takes place in *melanosomes,* which are round or elliptic membrane-bound organelles thought to be derived from endoplasmic reticulum and containing enzymes from the Golgi and lysosomal system. Melanosomes are designated type I through type IV, according to their stage of maturation. Type I melanosomes contain no melanin and are electron-lucent, whereas type IV are mature melanosomes that are electron-dense and migrate to the tips of the dendritic processes to be transferred to adjacent epithelial cells. Melanogenesis in round melanosomes produces *eumelanins, the black pigments,* and in elliptic melanosomes produces *pheomelanins, red and yellow pigments.* Pigment types in horses, sheep, goats, and llamas have been analyzed. These melanin pigments arise from the common metabolic pathway of conversion of tyrosine to DOPA and then oxidation to DOPAquinone. *Tyrosinase,* a copper-containing enzyme, is the critical and rate-limiting enzyme in this pathway, catalyzing tyrosine to DOPA. Many gene products are sequentially important to the melanoblast and melanocyte during their development and maturation. Apart from tyrosinase, the molecular role of these gene products has not been completely characterized, but it appears that platelet-derived growth factor (PDGF), and receptors for fibroblast growth factor (FGF-2), endothelin-B, and the Steel factor (cKIT) are crucial.

Cutaneous pigmentary disorders can be divided into disorders of *hyperpigmentation* and *hypopigmentation.*

Disorders of hyperpigmentation

Acquired hyperpigmentation

Acquired hyperpigmentation of the skin (**melanoderma**) is encountered frequently. It is usually post inflammatory, a result of minor or chronic irritation, and may be accompanied by mild hyperkeratosis. *Both melanosis and hyperkeratosis are common responses to mild injuries by agents as diverse as mites and irradiation.* Hypermelanosis results from an increased rate of melanosome production, an increase in melanosome size, or an increase in the degree of melanization of the melanosome. It is usually associated with an accelerated melanocyte turnover with an increased number of melanosomes, as occurs following trauma and ultraviolet light exposure. Inflammatory mediators likely play a role in stimulating melanocyte production. Activation of pre-existing immature melanocytes by sunlight, estrogen, and progesterone is thought to occur. Endothelin-1, which is produced and secreted by keratinocytes after UV-irradiation, has been shown to accelerate melanogenesis. Basic fibroblast growth factor (bFGF) has been shown to be a mitogen for human melanocytes. Proliferating human epidermal cells in culture produce bFGF, perhaps illustrating the mechanism behind the hyperplastic and hyperpigmented lesions that typify many chronic dermatoses.

Acquired hyperpigmentation may also involve hair (**melanotrichia**). This is usually seen as a result of inflammatory skin disorders, especially those caused by biting insects in the horse and also has been described in white Merino sheep exposed to ultraviolet light.

Focal macular melanosis

Lentigo simplex has been reported in *cats and dogs*, and is most common in cats with orange, cream, or tricolored coats. The lesions are flat, or minimally raised, pigmented macules and usually occur on the mucocutaneous junctions of the mouth, eye, and nose, and the footpads. Lesions tend to start at less than one year of age and may increase in size and number with age. *The lesions are of no significance except that they can be confused clinically with melanoma or pigmented nevus.* Histologically, lentigines are characterized by minimal to mild epidermal hyperplasia with formation of elongated rete ridges. There are increased numbers of melanocytes, particularly in the stratum basale, and usually increased melanin in basal keratinocytes. Low numbers of melanophages may be present in the underlying dermis. Papillated epidermal hyperplasia and hyperkeratosis are not present. Generalized lesions have been reported in a silver cat.

Merino **sheep** may acquire pigmented macules, particularly after shearing. *Lesions are concentrated on the back suggesting a role for sunlight exposure.* Experimental exposure to ultraviolet light induced lesions as early as 10 days post-irradiation. Histologically, these lesions are characterized by increased numbers of epidermal melanocytes at the dermoepidermal junction and in the normally non-pigmented outer root sheath epithelium.

Canine acanthosis nigricans

Canine acanthosis nigricans *is an idiopathic dermatitis, characterized by progressive hyperpigmentation, alopecia, and lichenification.* The lesions are roughly bilaterally symmetrical and typically start in the axillae, spreading to involve proximal limbs, ventral abdomen, neck, and inguinal area. Seborrhea, *Malassezia* infection, and bacterial pyoderma are frequent complications. Histologic examination reveals a hyperplastic dermatitis with orthokeratotic and parakeratotic hyperkeratosis, acanthosis and rete ridge formation. All layers of the epidermis are heavily melanized. Spongiosis, neutrophilic exocytosis, and serous crusts may also be present. The dermal inflammatory reaction is mild, pleomorphic in cell type, and superficial perivascular in location.

The primary or idiopathic form of acanthosis nigricans occurs predominantly in Dachshunds. In view of the early age of onset (usually <1 year old) and the strong predilection for dachshunds, it is probable that canine idiopathic acanthosis nigricans is a *heritable disorder*. In man, some forms of acanthosis nigricans are associated with internal malignancies, hyperinsulinemia, insulin resistance, drug administration, endocrine dysfunction, and concurrent autoimmune disease; a similar correlation has not been demonstrated in dogs. The histologic lesions of primary acanthosis nigricans are virtually identical to the common histologic changes associated with chronic pruritic dermatitides (sometimes referred to as pseudo-acanthosis nigricans or secondary acanthosis nigricans) due to several causes, including chronic pyoderma, atopy and seborrheic dermatitis, and some endocrine disorders. *The diagnosis of primary acanthosis nigricans requires clinical correlation together with the histologic findings to support the diagnosis in a young Dachshund with compatible distribution of lesions.*

Acromelanism

Acromelanism is seen in Siamese and Himalayan cats, rabbits, and mice. It is a condition in which coat color can be influenced by external temperature (high temperatures producing light hairs, low temperatures producing dark hairs) and factors affecting heat production and loss (alopecia, inflammation). *The coat color changes are usually temporary*, and the hair returns to the normal color with the next hair cycle. *These phenomena are due to a missense nucleotide substitution in tyrosinase making the enzyme thermally unstable.*

Disorders of hypopigmentation

Leukoderma and leukotrichia

Reduction in pigmentation of the skin is **leukoderma**, and of the hair is **leukotrichia**. Leukoderma and leukotrichia may occur independently. They can result from a decrease in melanin (**hypomelanosis**), a complete absence of melanin (**amelanosis**), or from a loss of existing melanin (**depigmentation**). These events result from either an absence of the pigment-synthesizing melanocytes or from a failure of melanocytes to produce normal amounts of melanin or to transfer it to adjacent keratinocytes.

Hereditary hypopigmentation

Hereditary hypopigmentation can be divided into *melanocytopenic hypomelanosis* characterized by the absence of melanocytes in affected areas, and *melanopenic hypomelanosis* in which melanocytes are present but defective. The condition can be localized, focally extensive, or generalized. Melanocytopenic hypomelanosis can be extensive, as is seen in animals with Waardenburg syndromes and in piebaldism. In these cases, there is failure of melanoblasts to migrate from the neural crest into the skin, or failure to survive in the skin. Melanocytopenic hypomelanosis can also be localized, as in vitiligo, in which there is genetically programmed destruction of melanocytes. Melanopenic hypomelanosis is seen in the various forms of albinism.

Melanocytopenic hypomelanosis

Syndromes analogous to the human **Waardenburg syndrome** have been reported in cats, dogs, horses, and rabbits. *Affected animals typically have white coats and blue or heterochromatic irides, and are deaf.* In *cats*, this has been shown to be due to an autosomal dominant mutation with complete penetrance for loss of pigmentation and incomplete penetrance for deafness. In *dogs*, this syndrome has been described in breeds such as the Dalmatian, Bull Terrier, Sealyham Terrier, Collie, and Great Dane. A syndrome analogous to human Waardenburg type-4 (Hirschsprung disease) has been reported in mice with lethal spotting mutation, and in American Paint horses in which white foals from overo mares are born with aganglionic colons. These foals develop colic and die shortly after birth.

Piebaldism is also a form of genetic melanocytopenic hypomelanosis resulting in *multifocal white patches* in which there is absence of melanocytes due to a congenital failure of melanoblasts to migrate from the neural crest to the skin, or by their inability to survive and proliferate in the skin. Piebaldism has been *seen in many species* including horses, dogs such as the Dalmatian, cats, cattle, and rodents. The defect has been shown to be a mutation in the gene encoding c-kit tyrosine kinase receptor, or a mutation in the gene for stem cell factor, which is the receptor ligand. The c-kit tyrosine kinase receptor is associated with proliferation and survival of melanoblasts.

Literally meaning, "blemish," **vitiligo** is a melanocytopenic hypomelanosis of humans and animals, which is characterized by *gradually expanding pale macules that are often symmetrical or segmental in distribution* (Fig. 5.35). Vitiligo has been described in the dog, cat, horse, cattle, and the Smyth chicken (DAM chicken) which has been used as an animal model of the human disease. The immediate cause of vitiligo is the destruction of melanocytes. It is considered to be a *genetic amelanosis inherited as an autosomal recessive trait in animals*. It is thought to be a polygenic disease necessitating simultaneous mutations in several genes resulting in melanocyte destruction or increased risk of immune-mediated destruction of melanocytes. Theories regarding the pathogenesis of this disease include autoimmune destruction of melanocytes, a neurogenic theory involving release of a neurochemical from peripheral nerves that inhibits melanogenesis, a self-destruction theory that involves failure of protection of melanocytes against the toxic effects of melanin precursors, or a combination of factors. Circulating antimelanocytic antibodies have been detected in some studies, lending support to an immune-mediated pathogenesis.

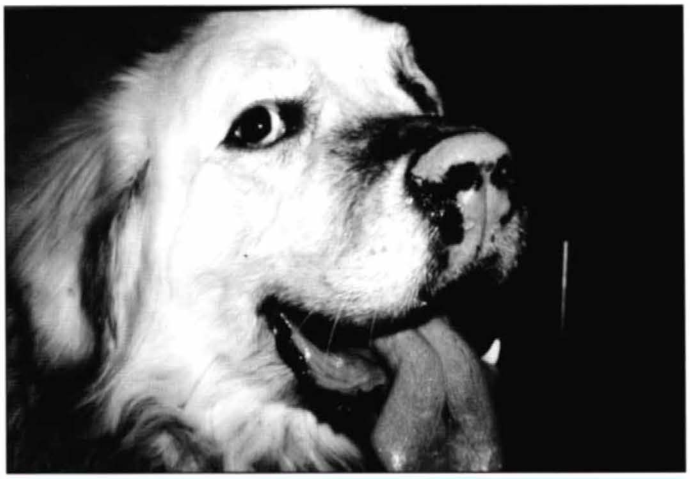

Figure 5.35 Vitiligo in a dog. Coalescing pale macules on the skin of the nasal planum and lips. (Courtesy of B Dunstan.)

Vitiligo in the **dog** has been described in Belgian Tervuren, Doberman Pinscher, Newfoundland, Rottweiler, German Shepherd, Dachshund, German Shorthaired Pointer, and Old English Sheepdogs. Vitiligo in a Dachshund developed concurrently with juvenile-onset diabetes mellitus. The condition best characterized is seen in Belgian Tervurens. The depigmentation in this breed occurs chiefly on the pigmented skin and mucous membranes of the face and mouth in young adult dogs. Histologic examination of affected skin shows an epithelium devoid of both pigment granules and DOPA-positive cells. Electron microscopy confirms the lack of melanocytes in the lesions; their place is taken by Langerhans or indeterminate dendritic cells. Antimelanocytic antibodies have been demonstrated in affected dogs but not in normal animals.

Vitiligo has also been described in **horses**. In one form, the "**Arabian fading syndrome**," affected animals develop round, depigmented macules on the lips, muzzle, around the eyes, and occasionally the anus, vulva, prepuce, and hooves. The disease can start at any age, but is more common in horses under 2 years of age. Circulating antimelanocytic antibodies have been detected in some cases.

In **cattle**, vitiligo-like lesions have been described in Holstein-Friesians, in black Japanese cattle, and in water buffalo.

Siamese cats may develop vitiligo. Antibodies to an 85-kDa surface antigen of melanocytes were demonstrated in four cats with vitiligo. No antibodies were detected in three normal Siamese cats tested.

Melanopenic hypomelanosis

The various forms of **albinism** are examples of melanopenic hypomelanosis. In albino animals and people, melanocytes are present and normally distributed but are defective in function and fail to synthesize melanin. The extent of the biochemical defect varies, so that *albinism covers a spectrum from amelanosis, oculocutaneous albinism (OCA), through graded pigmentary dilution.* Oculocutaneous albinisms and pigment dilutions are inherited as autosomal recessive traits. In albino animals with white hair and skin, and translucent irides, there is a mutation in the tyrosinase gene resulting in no residual enzyme activity. A mutation resulting in residual enzyme activity produces animals born with white hair but producing blond or pigmented hair as juveniles. The skin remains white but can develop pigmented nevi. This form has been reported in a gorilla.

Chediak-Higashi syndrome in humans, Hereford, Brangus and Japanese Black cattle, Persian cats, mink, blue and silver fox, and various other animal species is an example of *partial albinism and is inherited as an autosomal recessive trait.* While melanin is produced, there is a mutation of the *beige* gene, which plays a major role in generating cellular organelles. This results in a membrane defect leading to the formation of giant melanosomes that are passed with difficulty to the keratinocytes. The clumping of these giant melanosomes produces the color dilution effect. Chediak–Higashi syndrome is discussed with the Hematopoietic system.

Cyclic hematopoiesis (cyclic neutropenia), a lethal hereditary disease of Collie dogs, is caused by an autosomal recessive gene with a pleiotropic effect on coat color dilution. Affected dogs are silver-gray. The abnormal hair pigmentation results from the diminished formation of melanin from its precursor tyrosine rather than from pigment clumping. The normal collie coat color is restored in animals receiving bone marrow transplants to correct cyclic hematopoiesis. The hematological aspects of this disease are considered with the Hematopoietic system.

Coat color dilution has been reported in many species. It occurs in many breeds of dog, in cats, particularly Siamese cats, horses, and cattle. The pale coat coloration is due to clumping of large melanin granules in hair follicles and sometimes in the epidermis. In cats, dilute coat color is thought to be due to an autosomal recessive trait (*Maltese dilution*). **Color-dilution alopecia**, a tardive-onset hypotrichosis associated with color dilution traits in the dog, is discussed under Congenital and hereditary diseases of the skin.

Acquired hypopigmentation

This follows damage to the epidermal melanin unit by various insults, including trauma, inflammation, radiation, contactants, endocrinopathies, infections and nutritional deficiencies. In general, the severity of the injury determines whether an insult will result in hypo- or hyperpigmentation. *Mild injury results in pigmentary incontinence and epidermal hypopigmentation*; however a mild injury allows accelerated keratinocyte turnover and a subsequent increase in production of melanosomes. *Severe injury results in the death of melanocytes and no subsequent repigmentation.*

Examples of depigmenting diseases in **horses** include onchocerciasis, *Culicoides* hypersensitivity, ventral midline dermatitis, and coital vesicular exanthema. Depigmenting lesions in horses may result from contact with equipment such as rubber bit guards or crupper straps or with feed buckets. Monobenzene ether of hydroquinone, a common ingredient in rubber, inhibits melanogenesis.

In **dogs**, hypopigmentation can occur in immune-mediated diseases such as lupus erythematosus, drug eruptions, bullous pemphigoid, and the various forms of pemphigus. Acquired depigmentation of the lips and/or nose also occurs in dogs as a result of contact with rubber dishes or toys containing dihydroquinone monobenzene ethers. Microbial lesions, such as deep pyoderma, may heal with depigmentation. Depigmenting lesions have been noted also in canine leishmaniasis and in dermatophytosis caused by *Microsporum persicolor*. Epitheliotropic lymphoma often presents with depigmenting, ulcerative lesions of skin and mucocutaneous junctions. Transient depigmentation has been reported in drug eruptions. Subcutaneous injection of corticosteroid or progesterone hormones may lead to focal hypopigmentation in the dog.

Uveodermatologic syndrome (Vogt–Koyanagi–Harada-like syndrome)

A depigmenting condition in dogs, partially resembles an extremely rare condition in humans, the Vogt–Koyanagi–Harada syndrome. *The arctic breeds such as the Akita, Siberian Husky, Samoyed, and Malamute are predisposed to this condition*, however it has been reported in many breeds. The cause is unknown, although an immune-mediated attack on melanocytes, as in the human disease, is presumed. The canine

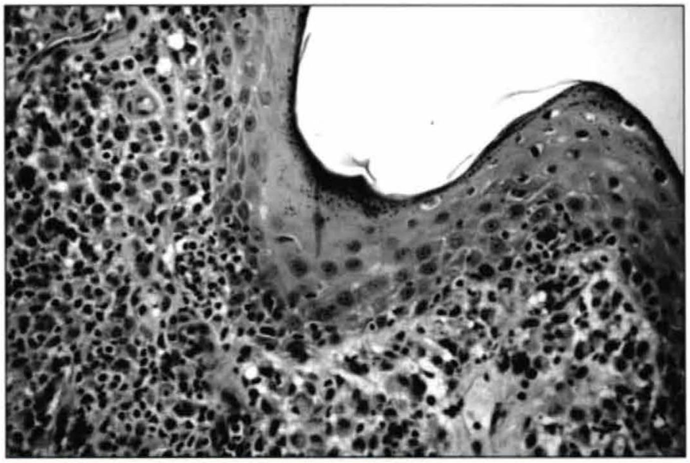

Figure 5.37 Uveodermatologic syndrome in a dog. Lichenoid interface, predominantly histiocytic, dermatitis with rare degeneration of basal keratinocytes and pigmentary incontinence.

lesions comprise *bilateral panuveitis* (see Vol. 1, Eye and ear) and *bilateral cutaneous depigmentation*, chiefly of the lips, nose, and periorbital skin (Fig. 5.36). Ocular lesions most often precede onset of cutaneous lesions. The scrotum, vulva, perianal skin, and footpads are less often affected. Leukotrichia is a common finding around the areas of leukoderma. Occasionally, depigmented lesions become ulcerated, erythematous or crusted. The histologic pattern of the cutaneous lesion is an *interface dermatitis with uncommon degeneration of basal keratinocytes, and a lichenoid inflammatory cell infiltrate in which large histiocytic cells usually predominate* (Fig. 5.37). Pigmentary incontinence is a common finding in areas of depigmentation but vacuolar change of the basal keratinocytes is not. This, and the histiocytic nature of the inflammatory infiltrate, are *major features of differentiation from discoid and systemic lupus.*

Leukotrichia

Reticulated leukotrichia, colloquially known as "tiger stripe," is recognized in the Standardbred, Thoroughbred, and Quarter Horse breeds. The lesions occur predominantly in yearlings and comprise linear crusts arranged in a cross-hatch pattern on the dorsal midline from the withers to the tail. Transient alopecia and a regrowth of permanently white hair follow crusting. The underlying skin has normal pigmentation. Well-documented precise descriptions of the expected histologic lesions are lacking. Some reports indicate an interface lichenoid dermatitis may be present, while others suggest that a mild superficial dermal mononuclear cell infiltrate and pigmentary incontinence are to be expected. The etiology and pathogenesis are unknown. **Spotted leukotrichia** occurs in the horse as multiple, often somewhat symmetrical, small circular areas of white hair. The spots occur most commonly on the rump and thorax, and Arabians have a predilection. The etiology and pathogenesis are unknown. **Hyperesthetic leukotrichia**, so-called because the lesions are extremely painful, has been reported only in Californian horses. Single or multiple crusted lesions occur on the dorsal midline and heal leaving permanently white hairs. Leukotrichia, also termed *poliosis*, has been reported in **dogs** in association with Vogt–Koyanagi–Harada syndrome, tyrosinase deficiency in Chow Chows, and as an idiopathic, possibly heritable condition in a litter of Labrador Retrievers. In the last example, the condition resolved.

Alopecia areata and universalis

Leukotrichia can be associated with alopecia areata. These disorders are discussed in more detail under Other immune-mediated dermatoses.

Copper deficiency

This pigmentary disorder is seen primarily in *cattle and sheep*. It has also been reported in *moose*, and experimentally in *dogs*. Copper deficiency may be simple or conditioned by other dietary substances, particularly sulfate and molybdenum. Since copper is an essential constituent of tyrosinase, there is *depressed tyrosinase activity*, and deficient animals show depigmentation of hair or wool. Affected cattle with normally black coats become rusty-brown and develop "spectacle" lesions round the eyes. Black sheep develop intermittent bands of light-colored wool corresponding to periods of restricted availability of copper (Fig. 5.38). The deficiency of copper also affects the physical nature of the wool or hair. In sheep, *the wool has less crimp*, prompting the colloquial name of "string" or "steely" wool. The straightness of the wool is due to inadequate keratinization, probably caused by imperfect oxidation of sulfhydryl groups in prekeratin, a process that involves copper (Fig. 5.39).

PHYSICOCHEMICAL DISEASES OF SKIN

The integument has a large surface area in direct contact with the environment and is hence extremely vulnerable to chemical and physical injuries. *Physical stresses* include friction, pressure, vibration, electricity, high and low ambient temperatures, humidity, visible light, and ultraviolet, infrared and ionizing radiation. Cutaneous reactions to visible light are discussed separately. *Chemical toxins* may exert their effect directly as in irritant contact dermatitis or envenomation or indirectly, as in thallium poisoning.

Physical injury to skin

Mechanical, frictional, and traumatic injury

The hair coat of most domestic animals protects from "blisters" that so commonly develop in human skin subjected to prolonged pressure or frictional contact with a hard surface. The following examples tend to occur in heavy animals with skin exposed to repeated or constant pressure such as in animals immobilized by paralysis, or in those exposed to a physically harsh environment.

Dogs

Calluses occur when continual or repetitive pressure or friction is applied to a localized area of skin and represent a protective response of the integument to the physical injury. They tend to occur over bony prominences, particularly the hocks, elbows, lateral surfaces of the digits and on the sternum. Callosities can develop in all domestic animal species, but are most common in dogs, particularly the giant breeds, and in pigs housed on concrete floors with inadequate bedding. They are characterized by epidermal proliferation with prominent epidermal and follicular hyperkeratosis. Dilated hair follicles may lead to furunculosis with secondary pyoderma, severe suppurative to pyogranulomatous dermatitis and eventual fibrosis. Grossly, callosities are *well-circumscribed, lichenified, raised, alopecic, gray, keratinous plaques*. Ulceration may occur. The pig may also develop bursitis.

A **hygroma** *is a false or acquired bursa, which develops subcutaneously over bony prominences.* Hygromas are most common in the giant breeds of dogs at pressure points such as the lateral aspect of the elbow, the greater trochanter of the femur and the tuber coxae. Hip dysplasia in dogs can lead to elbow hygromas as dogs develop an abnormal method of lying down that relies upon dropping to the olecranons to spare the hips. Usually pressure induces a protective callus, but in some animals persistent decubitus ulcers or recurrent hematoma formation eventually lead to the induction of a hygroma. The gross lesion is a variably sized cystic cavity separated from the skin by loose connective tissue. The wall of the hygroma is dense connective tissue that may have a smooth or a villus inner lining. The contents are mucinous and yellow to red, depending on the degree of hemorrhage. *Histologically, the wall is composed of granulation tissue of variable maturity.* A flattened layer of fibroblasts may give the appearance of an epithelial lining. The cavity may contain clumps of fibrin. Organization of fibrin deposits at the margin of the cavity gives rise to the grossly apparent villus projections that occasionally undergo cartilaginous metaplasia.

Decubitus ulcers *are the result of ischemic necrosis that follows application of constant pressure to a localized area of skin.* Studies in Greyhounds suggest that intermittent repeated focal vascular occlusion leads to increased tissue damage from *reperfusion injury*. Thromboxane A_2 and its metabolite, thromboxane B_2, are thought to contribute to vasoconstriction and platelet aggregation. Predisposing conditions include prolonged recumbency, lack of proper bedding, improperly applied bandages or casts, poorly fitting tack, atrophy of muscle, loss of fat, malnutrition associated with systemic disease, contusions, irritation from feces or urine, and body types with large bones, thin skin and low body fat. In large animals, post-anesthetic myopathies, laminitis, and neurologic diseases are predisposing conditions. The "downer" cow is particularly prone to decubitus ulcers. *Decubitus ulcers are graded from I to IV.* In grade I, the lesion consists of focal erythema. In grade II, an ulcer extends into the subcutis. In grade III, the ulcer extends into the deep fascia and the wound edges may be undermined. Grade IV ulcers extend to bone, have undermined edges, and possibly underlying osteomyelitis and septic arthritis.

Intertrigo *refers to localized dermatitis affecting folded areas of skin.* The combined effect of friction, heat, maceration, bacterial or yeast proliferation and irritation by retained secretions leads to superficial inflammation. Examples in dogs include *facial, lip, vulvar and tail fold dermatitis*. Obesity is a predisposing factor. Body fold dermatitis is particularly common in Chinese Shar-Pei puppies. Udder-thigh dermatitis occurs predominantly in first-calf *dairy heifers*. Udder edema is a predisposing factor. Lesions are erythematous and swollen, sometimes ulcerated and often have an unpleasant odor. Histologically, the epidermis is hyperplastic, spongiotic and possibly eroded or ulcerated. Surface pustules, neutrophilic exocytosis, and pigmentary incontinence may be present. The dermis has a dense band of lymphocytes and plasma cells at the dermoepidermal junction. Mucocutaneous pyoderma is the primary differential.

Traumatic injury to the skin is quite common in dogs and is often associated with *compound fractures* sustained in motor vehicle accidents. *Dogfight wounds* tend to be tears rather than punctures, as occur in cats; consequently abscesses are a less common sequel. A plethora of **foreign bodies** may penetrate the canine integument, two of the more dramatic examples being *foxtails* and *porcupine quills*. The external ear canal and interdigital webs are favored sites for grass awn entry and subsequent migration. Retrievers or other animals wounded with *steel shot* may develop fistulous tracts or abscesses as steel shot corrodes when embedded in tissues.

Myospherulosis is a rare form of foreign body reaction in which endogenous erythrocytes interact with an exogenous substance, such as antibiotics or ointments, or with endogenous fat. *The lesions are subcutaneous nodules composed of sheets of large macrophages in which the cytoplasm is filled with homogeneous eosinophilic spherules.* These structures may resemble fungal organisms but are negative with fungal special stains such as periodic acid-Schiff. The spherules stain for endogenous peroxidase, thus establishing their identity as erythrocytes.

Traction alopecia has been reported in dogs. It results from low-grade local ischemia induced by traction on hairs. The traction force is applied by elastic ties or hair barrettes applied to pull the forelock hair into a topknot. The lesions are focal patches of cutaneous atrophy and alopecia that may become eroded and crusted. Histologically, the lesion is an *atrophic dermatosis*. The epidermis is thin and may occasionally show single cell necrosis, erosion or ulceration. The hair follicles are inactive and atrophic, pale staining and appear "faded." Inflammation is minimal and is restricted to areas of surface ulceration.

Pyotraumatic dermatitis or "hot spot" is a common complication of allergic dermatitis or any pruritic dermatosis that leads to an *itch–scratch cycle*. It occurs most often in times of warm, humid weather. Breeds with a thick undercoat, such as German Shepherds, Golden Retrievers, Labradors, and Saint Bernards, are particularly susceptible. Lesions are extremely painful and occur at sites of *self-trauma*, such as the dorsal rump in a flea-infested animal. Grossly, the initial lesions are erythematous, exudative, sharply demarcated patches, spreading extensively if not treated. The surface may be colonized by gram-positive cocci. Alopecia and hyperpigmentation are the typical sequelae. Pyotraumatic dermatitis is characterized histologically by *epidermal ulceration*. A thick serocellular inflammatory crust covers the denuded dermis. The predominantly neutrophilic reaction tends to be restricted to the area beneath the ulcer. Folliculitis and furunculosis are not features of classical pyotraumatic dermatitis but occasionally are concurrent conditions as indicated clinically by scattered papules at the periphery of the lesion. Eosinophils and/or folliculitis were common in one series of cases.

Cats

This species is particularly prone to develop subcutaneous abscesses or cellulitis as a result of fight wounds. The cat bite produces a puncture-type wound that seals over and enables the introduced bacteria (chiefly oral flora) to multiply in the damaged tissue.

Cattle

Tail tip necrosis of feedlot beef cattle is a disease in which slatted-floor housing has been shown to be an important causal factor. The pathogenesis is presumed to be *ischemia*, secondary to compression of, or blunt trauma to, the more proximal parts of the tail. Clinically, there is alopecia, scaling and crusting. Ulceration and suppuration are frequent sequelae. In early lesions, histologic examination reveals only perivascular edema and hemorrhage. Fully developed lesions are characterized by dermal scarring, follicular atrophy, vascular wall hypertrophy, and fragmentation of extravasated erythrocytes.

Pigs

Intensive rearing systems for swine production have increased the occurrence of a variety of traumatic lesions. Those in piglets probably result from contact with *concrete floors* in farrowing crates. The knees are the most common site affected, followed by the fetlocks and hocks. The nipples, particularly the cranial pair, are often involved, as is the tail. The lesions occur within a few hours of birth as circumscribed red macules followed by necrosis, ulceration and crusting. The ulcers heal over 3–4 weeks leaving no permanent defect. The supernumerary digits of the hind legs are subject to trauma in sows housed on concrete slats. Trauma resulting from *vices* such as tail biting, ear biting and flank biting are increasingly common in growing pigs under intensive rearing systems of management. Wounds from a variety of causes, including fight wounds, often develop into subcutaneous abscesses in pigs.

Horses

Cutaneous wounds are common in horses and can be largely attributed to the flighty temperament of the species. *Exuberant granulation tissue, "proud flesh,"* is a relatively frequent and serious sequel to wounds of the distal limbs. Poor circulation, minimal soft tissue, lack of adequate drainage and a tendency for excessive movement predisposes the distal limbs to the development of excess granulation tissue. The gross lesion, *a tumor-like mass of red-brown tissue, must be distinguished from equine sarcoid, cutaneous habronemiasis, mycoses, pythiosis, and squamous cell carcinoma*. Histologically, immature capillaries and capillary loops arranged perpendicularly to the elongated fibroblasts and newly synthesized collagen are distinctive features. A superficial layer of granulation tissue may form in association with any of the above-mentioned conditions, and the entire lesion should be examined before a diagnosis is made.

Injection site reactions are not uncommon in domestic animals. Subcutaneously administered vaccines and therapeutic drugs may be responsible. The nodules may ulcerate or fistulate and are often suspected to be neoplasms. *Histologically, the classic injection site reaction is composed predominantly of nodular aggregates of lymphocytes arranged around a central core of caseous necrosis.* Lymphocytes may form follicles. Irregular refractile or faintly basophilic granular material is often embedded in the eosinophilic debris or found within phagocytic cells. Plasma cells, macrophages and multinucleated giant cells are also present, but in lesser numbers than the lymphocytes. The strong antigenic stimulus provided by the exogenous antigen sometimes results in the formation of germinal centers. The heterogeneity of the cell population and the lack of anaplastic characteristics in the lymphoid cells may differentiate these lesions, sometimes termed *pseudolymphoma*, from genuine lymphoma. Vaccine administration in **cats** has been linked to the development of a variety of sarcomas, including fibrosarcomas, osteosarcomas, malignant fibrous histiocytomas, chondrosarcomas, and rhabdomyosarcomas. **Vaccine-associated sarcomas** have the unique features of a *subcutaneous location, concurrent lymphocytic infiltrates, and possibly macrophages containing granular foreign material.* The proposed mechanism involves an over-zealous reparative response followed by malignant transformation of mesenchymal cells. Antigen load and degree of inflammation present at the vaccination site are possible influencing factors. Aluminum adjuvant particles have been identified in tumor associated macrophages, however, vaccine-associated sarcomas have also been documented to arise from the use of non-adjuvanted vaccines. Injection of killed **rabies vaccine** in **dogs** can lead to focal mononuclear vasculitis and ischemic atrophy of surrounding follicles resulting in a focal area of alopecia and is further discussed under Immune-mediated dermatoses. **Injection site eosinophilic granulomas** with necrotic centers developed in some **horses** within 1–3 days as a response to the use of silicone coated hypodermic needles. The lesion is suspected to be a form of delayed hypersensitivity.

Psychogenic injury

Several conditions in animals are considered to be similar to **obsessive-compulsive disorders** in humans. In theory, stress causes an increase in the production of endorphins creating reinforcement of the stereotypic behavior characterizing each syndrome.

Psychogenic alopecia in **cats**, a self-induced form of alopecia precipitated or exacerbated by environmental stress, is similar to the obsessive-compulsive disorder of humans, trichotillomania. The condition can occur in any cat but is most common in oriental breeds. Clinically, cats groom excessively, licking and pulling at the haircoat. Psychogenic alopecia/dermatitis has *two clinical forms*. In one, *psychogenic dermatitis*, affected cats lick and chew at a single site creating a well-demarcated erythematous, ulcerated lesion of variable size, which usually is located on an extremity, the abdomen or flank. The lesion grossly resembles those of eosinophilic plaque. The second, or *alopecic form*, is characterized by partial alopecia, broken hairs and normal skin. The lesions often occur as a "stripe" along the dorsal mid-line but may involve perineal, genital, caudomedial thigh, medial elbow, or abdominal areas. This distribution pattern is usually symmetrical resembling feline endocrine alopecia but *the hairs in psychogenic alopecia are broken off rather than easily epilated as occurs in endocrine alopecia*. Diagnosis is largely dependent on history and clinical signs. A trichogram examination of epilated hairs reveals a normal anagen to telogen ratio and fractured tips of hairs rather than tapered ends. *Microscopic examination of skin in the alopecic form is usually normal*, although wrinkling of the outer root sheath and intra- and perifollicular hemorrhage may reflect the trauma applied to the hairs. The inflammatory form has no distinctive histologic features, as it is a nonspecific, ulcerative, hyperplastic, superficial perivascular dermatitis. *Differentials for the alopecic form include endocrine dermatopathy and pruritic skin conditions such as atopy, flea allergic dermatitis, and cheyletiellosis.* As pruritus in the cat is manifest in part by excessive grooming, any degree of perivascular eosinophilic dermatitis should be considered indicative of an underlying hypersensitivity disorder. The condition must also be differentiated from **feline acquired hair shaft abnormality**, a condition resembling *trichorrhexis nodosa* in humans. In this condition, cats with an underlying pruritic skin disease such as flea allergic dermatitis groom excessively. Weakened hair shafts break easily and lead to alopecia. A trichogram reveals white nodes on the hair shafts corresponding to foci of frayed cortical fibers. A biopsy should show evidence of the underlying hypersensitivity condition.

Dogs also develop *psychogenic dermatitis including foot chewing and licking, tail-biting, and flank-sucking*. The gross lesions may be slight but the superficial excoriations often develop into pyoderma. **Acral lick dermatitis**, otherwise known as "lick granuloma" or neurodermatitis, is a relatively common psychogenic dermatitis of dogs, particularly in large active breeds younger than 5 years. Males are affected twice as frequently as females. The areas traumatized by persistent licking and chewing are most commonly the cranial carpus and metacarpus, followed by the radius, tibia and metatarsus. Erythema and epidermal excoriations give rise to a single well-circumscribed, eroded or ulcerated, oval plaque. Occasionally, lesions are multiple. Secondary bacterial infection may result. Re-epithelialization of the lesion leaves a well-circumscribed alopecic plaque often with peripheral hyperpigmentation. Histologically, acral lick dermatitis is a *hyperplastic superficial perivascular dermatitis with marked orthokeratotic and parakeratotic hyperkeratosis, acanthosis and rete ridge formation* (Fig. 5.40). There is a sharp transition between the hyperplastic and ulcerated epidermis, which is covered by a thick scale-crust. Superficial dermal fibrosis is usually marked and collagen fibers in dermal papillae are often arranged perpendicular to the surface epithelium (Fig. 5.41). *This "vertical streaking" of collagen is thought to result from chronic irritation.* Perifolliculitis, folliculitis and sometimes furunculosis are often present. Plasmacytic infiltrates often surround the sweat glands. Sebaceous glands and hair follicles appear hyperplastic. *The primary differential is self trauma due to a pre-existing localized bacterial infection.*

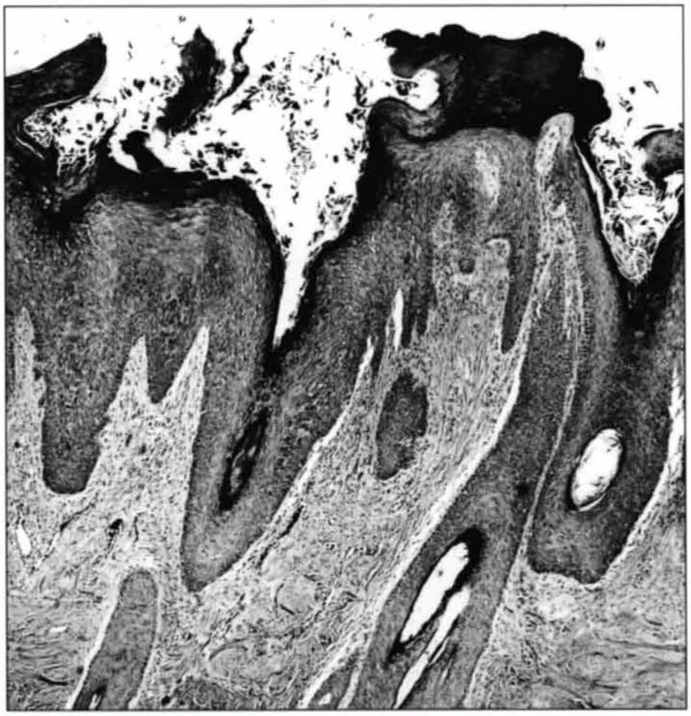

Figure 5.40 Acral lick dermatitis in a dog. Hyperplastic superficial perivascular dermatitis with marked orthokeratotic and parakeratotic hyperkeratosis, acanthosis and rete ridge formation.

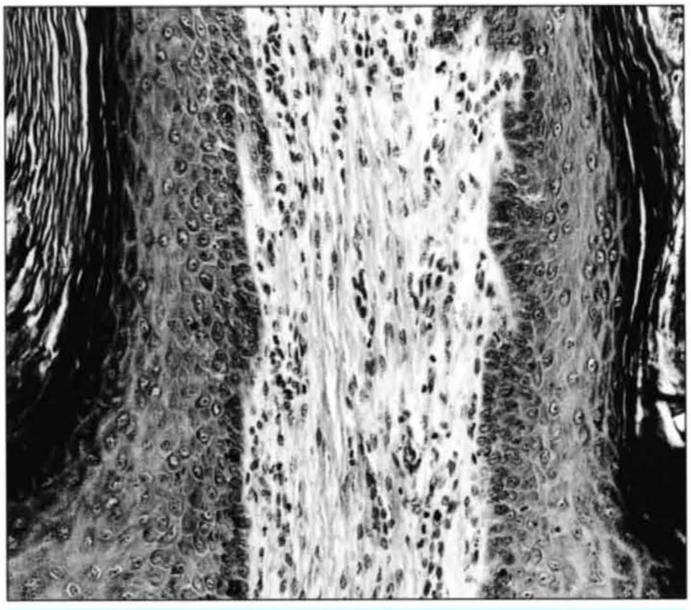

Figure 5.41 Acral lick dermatitis in a dog. Vertical alignment of collagen.

In **horses**, the **equine self-mutilation syndrome** can be misinterpreted as a possible cutaneous disorder as horses bite, kick, or rub the flank or pectoral areas. The behavior is usually accompanied by vocalization, spinning or rolling and is most common in *stallions*.

The condition is thought to be *stress related*. There are no primary cutaneous lesions, however secondary excoriations may be present.

A **self-destructive behavioral condition** primarily affecting **first-calf heifers** is characterized by *excessive licking of the udder and teats* sometimes leading to teat necrosis and culling. The condition is associated with udder edema and increased levels of histamine in the udder tissue leading to pruritus.

Mineral deposition in cutaneous tissues

Deposition of insoluble calcium salts within cutaneous tissues can occur as a result of injury or degeneration of skin components (**dystrophic mineralization** or calcification), secondary to calcium/phosphorus metabolic alterations (**metastatic mineralization** or calcification), as an idiopathic condition, or may occur iatrogenically. Mechanisms leading to calcium salt deposition are complex and involve such factors as the lower pH of injured tissue, mitochondrial concentration of calcium and phosphorus, and the influx of calcium into injured cells in dystrophic forms. In metastatic forms, loss of mineralization inhibitors, changing of ions into a solid phase, and phosphate ion initiation of crystal formation are implicated in salt formation. Mineralization can be *localized*, as in inflammatory foci (granulomas), in degenerative lesions (follicular cysts), or in neoplasms (pilomatricomas), or may be *generalized* as in the tissue mineralization associated with chronic renal failure.

The most well-known form of cutaneous mineralization is the classic form of **calcinosis cutis** associated with hyperadrenocorticism, which is discussed in Endocrine diseases of skin. For ease of comparison, other known types of cutaneous mineralization are discussed here. **Calcinosis universalis** *refers to widespread areas of calcinosis cutis* and can be seen with hypercortisolism, percutaneous absorption of calcium-containing products, or from the iatrogenic administration of calcium-containing solutions. Some forms of calcinosis cutis can be indistinguishable histologically from calcinosis cutis associated with hyperadrenocorticism. The clinical presentation, concurrent abnormalities, signalment and history should allow distinction of the various forms of calcinosis cutis.

Percutaneous absorption of products containing **calcium chloride or calcium carbonate** has occurred naturally in *dogs*. Multifocal, flat-topped and centrally ulcerated papules and small nodules affected glabrous skin, such as the lips, axilla, inguinal and interdigital skin. Histologically, the lesions comprised granulomas centered on degenerate, mineralized collagen fibers. Ultrastructural examination of experimental lesions indicated that mineral was deposited within the collagen bundles within 24 hours of initial skin contact. The main differential diagnosis was *calcinosis cutis of hyperadrenocorticism*, to which the lesions are histologically identical.

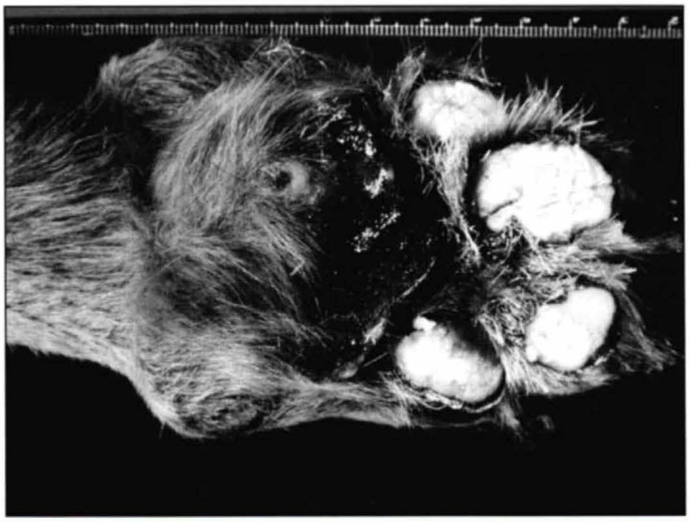

Figure 5.42 Calcinosis circumscripta in a dog. Note chalky material exuding from footpads. (Courtesy of B Dunstan.)

A chemically induced, iatrogenic form of calcinosis cutis has been reported in humans and a dog as a consequence of the subcutaneous administration of a **10% calcium gluconate** solution for treatment of hypoparathyroidism. In the dog, calcium salts formed on basement membranes, dermal collagen, vessel walls and adipocyte membranes. Dermoepidermal separation, pyogranulomatous dermatitis, panniculitis and vasculopathy ensued, leading to marked necrosis and sloughing of the skin. Concurrent hyperphosphatemia was thought to predispose to precipitation of calcium salts.

Dogs with systemic blastomycosis treated with **amphotericin B** developed lesions that resolved over time and were *indistinguishable from calcinosis cutis of hypercortisolism*. Dogs had severe granulomatous cutaneous lesions that may have been predisposed to dystrophic mineralization, but mineralizing lesions were more extensive or separate from primary inflammatory lesions. The dogs had no clinically significant serum calcium/phosphorus abnormalities. Additional factors suspected to contribute to mineralization included mild intermittent serum calcium fluctuations, mononuclear cell production of factors leading to increased osteoclast-mediated bone resorption, and alteration of vitamin D metabolism.

Calcinosis circumscripta (tumoral calcinosis) occurs most often in *dogs, horses* and occasionally *cats* (see also Ectopic mineralization and ossification, in Vol. 1, Bones and joints). Lesions in dogs are most often solitary but can be multiple and occur most often in large breeds <2 years of age. German Shepherd Dogs are predisposed. The *skin over bony prominences of the limbs* is most often affected. The tongue and paravertebral soft tissues, footpads, edges of the pinna in dogs with cropped ears, and cheeks of Boston Terriers are other reported sites. Calcinosis circumscripta of the dorsal thoracolumbar region at a site of previous progestogen injection has been reported in a cat.

The gross and histologic features of the lesion evolve over time. Initially, the lesion may be bulging, fluctuant or cystic, variably ulcerated and contains chalky white material (Fig. 5.42). Histologically,

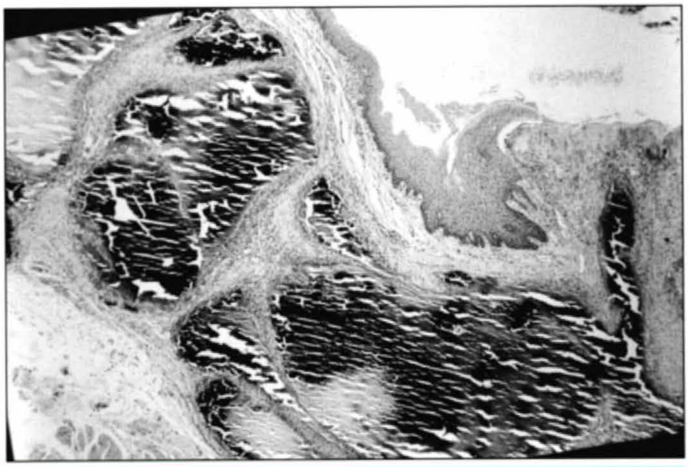

Figure 5.43 Calcinosis circumscripta in a dog. Dermal lakes of basophilic granular material are surrounded by mild fibrosis and giant cells, macrophages and fewer lymphocytes and plasma cells.

subcutaneous to deep dermal lakes of basophilic granular material that stain with von Kossa are surrounded by mild fibrosis and a cellular zone of variable width with giant cells, large macrophages and fewer lymphocytes and plasma cells (Fig. 5.43). Over time, the lesions become firm, progressively more mineralized, and associated with dense fibrous connective tissue bands. Inflammation may subside to some degree over time and osseous or cartilaginous metaplasia may take place. Epidermal sequestration or transepidermal elimination of mineralized material may lead to ulceration.

The pathogenesis of calcinosis circumscripta is not known. Dystrophic mineralization secondary to previous tissue trauma has been proposed based on the predilection for skin covering bony prominences. This explanation is not entirely satisfactory as the lesions do not recur after surgical excision, and trauma to these sites in large dogs would be expected to be repetitive. The name "apocrine cystic calcinosis" was previously applied to calcinosis circumscripta since it has been documented to arise from degenerating, cystic apocrine glands. A relationship to apocrine glands is not evident in most cases. Lesions have also developed at sites of previous injections, or in association with surgical sites sutured with polydioxanone sutures. Cases of calcinosis circumscripta have also been reported to occur in the footpads of dogs and cats with chronic renal failure, and in the footpads of an otherwise healthy German Shepherd Dog and in another German Shepherd Dog with pododermatitis. Symmetrical cases that resolved spontaneously have been reported in young dogs with underlying skeletal disease such as hypertrophic osteodystrophy. It is likely that multiple factors are involved in the pathogenesis of calcinosis circumscripta.

Cold injury

Most cold-induced cutaneous lesions (frostbite) result not only from direct freezing and disruption of the cells, but more importantly from vascular injury and resultant tissue anoxia. In experimental frostbite lesions in Hanford miniature swine, vacuolation of keratinocytes was the earliest change in the epidermis followed by spongiosis, epidermal necrosis, and separation of the necrotic epithelium from the dermis. Hyperemia and hemorrhage were also early lesions. Inflammatory changes, comprising neutrophilic infiltration and necrotizing vasculitis, occurred 6–46 h postinjury. Thrombosis of small arterioles increased in severity up to 1 week postinjury. By 2 weeks, considerable epithelial regeneration had taken place, either as a complete replacement or as crescents beneath the necrotic epidermis.

Cutaneous injury resulting from cold is uncommon in well-nourished, healthy domestic animals. Well-acclimatized long-haired animals can tolerate temperatures of –50°C for indefinite periods. Cold injury occurs most commonly on the tips of the ears and tail of cats, the scrotum of male dogs and bulls, and the tips of the ears, tail and teats in cattle. The teats are particularly vulnerable if cows are turned out into the cold with wet udders. Affected skin is cool, pale and hypoesthetic. The gross lesions include alopecia, scaling and pigmentary alterations of the skin, hair or both. In severe cases, the ischemic necrosis results in dry gangrene and sloughing of the affected part.

Thermal injury

Heat may be applied to the skin in a variety of forms and, depending on duration and intensity, will produce *mild to severe necrotizing lesions*. Longer exposure to lower temperatures is more damaging than short exposure to higher temperatures. The lowest temperature at which skin can burn is 44°C (111°F). *Dry heat causes desiccation and carbonization, whereas moist heat causes "boiling" or coagulation.* Thermal injury in domestic animals may be caused by hot liquids, steam, heating pads, hair dryers, drying cages, hot metals such as wood stoves or car engines, fires, friction from rope "scalds," electrical burns from chewing electrical wires, improperly grounded electrocautery units, or lightning strikes. Animals struck by lightning may show a jagged line of singed hair running down a shoulder or flank (Fig. 5.44). This finding is valuable in establishing an otherwise difficult diagnosis. Rarely, small animals incur microwave burns.

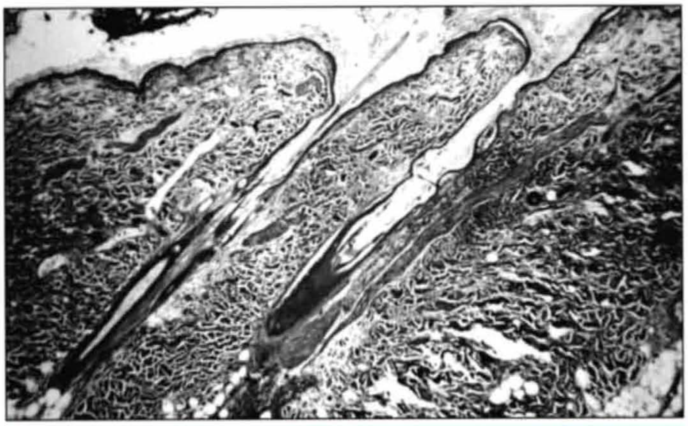

Figure 5.45 Burn. Note diffuse coagulative necrosis of the epidermis. (Courtesy of B Dunstan.)

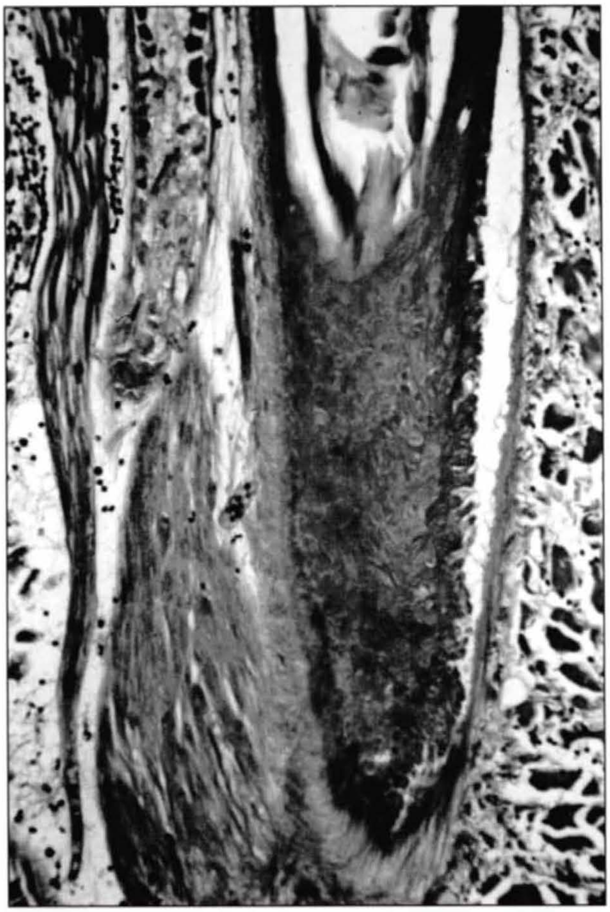

Figure 5.46 Burn. Coagulative necrosis of the epidermis can often "wick" down to involve the follicular epithelium. (Courtesy of B Dunstan.)

Burns are classified into four degrees according to depth of injury.

- **First-degree burns** *involve only the epidermis.* The heated areas are erythematous and edematous as a result of vascular reaction in the dermis, but vesicles do not form. The epithelial cells show no morphological sign of injury although there may be surface desquamation after a few days.
- *In* **second-degree burns**, *the epidermis and part of the dermis are damaged.* The cytoplasm of the epithelial cells is hypereosinophilic, and the nuclei are shrunken or karyorrhexic. Coagulative necrosis of the epidermis (Fig. 5.45) can occur in the absence of substantial dermal injury and often "wicks" down to involve the follicular epithelium (Fig. 5.46). The vascular changes are more prominent than in lesser burns, with marked dermal edema and spongiosis. Vesicles and bullae form in the epidermis, often at the dermoepidermal junction. The bullae contain serum, granular debris, and leukocytes. Healing can be complete if secondary infection does not lead to deeper injury.
- *In* **third-degree burns**, *the destructive effect of the heat extends full thickness through the epidermis and dermis*, causing coagulation necrosis of connective tissues, blood vessels and adnexa. Thermal injury causes thrombosis of blood vessels and vascular leakage leading to the coagulative necrosis of more superficial tissues. Heat of sufficient intensity or duration to penetrate this deeply usually desiccates and chars the outer epidermis. Coagulation necrosis of the dermis produces a swollen amorphous accretion of the connective tissues accompanied by an acute inflammatory reaction. Over time, histiocytes infiltrate the subcutis and fibrosis ensues. Subcutaneous vasculitis may be present. The necrotic tissue sloughs, and the defect is filled in by granulation tissue. Permanent scarring with loss of adnexa results.
- **Fourth-degree burns** *are similar in character to those of third degree but penetrate below the dermis to and beyond the subcutaneous fascia*; their local consequences depend on what lies underneath. Heat in surface tissue is conducted to deeper tissues via the blood and lymph. The degree of injury may not be evident for several days after the insult occurred. Follicular and sweat gland damage continues for 24–48 hours. Once lesions fully develop, the progress of injury should cease, which is helpful in making the diagnosis. Histologically, thermally induced tissue damage is not sharply demarcated and should dissipate gradually with increasing depth of the biopsy. *Clinical differentials* include toxic epidermal necrolysis, erythema

multiforme major, bullous pemphigoid, pemphigus vulgaris, vasculitis, trauma, and other causes of ischemia. Lesions from thermal injury sometimes have an abnormal anatomical distribution or pattern such as drips, angles, lines, or areas of contact that may be helpful in the differential diagnosis.

Microwave burns are unique in that the lesions are sharply delineated histologically without a tapering of the degree of coagulative necrosis in the deeper tissues. The degree of injury is uniform throughout the tissue and inflammation is minimal. The depth of damage depends on the frequency of the microwaves with some frequencies sparing the superficial tissues and coagulating the deeper tissues. Pain perception may not occur until the damage is done and lesions may not be evident for up to 6 days. There is no surface charring, blister formation, or edema. There is thrombosis of vessels and the tissue is mummified. Injury is due to ionizing radiation leading to heat generated from the vibration of molecules in the tissue.

Full-thickness cutaneous burns have been reported to occur in black-haired spots of Dalmatians as a result of **solar radiation**. Normally, cutaneous injury from solar radiation affects lightly pigmented sparsely haired skin rather than areas protected by pigment. *Black skin absorbs approximately 45% more solar radiation than white skin.* The absorption of visible light (400–700 nm) can result in the production of thermal energy resulting in a burn. UV light (100–400 nm) does not penetrate into the dermis and does not produce substantial thermal energy, but has other deleterious effects (see Actinic diseases of skin). Pain, prompting moving to the shade, was likely not perceived by the dogs as the burns were multifocal involving only black-haired areas and Dalmatians are primarily white.

Another unique type of thermal injury, **radiant heat dermatitis**, is similar to *erythema ab igne* in humans. Tissue damage occurs from repeated exposure to moderate heat. Radiant heat dermatitis has been reported as an asymptomatic condition in dogs sleeping next to wood burning stoves or fires, or chronically exposed to heat lamps. The lesions were on the dorsolateral trunk and had a drip-like configuration. Grossly, irregular areas of alopecia were erythematous and hyperpigmented peripherally. Centrally, the lesions are scaly and depigmented. In the acute form, lesions resemble actinic dermatosis with epidermal thinning, basal cell vacuolation, and possible epidermal dysplasia. The dermis has thin fragmented collagen, increased elastin fibers, and melanin and hemosiderin deposits. Over time, epidermal and infundibular hyperplasia, hyperkeratosis and dyskeratosis develop with focal spongiosis and cell necrosis. Karyomegaly of basal cells, dermal edema and mucinosis, hyperplastic sebaceous glands, dilated apocrine glands, and mixed perivascular dermatitis may be present.

Radiation injury

Advances in the treatment of cancer in companion animals have made the possibility of **radiation-induced skin injury** more likely. Clinicians and pathologists need to be able to recognize these lesions in order to provide the best management options and accurate prognosis for resolution of the lesions. *The varieties of radiation modalities available have variable degrees of tissue penetration and potential for tissue injury.* Some forms of radiotherapy penetrate deeper tissues while sparing the skin and others are more concentrated in the superficial tissues or are preferentially absorbed by specific tissues. The type of radiation therapy, source, dose, intensity, and duration of exposure dictate the range of possible side effects. Ionizing photons disrupt chemical bonds in cells leading to injury or cell death. Some cells are not lethally damaged but sustain DNA damage to the extent that replication/replacement are not possible. The effects of radiation damage can be divided into acute and chronic forms.

Acute radiation injury to the skin is a result of damage to rapidly dividing cells. Damage is self-limiting and recovery is associated with rapid cell turnover. Clinical lesions of radiation dermatitis appear 2–4 weeks after exposure. Initially, there is erythema, pain, edema, and heat, followed several weeks later by dry or moist desquamation depending on the degree of injury. Histologically, the lesions resemble a second-degree burn, with suprabasilar or subepidermal bullae formation, dermal edema with fibrin exudation, and a marked leukocytic infiltrate. Re-epithelialization occurs over a period of 10–60 days. The damage sustained to germinal epithelium of hair follicles and sebaceous glands leads to *alopecia* within 2–4 weeks after exposure. Hair re-growth will follow over the next several months but damage to sebaceous glands is not reversible and leads to *permanent scaling*.

The *chronic lesions of radiation injury* are evident months to years after treatment and are primarily *due to damage to the microvasculature*. The epidermis is thin, friable, and in some areas hyperplastic, and may become neoplastic. There is hyperpigmentation and hyperkeratosis. Chronic exudative ulcers may develop but granulation tissue does not form. The dermis is fibrotic with atypical fibroblasts, telangiectasia, and possibly deep arteriolar changes. Endothelial swelling, necrosis and thrombosis lead to occlusion and excessive endothelial proliferation, that when combined with the effects of vascular leakage, leads to vascular collapse. This condition of progressive vessel abnormalities is referred to as *obliterative endoarteritis* and is known to form a "histohematic" barrier to surrounding tissue, leading to continued anoxia and nutrient shortage.

Chemical injury to skin

Primary irritant contact dermatitis

One of the important functions of the skin is to provide protection against external noxious agents. *The stratum corneum is the major* *protective barrier.* Its integrity is highly dependent on its water content, which in turn is protected by the lipids of the stratum corneum.

Penetration of the skin is enhanced by physical damage to the stratum corneum, chemical alteration of the barrier components, overhydration of the stratum corneum by excess moisture, increased temperature, or alterations of the skin pH. Irritant substances may induce damage by altering the water-holding capacity of the keratin layer or by penetrating the epidermis and directly damaging the cells. Irritant substances vary markedly in their potency. Some, such as strong acids or alkalis, induce immediate and severe tissue damage; others, such as mild detergents or soaps, may require repetitive applications and covering of the area to assist penetration before lesions develop.

Primary irritant contact dermatitis must be distinguished from allergic contact dermatitis (discussed under Hypersensitivity dermatoses). *Irritant contact dermatitis is the more common condition in animals and does not involve prior sensitization.* It may occur in any species, but is most frequent in the horse, cow and dog. The types of agents capable of causing direct cutaneous damage include acids, such as carbolic or sulfuric, alkalis, cresol tars, paints, kerosene, turpentine, antiseptics, and insecticides. An example of the last-mentioned is "flea collar dermatitis" of dogs and cats. Feces and urine are also potential irritants.

The distribution of gross lesions of contact irritant dermatitis in the dog and cat typically involves the glabrous skin of the ventral abdomen, axilla, medial thigh, perianal and perineal areas, footpads (Fig. 5.47A), ventral tail, chin, and inner aspect of the pinnae. The hairy skin is only involved if the irritant substance is in an aerosol or liquid form. Flea collar dermatitis lesions occur as a band around the neck corresponding to the position of the offending collar. In horses, lesions occur most commonly on the muzzle, lower limbs and in areas of contact with the riding tack. Horses with diarrhea may develop severe irritant dermatitis on the soiled perineum.

The *gross lesions*, which typically have a sudden onset, are marked erythema, swelling, and a transient papular-vesicular stage that leads to ulceration and, in severe cases, sloughing of the affected skin. The sequelae include alopecia, scarring, and alteration in skin and hair pigmentation. Hyperpigmentation occurs in most species of domestic animals, but in horses, leukoderma or leukotrichia may be a permanent result of irritant contact dermatitis. Severe lesions can be considered a chemical burn. Differentials include thermal injury and allergic contact dermatitis.

The histologic lesions of irritant contact dermatitis are not pathognomonic, nor can they be distinguished from those of allergic contact dermatitis (Fig. 5.47B). Superficial spongiotic or hyperplastic perivascular dermatitis characterizes both, and vesicles may form. The inflammatory infiltrate is variable in nature, probably reflecting such factors as chronicity, self-trauma and secondary infection. *The diagnosis of irritant contact dermatitis depends largely on the history and the clinical signs, particularly the distribution of the lesions.*

In **swine**, cutaneous erythema and pruritus have been observed within 48 hours of *tiamulin* administration. The most severely affected pigs were recumbent and developed *fatal necrolytic dermatitis.* The areas most severely affected were those in contact with feces and urine. Histologic lesions included full-thickness epidermal necrosis, intraepidermal pustules, and serocellular crusting. It was hypothesized that the lesions represent a severe form of contact

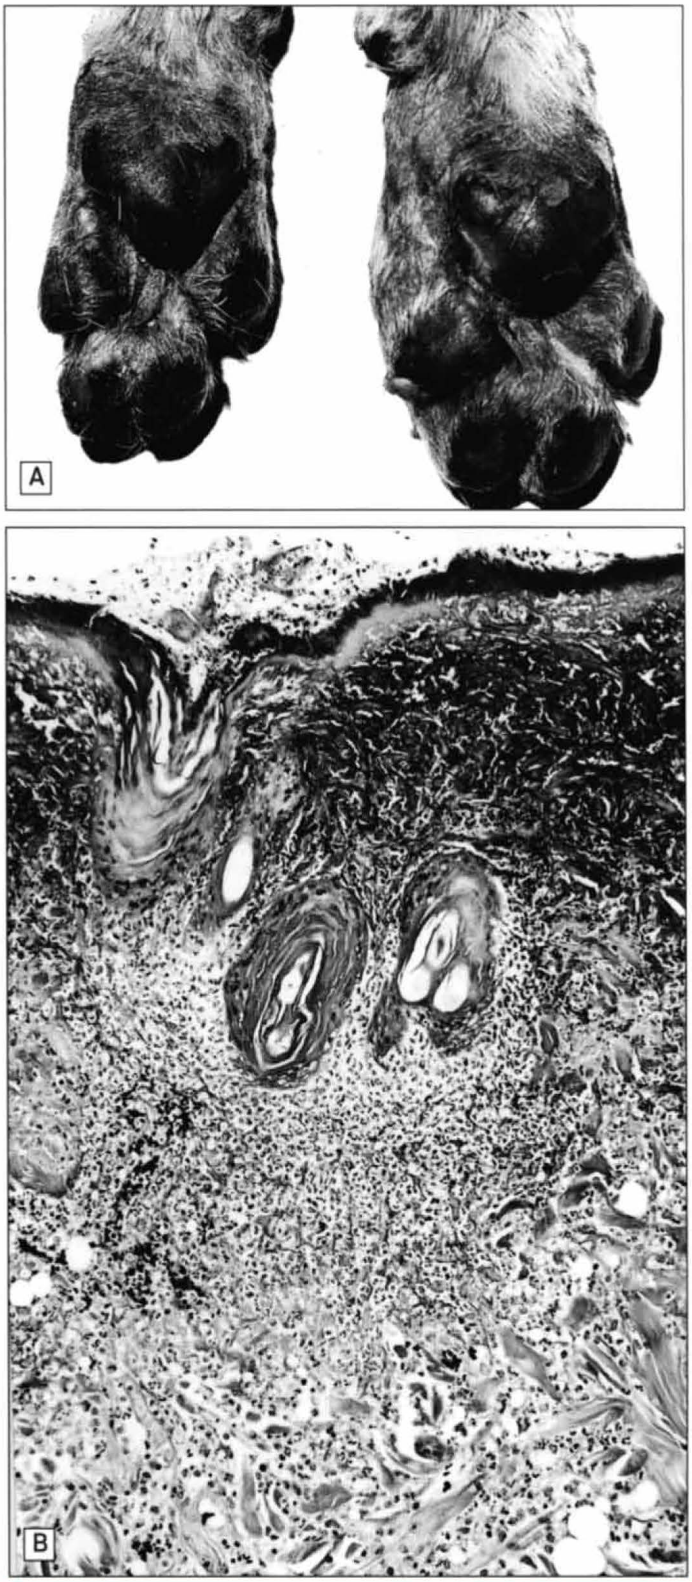

Figure 5.47 Irritant contact dermatitis in a dog. **A.** Footpad swelling and erythema, due to alkali exposure. (Courtesy of RP Johnson.) **B.** Coagulative necrosis of the epidermis and superficial to mid dermis, due to Varsol burn.

irritant dermatitis to tiamulin or one of its metabolites in the excreta. Skin lesions regressed when the drug was withdrawn.

An eosinophilic dermatitis was observed in pigs following heavy salting of pen floors. Lesions were present on the feet.

Envenomation

The venom of insects, spiders, other arthropods and snakes can cause mild or severe skin lesions with or without systemic signs. Effects are dependent upon composition of the venom, individual victim response, anatomic location of the envenomation, and specific characteristics of the offending organism which may be influenced by season of the year, geographic location, time since last inflicted bite or sting, depth of injury, etc. Different species of animals respond differently to the same venom.

Stings from *Solenopsis invicta*, the **imported fire ant** are common in humans in South America and in most of the southern United States. The ants swarm by the hundreds, covering objects or parts of victims and simultaneously inflict numerous painful stings. The fire ant venom is primarily comprised of an insoluble alkaloid (solenopsin A), shown to be cytotoxic, bactericidal, fungicidal, insecticidal, and hemolytic. Lesions in dogs have been documented and consist of initial swelling progressing to erythematous nodules within 10–20 minutes. Histologically, the sting in dogs produces a vertically oriented zone of coagulative dermal necrosis with variable epidermal necrosis. Necrosis includes the adnexa and may extend into the subcutis. Lesions resolve quickly. Severe type I hypersensitivity (anaphylaxis) reactions are possible.

Stings from **hymenopteran insects** such as *bees, wasps, and hornets* produce effects of a local (angioedema) or possibly systemic type I hypersensitivity reaction due to the histamine, serotonin, and kinins in the venom (see Hypersensitivity dermatoses). Multiple stings dermatoses lead to toxic reactions that can be fatal.

Spider bites are rarely documented definitively in animal or human patients as the initial bite goes unnoticed and the spider is no longer recoverable by the time lesions develop. Bites occur most often on the face and extremities. Most spider bites produce localized pain, erythema and swelling and are not of further consequence. Spiders of importance to the study of the integumentary system are those with venoms leading to *dermonecrosis and eschar formation, a condition referred to as "necrotic arachnidism."* The **brown recluse spider** (*Loxosceles reclusus*) is the spider most well-known to induce dermal necrosis, although there are a number of others. Brown recluse venom contains hyaluronidase and sphingomyelinase-D, which degrade tissues. A blister with a surrounding pale halo and more peripheral erythema characterizes initial reactions documented in humans and some experimental animals. Necrosis and eschar formation occur within 5–7 days. Ulceration may be extensive. Histologically, there is hemorrhage and edema, neutrophilic vasculitis and arterial wall necrosis. The epidermis and dermis undergo necrosis that may extend into the subcutis and underlying muscle. Panniculitis may be present. Eventually, there is dermal scarring and replacement of the subcutis and muscle by hypocellular connective tissue. Brown recluse spider bites in humans can also lead to massive hemolysis. *Differentials include other venomous bites, vasculitis, slough due to iatrogenic injection of irritating substances, thermal burns, necrotizing fasciitis or other cutaneous infection, septic embolization, or trauma.* Compatible lesions, environmental history, and ruling out other conditions producing similar lesions can lead to the presumptive diagnosis of a spider bite.

Snakebite envenomation produces local tissue necrosis and variable systemic effects. Snake venom contains various enzymes, proteins, peptides, and kinins. Systemic effects of snake venom include paralysis, coagulation disturbances, shock, increased capillary permeability, myocardial damage, rhabdomyolysis, and renal failure. Of the five genera of venomous snakes, *crotaline* (rattlesnake, copperhead, cottonmouth and others) *venom* contains the highest concentration of proteolytic enzymes. Local effects include pain, edema, hemorrhage, bullae formation, necrosis, and sloughing of tissue. Bites inflicted in the head or neck region may lead to swelling that interferes with respiration. Bites of pit vipers also introduce potentially dangerous bacteria such as *Clostridial* sp. into the puncture wound. Bites are common in the dog, horse, and, to a lesser degree, cats, and most often are inflicted on the head or legs. The differential diagnoses are similar to those for necrotic arachnidism.

Thallotoxicosis

The heavy metal thallium is a potent toxin with pharmacological actions similar to lead and mercury. Thallium salts are odorless, tasteless, colorless, and water soluble. Thallium was used extensively as a rodenticide and insecticide prior to 1963 when its sale to the general public in the United States and some other countries was banned. It continued to be used by government agencies as a pesticide and in various industries, such as the manufacture of optical lenses, jewelry, and scintillation counters, until the US Environmental Protection Agency banned thallium manufacture in 1972. Thallium is still used in some parts of the world, and its use may increase as pests develop resistance to more selective poisons.

Accidental or malicious thallium poisoning is rare and is due to the use of undestroyed supplies of old, but newly exposed baits. *It occurs chiefly in dogs*, less often in cats and is reported in sheep, cattle and pigs. The LD_{50} for the dog is 10–15 mg/kg, and the toxin is cumulative. Absorption occurs rapidly from the gastrointestinal and respiratory tracts and skin. The toxin is disseminated widely in the body and is persistent, being very slowly excreted in bile and urine.

The mechanism of toxicity is not fully understood. There are two main hypotheses. The first holds that thallium exerts its toxic effect by combining with sulfhydryl groups, a mechanism common to many heavy metals and leading to disruption of mitochondrial respiratory chain enzymes. The second, which is based on the similarity of ionic radii between thallium and potassium, suggests that thallium may replace potassium in many critical biochemical functions, thus acting as a general cellular poison. The toxic effect may be, in part, due to thallium interacting adversely with derivatives of riboflavin. Thallium can depolarize nerve cell membranes and antagonize effects of calcium on the heart.

The clinical effects depend on the dose and rapidity of administration. Signs of *acute thallotoxicosis* are evident within 12 hours of exposure and are characterized by severe gastrointestinal irritation and neurological signs, including motor paralysis. Glossitis, stomatitis, rhinitis, and bronchitis develop. Death by respiratory failure may occur. Animals may survive the acute episode to develop the chronic syndrome or may bypass the acute disease altogether. Cutaneous, renal and neurological abnormalities, progressive debilitation, and death characterize the *chronic syndrome*.

The *cutaneous lesions* develop 7–10 days after ingestion of thallium and principally affect frictional areas. The pattern of skin involvement in cats and dogs is characteristic, beginning at the commissures of the lips or nasal cleft, occasionally on the ear margins and expanding over the face and head. The mucous membranes are characteristically "brick-red" and may be ulcerated. Lesions also develop on the interdigital skin, footpads, axillae, inguinal areas, perineum and lateral extensor surfaces. The lesions are *marked erythema, scaling, alopecia, exudation, and crusting*. The layers of scale-crust exfoliate with attached hairs to leave a raw, oozing surface. The paws often become very swollen. In more chronic cases, thick scales on the footpads resemble "hard pad" disease conventionally associated with canine distemper. In less severely affected animals, *ease of depilation may be the only clinical indication of thallium poisoning*. The pathogenesis of the alopecia is not fully understood. While thallium enters the hair, as do other heavy metals, by binding to sulfhydryl groups in the keratin, this is unlikely to be destructive to the hair follicle. Thallium may interfere with the energy metabolism of the rapidly dividing matrix cells of anagen follicles. In experimental intoxication of rats, a rapid decline in the mitotic rate is followed by necrosis of the matrix cells within 48 hours. The follicle passes into an abnormal catagen phase followed by complete involution (telogen). However, no club attachment is formed and the hairs are rapidly shed. If the animal survives, hair growth is resumed. Thallium also severely alters the keratinization process and both the surface and external root sheath epithelium demonstrate marked parakeratotic hyperkeratosis.

The *microscopic lesions* in the skin are dominated by *massive, diffuse parakeratotic hyperkeratosis*, which affects both surface and external root sheath epithelia. There is accompanying follicular plugging, hypogranulosis and epidermal hyperplasia (Fig. 5.48). Neutrophil exocytosis and spongiform pustules develop in both surface and follicular epithelia. Partial or full thickness necrosis of the surface epithelium may also occur. The dermal lesions include marked hyperemia, edema, erythrocytic exocytosis and infiltration of neutrophils and mononuclear cells. There may be focal necrosis of sweat and sebaceous glands. Hair follicles are mostly in catagen or telogen. Degenerative changes are noted in anagen follicles.

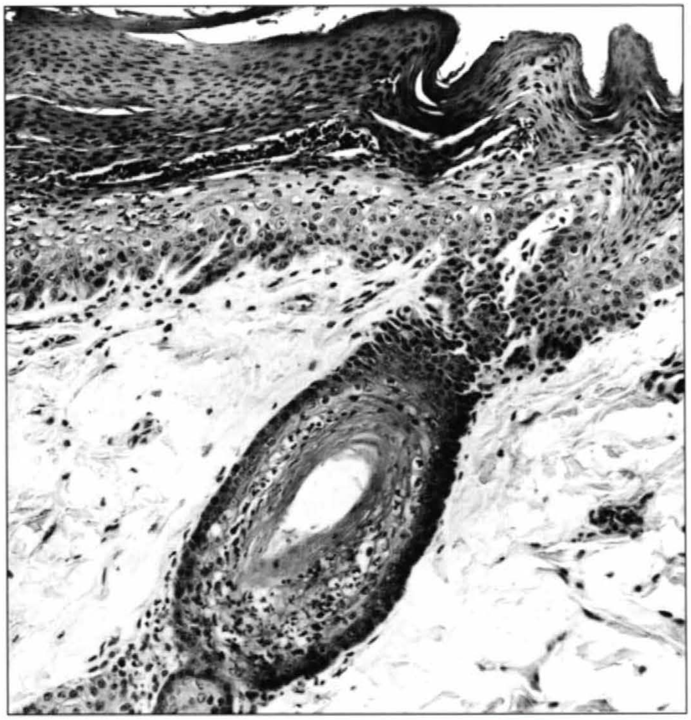

Figure 5.48 Thallium toxicity in a dog. Marked parakeratosis.

Histologic lesions in *other tissues* include multifocal necrosis of myocardial and skeletal muscle fibers, nephrosis, pulmonary edema, reticuloendothelial hyperplasia and lymphoid depletion of spleen and lymph nodes. Secondary bacterial bronchopneumonia may occur as a result of the damage to ciliated epithelia and resultant disturbance of the mucociliary apparatus. Hemorrhagic gastroenteritis occurs in acute thallotoxicosis. Focal suppurative pancreatitis has been described in several animals, but its causal relationship to thallium is not established. Ulcerative esophagitis follows dilation secondary to neuronal damage. Lesions in the central nervous system include neuronal chromatolysis, neuronophagia, and severe edema with little glial reaction. Myelinated peripheral nerves have degenerative lesions including focal distension of myelin sheaths and swelling and occasional fragmentation of axons.

The *differential diagnoses* of acute thallium toxicity include other heavy metal toxicoses, infectious and noninfectious causes of hemorrhagic gastroenteritis, and pancreatitis. Differentials for the clinical lesions include superficial necrolytic dermatitis, zinc-responsive dermatosis, generic dog food dermatosis, toxic epidermal necrolysis, mucocutaneous candidiasis, epitheliotropic lymphoma, and autoimmune diseases such as pemphigus vulgaris and bullous pemphigoid. The *microscopic lesions of thallium toxicosis, zinc-responsive dermatosis, and superficial necrolytic dermatitis are similar* and confirmation requires a compatible history and demonstration of thallium in the urine by the Gabriel–Dubin colorimetric assay or in the stomach contents, suspected bait, urine, liver or kidneys by atomic absorption spectroscopy.

Arsenic toxicosis

Arsenic is the metal most toxic to the skin and is found as a component of wood preservatives, herbicides, insecticides, insulation materials, paint pigments, feed additives, and some medications, and is a by-product of some mining activities. It is a water supply contaminant in some parts of Mexico, Argentina, Chile, Taiwan, India, the UK, and the USA. Safe standards for levels of arsenic in drinking water have not been established. Arsenic is absorbed by the gastrointestinal tract and skin and is excreted in urine, bile, milk, hair, nails, and exfoliated epidermal cells. Its presence in the skin increases the skin's susceptibility to damage by UV light. Chronic arsenic exposure in humans occurs in environmental (water contamination) and industrial settings and is associated with increased incidence of visceral and cutaneous malignancies, Bowen's disease, palmar and solar hyperkeratoses, and cutaneous pigmentary disturbances. The generation of free radicals with resultant nucleic acid damage is suspected to be involved in arsenic-related carcinogenesis. Arsenic may lead to cellular proliferation through increased production of keratinocyte-derived growth factors. *Urine, hair, and liver are the tissues of choice for establishing arsenic exposure.*

Acute arsenic poisoning is an important toxicosis in domestic animals, particularly cattle and dogs, and is due to sulfhydryl group binding and inhibition of cellular metabolism. Signs and lesions are referable to the gastrointestinal tract, liver, and kidneys. Skin lesions are the result of chronic systemic low-level arsenic exposure or to direct contact. *Arsenic is an established low-grade corrosive that produces irritant contact dermatitis.* Contact lesions occur in animals sprayed or dipped in a concentrated arsenic solution or in dogs lying on heavily contaminated ground. Lesions include erythema and epidermal necrosis leading to the formation of non-healing ulcers. Lesions may affect oral cavity, lips, other mucocutaneous junctions and the feet. Less is known about the effects of chronic systemic exposure of arsenic on the skin in animals, however, chronic arsenic poisoning in farm animals is associated with ill thrift and a dry, seborrheic, alopecic coat.

Mercury toxicosis

Organomercurial toxicosis in domestic animals is associated chiefly with neurologic and renal disorders and is discussed in Vol. 1, Nervous system and Vol. 2, Urinary system, respectively. In chronic poisoning in **cattle**, skin manifestations including *pustules, ulcers, hyperkeratosis and alopecia* at the tail head are described, but their pathogenesis is poorly understood. **Horses** ingesting mercury-treated seed grain develop *total body alopecia*, followed by loss of the long hairs of mane, tail and forelock. The hooves are not affected and the cutaneous lesion is mild scaling. Experimental chronic methylmercury intoxication in horses produces *exudative dermatitis*, but histologic lesions are not described. Local toxic contact dermatitis follows application of mercurial-containing counterirritants to the legs in horses.

Cutaneous iodism

Iodides have widespread use as antiseptics, expectorants, intravenous contrast agents, bronchodilators, antithyrotoxicants, and as salt or feed additives. Iodine is readily absorbed from the skin. The majority of reports of adverse effects of iodine occur as hypersensitivity reactions and not toxicoses. *Generalized seborrhea sicca* is reported in horses and cattle accidentally overdosed with iodine-containing drugs or medicated feed. In experimental toxicosis of calves, the cutaneous lesions were limited to scaly patches without alopecia. Conversely, suspected iodism in a horse produced generalized alopecia, sparing only the face, mane and tail.

Selenium toxicosis

Selenium is a metalloid that acts as an antioxidant with toxic potential. It has chemical properties similar to sulfur. It is excreted from the body in urine, feces, and sweat and integumentary structures. Experimental studies in rodents suggest that selenium may diminish UV radiation-induced skin damage when applied topically. However, some forms are strong contact irritants and vesiculants. The toxic potential of selenium in the diet varies by the chemical form present, nature of the diet, rate of consumption, and by the species and individual animal. The mechanism by which selenium might exert its effects on the integument and appendages is not known, but conceivably, being competitive with sulfur, it modifies the structure of keratin.

Selenium is widely distributed in soils at concentrations ranging from 0.01 parts per million (ppm) or less to 500 ppm or more. Areas of high soil concentration are particularly extensive in parts of the USA (Wyoming, Montana, Utah, Colorado, North and South Dakota, Arizona, Kansas, and Nebraska) and in western Canada, but also occur in parts of Australia, New Zealand, China, Ireland, Mexico, and Israel, among other countries.

Selenium toxicosis occurs in *horses, cattle, sheep, and pigs*, chiefly as a result of the ingestion of plants that have accumulated toxic levels of selenium, but occasionally as a result of accidental overdose of selenium supplements. Plants are divisible into seleniferous and nonseleniferous species. **Seleniferous plants** can selectively concentrate selenium in their foliage and seeds as compared with nonseleniferous species grown under the same conditions. The seleniferous species are subdivided into obligate accumulators, which require high levels of selenium for survival and facultative accumulators. The former, which include members of the genus *Astragalus*, *Machaeranthera* and *Stanleya,* may accumulate over 1000 ppm selenium. Because of their high requirement for selenium, they are known as "indicator" species. Facultative or secondary selenium accumulators such as *Aster, Atriplex, Castilleja,* and *Gutierrezia* take up lesser amounts of selenium. Many nonseleniferous weeds, crop plants, and grasses are capable of passively accumulating selenium if growing on soils with high selenium content. Also, indicator plants increase the availability of selenium to nonseleniferous plants by converting insoluble selenites to soluble selenates and returning these to the soil. Selenium poisoning can occur whenever seleniferous plants are eaten irrespective of levels of selenium in the soil, and it can occur whenever the levels of water-soluble selenium in the soil are high, irrespective of the botanical composition.

Seleniferous plants are not palatable and indigenous stock learns to avoid them. Selenium poisoning occurs chiefly in newly introduced or traveling animals and in indigenous animals forced to eat the seleniferous plants in times of scarcity. Clinically, there are acute and chronic syndromes associated with the ingestion of seleniferous plants such as *Astragalus* and *Oxytropis*. *Acute toxicity* causes severe gastrointestinal and cardiovascular signs with mortality in some instances approaching 100%. Two different syndromes have been described as *chronic selenium poisoning*. "**Blind staggers**," characterized by neurological signs, is probably not due to selenium alone but to other toxic principles in the seleniferous plants. The second syndrome is named "**alkali disease**" because it was originally believed that the pH of the selenium-rich soils was a factor in its pathogenesis. Unlike blind staggers, alkali disease is reproducible in ungulates fed sublethal concentrations of selenium. The presence of internal lesions such as nephrosis, myocardial degeneration, and hepatic fibrosis in chronically poisoned livestock is not found in experimentally reproduced disease, suggesting other factors are involved.

Horses and cattle chronically intoxicated with selenium become emaciated and develop partial alopecia and a general roughness of coat. Foals delivered from affected mares may have lesions. Initially, there is loss of the long hairs in the mane, forelock, and tail of horses (leading to the name "bobtail" disease), and loss of the long tail hairs in cattle. Sheep do not show cutaneous lesions, although in Australia fleece shedding has been attributed to selenium toxicity on some properties. Selenium toxicity is also suspected in alopecias of the beard and flanks of goats in the western United States. In all species, lesions commencing at the coronary band may lead to separation and shedding of the hoof or to the formation of dystrophic grooves, cracks, or corrugations that parallel the coronary band resulting in lameness (Fig. 5.49). Lesions take months to develop. *Histologic lesions* of experimental chronic selenium toxicosis in cattle showed extensive separation of the stratum medium of the hoof with replacement by parakeratotic cellular debris. The germinal epithelium of the hoof wall was disorganized, parakeratotic and hyperplastic. Hair follicles from the tail were atrophic with dyskeratosis and mild hyperkeratosis.

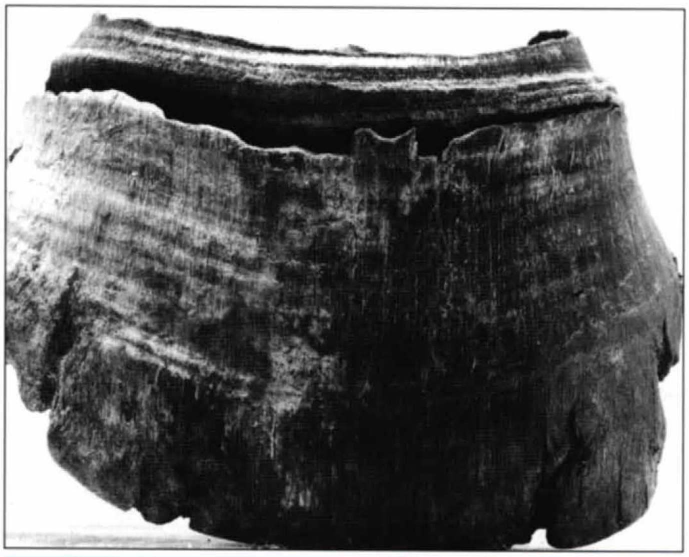

Figure 5.49 Selenium toxicosis in a horse. Hoof wall deformed by rings and grooves. (Courtesy of Queensland Department of Agriculture.)

Diagnosis requires the demonstration of compatible clinical signs, progression of lesions, and identification of a dietary source of selenium with a concentration in the air-dried feed sample of >5 *ppm selenium*. High levels of selenium in the blood (>2 ppm) or integumentary tissues such as hair, hoofwall or sole (>10 ppm) should also be present. Individual animals have a variable response to selenium exposure and some animals with high levels of selenium may not show signs of toxicosis.

Organochlorine and organobromine toxicoses

Organochlorine and organobromine compounds implicated in toxicities causing, among others, cutaneous lesions, include the *highly chlorinated naphthalenes (HCN), polybrominated biphenyls (PBBs),* and *dibenzofurans. Polychlorinated biphenyls (PCBs)* are the cause of an important industrial dermatitis of humans known as *chloracne.*

Highly chlorinated naphthalene (HCN) toxicosis (X-disease, bovine hyperkeratosis), the result of exposure to tetra-, penta-, hexa-, hepta-, or octachloronaphthalenes, is largely of *historical interest.* HCNs were found to be responsible for high mortality and large economic losses in the cattle industry within the United States, Australia, New Zealand, and Germany during the 1940s and early 1950s. HCN was a common additive in many petroleum products including those used as lubricants for farm machinery such as feed pelleting equipment, wood preservatives, roofing paper and building board. HCNs were a frequent feed contaminant. *These chemicals have not been used in lubricants since 1953.* Recent reports are the result of animals exposed to dumps with stores of old lubricant or abandoned machinery lubricated years ago with HCN containing products. Percutaneous exposure produces cutaneous lesions, whereas parenteral exposure results in both cutaneous and visceral lesions. The poison is cumulative and the disease is chronic. Lesions of HCN toxicity result from interference with the conversion of carotene to vitamin A and resemble the lesions of vitamin A deficiency. The first sign of poisoning is a fall in vitamin A levels in the plasma.

Cattle are the most susceptible species. Initial signs are increased lacrimation and drooling, depression, decreased appetite, and weight loss. Within the first few months, *hallmark cutaneous lesions of marked alopecia with nonpruritic, lichenified, deeply fissured plaques of hyperkeratotic scale are evident on the skin of the neck, shoulders and perineum.* Lesions gradually generalize, sparing only the legs. Marked involvement of the skin of the medial thighs is characteristic. Horn growth may be delayed. The animal may die before the skin lesions are severe, if exposure is high. Concurrent severe secondary infections with *Bovine papular stomatitis virus,* papilloma virus or dermatophytes may be present. The histologic lesions are marked hyperkeratosis of surface and follicular epithelia. Internal lesions are the result of hyperplasia and squamous metaplasia of the epithelial lining of ducts and glands of the body including liver, pancreas, kidneys, and reproductive tract. Bulls may present with epididymal enlargement early in the disease process from hyperplasia and squamous metaplasia of ducts.

Differential diagnoses include other markedly hyperkeratotic dermatopathies such as zinc or vitamin A deficiency, dermatophilosis, dermatophytosis, or toxicosis due to other polyhalogenated aromatic compounds. Definitive diagnosis is dependent upon identification of a source of HCN and extraction of the toxin by capillary gas chromatography and mass spectrometry. Vitamin A levels in the plasma and liver are low, but toxicosis cannot be reversed by vitamin A therapy and the prognosis is poor.

Cutaneous lesions in **cats** exposed to wood preservatives have been ascribed to chlorinated naphthalene toxicity. The lesions include bilateral alopecia and encrustations on the eyelid and around the nostrils.

Pentachlorophenol (PCP)-contaminated wood shavings used as bedding led to chronic toxicity characterized by a *proliferative dermatitis* with crusting, scaling and alopecia accompanied by a *multitude of systemic signs* including peripheral edema, bone marrow hypoplasia, liver disease and wasting in a group of horses. Gross and histologic cutaneous lesions resembled those of HCN toxicity. Wood shavings containing four times the maximal allowable levels of PCP/kg were traced to a lumber company using improper processing techniques. Toxicity was attributed to dibenzofuran and chlorinated dibenzo-p-dioxin isomers found as contaminants of the PCP. *Contaminants of PCP products include a large group of dioxin isomers with a wide range of toxicity that can vary by species exposed and among animals within the species.* PCP compounds are used as antiseptics, disinfectants, herbicides, fungicides, and wood and hide preservatives. The toxicity of the herbicide, agent Orange, widely sprayed in Vietnam, is attributed to *dioxin contaminants.* The compounds enter the body via oral, dermal, or respiratory routes. High exposure leads to rapid death due to uncoupling of mitochondrial oxidative phosphorylation. Chronic toxicity is more common. The contaminants in the PCP compounds are thought to bind to aromatic hydrocarbon receptors in the cell nucleus and influence gene expression. The response may be proliferative or suppressive. Elevated levels of the compounds can be demonstrated in the liver and adipose tissue years after exposure, whereas serum levels are cleared quickly. Similar cases of dioxin isomer toxicity have been reported in *horses* exposed to riding arenas sprayed with contaminated waste oil used for dust control.

Mimosine toxicosis

Mimosine is a *toxic amino acid* found as a main constituent in the tropical to subtropical, cultivated *leguminous shrubs, Mimosa pudica* and *Leucaena leucocephala* (formerly *L. glauca*). Mimosine and its metabolite, 3-hydroxy-4-(1H)-pyridone (DHP), are toxic. In ruminants, mimosine is a depilatory, whereas DHP is a goitrogen. Poisoning can be acute or chronic and is characterized by *alopecia, poor growth, oral ulcerations,* and *goiter* not prevented by iodine supplementation. Toxicity occurs in a number of countries and goes by a variety of local names: *jumbey* in the West Indies, *lamtoro* in Indonesia, and *koa haole* in Hawaii. A variation of animal susceptibility to mimosine toxicity in different parts of the world is due to the geographic distribution of ruminal bacteria capable of degrading DHP. In vitro antemortem assays for detection of DHP-degrading bacteria can be performed on feces or ruminal contents. A group of bacteria, *Synergistes jonesii,* can be inoculated into the rumen of livestock to prevent toxicity. Mimosine has been shown to reduce DNA synthesis and to block the progression of the cell cycle by chelating iron. DHP prevents iodine binding in the thyroid gland. *Mimosine toxicity occurs in horses, cattle, pigs, and sheep* and has been experimentally reproduced in cattle and laboratory animals.

Horses appear to be most susceptible and lose their hair, especially the long hair of the mane and tail. In severe cases, there is patchy loss of hair above and below the hocks and knees and on the flanks and neck. Disturbed growth at the coronet and periople may produce dystrophic rings on the hooves. There is loss of condition and weakness that perhaps is attributable to malnutrition rather than to mimosine.

Mimosine has a marked depilatory action on the fleece of **sheep**. The fleece becomes easily epilated 14 days after a single oral dose of 400–650 mg/kg body weight. DNA synthesis in the wool follicles is reduced. Mimosine toxicity causing depilation in **pigs** is reported from Indonesia and the Bahamas.

Gangrenous ergotism and fescue toxicosis

These two conditions can be considered together because the cutaneous lesions of chronic ergotism caused by *Claviceps purpurea* and those of poisoning by tall fescue, *Festuca arundinacea* or *F. eliator*, are identical.

Ergotism is the oldest known mycotoxicosis. The ergot of *Claviceps* spp. fungi is a *compacted mass of hyphae, the sclerotium*, which develops in the seed heads of many species of grasses and cereal grains and completely replaces the ovary. *Ergotism is the disease that results from ingestion of toxic alkaloids produced by the fungi.* The alkaloids are derivatives of lysergic acid and include *ergotamine, ergometrine and ergotoxine*, which is a composite of three alkaloids. The quantity and spectrum of alkaloids in the ergots vary considerably with the strain of fungus, type of plant, season of the year, climatic conditions and other regional factors. The ergots also produce a *variety of amines*, such as histamine, acetylcholine and other nitrogenous compounds with physiological activity.

Of the various pharmacological effects exerted by the ergot alkaloids, the most important in the pathogenesis of gangrenous ergotism is direct stimulation of adrenergic nerves supplying arteriolar smooth muscle. This produces *marked peripheral vasoconstriction.* Arteriolar spasm and damage to capillary endothelium leads to thrombosis and ischemic necrosis of tissues.

Gangrenous ergotism caused by *C. purpurea* is a disease mainly of cattle. It may occur in animals at pasture but is more common in housed animals fed infected grain. Gangrenous ergotism represents the chronic form of intoxication by ergot-producing fungi. Chronic ergotism develops after a week of feeding contaminated grain and begins with *acute lameness with redness and swelling of the extremities*. The hindlegs are more frequently affected than the forelegs. Lesions seldom extend above the fetlock (Fig. 5.50), but ischemic necrosis may extend to the mid-metatarsus. The feet become cold and insensitive with dry necrosis and a prominent line of separation between viable and dead tissue. The necrotic tissue may slough. Ergotism also causes *dry gangrene of the tips of the ears and tail.* Gangrenous ergotism has been described in goats feeding on ergot-infected pasture. The toxicosis can be produced experimentally in sheep, but the syndrome is quite different from that in cattle, being characterized by ulceration of the tongue and of the alimentary mucosae. Sows are relatively resistant but may develop agalactia as a result of central inhibition of prolactin secretion.

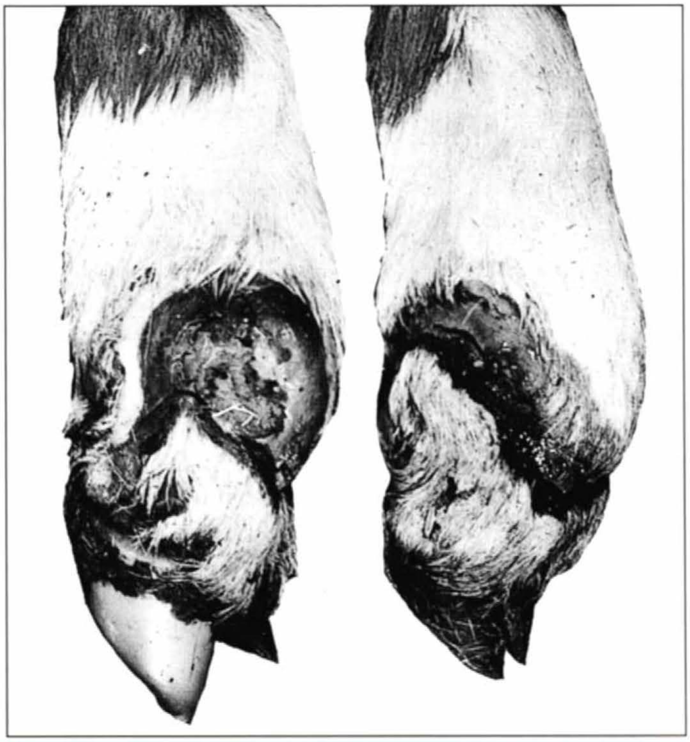

Figure 5.50 Ergotism in a calf. Sharply demarcated ischemic necrosis of distal extremities.

Fescue toxicosis has a variable presentation depending upon the animal species exposed. The most common manifestation, "*fescue foot*," is a disease of *cattle* characterized in the acute form by *dry gangrene of the extremities* commencing 2 weeks after ingestion of the tall fescue grass, *Festuca arundinacea*. This perennial grass is the most common pasture plant in the United States and is usually harmless. The endophytic fungus *Neotyphodium (Acremonium) coenophialum* infects approximately 75% of fescue pastures and imparts increased resistance of the plant to insects and extreme environmental temperatures. Under certain poorly understood conditions, the endophyte-infected plant is toxic. Fescue foot tends to occur with the onset of colder weather indicating that low ambient temperatures may contribute to its development. The alkaloids, *ergonovine, ergotamine, and N-acetyl loline* are responsible for toxicity and act as *peripheral vasoconstrictors*. The acute syndrome in cattle is virtually identical to ergotism.

A chronic disease in **cattle**, known as "summer slump," refers to an increased susceptibility to heat stress seen in certain breeds of cattle in conditions of high environmental temperature combined with intake of endophyte-infected fescue. Cattle have decreased skin temperature and open-mouth breathing suggesting defective thermoregulation. Experimental intravenous injection of alkaloids found in fescue produced lowered skin temperature, heart rate, and prolactin levels, and elevated blood pressure and respiratory rates in heifers. Ingestion of endophyte-infected fescue in **horses** does not lead to the visibly evident effects of peripheral vasoconstriction as in cattle, but experimental studies have demonstrated peripheral vasoconstriction does occur suggesting exposure could lead to foot or leg problems. The more commonly recognized manifestations of fescue toxicosis in the horse are *prolonged gestation, agalactia, thickened placentas, and possible abortion.* Abdominal lipomatosis associated with marked necrosis of abdominal fat and severe weight loss occurs in *domestic ruminants* and some species of wildlife consuming endophyte-infected fescue. A heritable predisposition exists in cattle.

Tricothecene toxicoses

Macrocyclic trichothecene toxins produced by the fungus *Stachybotrys* spp. cause **stachybotryotoxicosis**. *Ulcerative and necrotizing lesions of the skin and mucous membranes* have been reported in horses, cattle, sheep, and pigs, chiefly from Russia and Eastern Europe. Initial lesions affect the lips, buccal commissures and nostrils. Marked edema of the face may follow. Death follows development of *hemorrhagic diathesis, enteritis, and septicemia*. At necropsy, lesions in addition to the hemorrhagic diathesis include alimentary ulceration, pneumonia, renal infarcts, multifocal hepatic necrosis, and lymphadenitis. In many instances, these lesions may represent secondary mycotic or bacterial involvement.

T-2 toxin is a highly irritant trichothecene mycotoxin from *Fusarium* molds on grain, and causes cutaneous ulceration when applied locally to the skin of pigs. Experimental feeding of T-2 toxin contaminated feed, in combination with aflatoxin, induces crusting and ulceration of the lips, snout, buccal commissures and prepuce. The pathogenesis of the lesion is thought to be *contact irritant dermatitis* due directly to the T-2 toxin or to a urinary metabolite, HT-2 toxin.

Various other trichothecene mycotoxins are also cutaneous irritants and may cause vomition or feed refusal.

Vetch toxicosis and vetch-like diseases

Hairy vetch *(Vicia villosa* Roth*)* is a cultivated legume used as pasture, hay and silage in most of the United States, and in other countries such as Argentina, Australia, and South Africa. Hairy vetch toxicosis in **cattle** is seen as three unique syndromes: (1) acute neurological disease and hemolysis, followed by death after consumption of seeds; (2) swelling of the upper body accompanied by herpetiform eruptions of the oral mucous membranes, respiratory distress and death after consuming vetch pasture; and, (3) a syndrome characterized by *dermatitis, conjunctivitis, diarrhea, and granulomatous inflammation of many organs*. This third syndrome is the most common form of hairy vetch toxicosis and occurs in cattle and, to a lesser extent, *horses* after consumption of vetch-containing pastures. The clinical syndrome begins two or more weeks after consumption and consists of pruritic dermatitis, diarrhea (possibly bloody), and wasting. Morbidity is low and mortality is high. Holsteins, Angus and cattle 3 years or older are more often affected. Death in cattle occurs approximately 10–20 days after illness begins.

Initial lesions consist of a rough coat with papules and crusts affecting the skin of the udder, teats, escutcheon and neck, followed by involvement of the trunk, face and limbs. The skin becomes less pliable, alopecic, and lichenified. Marked pruritus leads to excoriations. At necropsy, *yellow nodular infiltrates disrupt the architecture of a wide range of organs*, but are most severe in myocardium, kidney, lymph nodes, thyroid and adrenal glands. The kidney may have radially oriented cortical infiltrates that follow the vasculature. Other affected organs may include the mammary and salivary glands, liver, urinary bladder, meninges, and spleen. Histologically, *the infiltrates consist of monocytes, lymphocytes, plasma cells, multinucleated giant cells, and in the cow, eosinophils.* The skin has similar perivascular to diffuse infiltrates, marked hyperkeratosis, and dermal and epidermal edema. This form of the disease has been induced experimentally in an Angus cow that had recovered from vetch toxicosis the previous year. Lesions were evident 11 days after feeding vetch. Death occurred even though vetch was removed from the diet at 12 days. Experimental lesions mirrored those of naturally occurring disease with the additional finding of necrosis of cutaneous apocrine glands.

Other species of *Vicia* and additional compounds are capable of inducing disease indistinguishable from vetch toxicity.

Pyrexia with dermatitis in dairy cows is a syndrome with similarities to hairy vetch toxicity. It has been reported in the United States, England, Wales, France, and the Netherlands. Friesian dairy cows developed pruritic papular eruptions affecting the head and neck, tail head and udder. Secondary lesions were due to self-trauma. In another outbreak, hemorrhages were a prominent clinical sign. The episode in Wales was associated with the introduction of a new silage additive on several farms. The outbreak in the Netherlands was associated with the feeding of *di-ureido-isobutane*

(DUIB) in the seed cake. This condition was reproduced in two cows by feeding a DUIB-containing diet for one month. Histologically, *the lesions of the Dutch outbreak also resembled those of the putative hairy vetch toxicity*. Visceral lesions resembling hairy vetch toxicity occur in dairy cows fed a diet containing *citrus pulp;* the syndrome resolves after removal of citrus pulp from the diet.

Hairy vetch toxicosis in **horses** resembles that in cattle except for the infrequent finding of eosinophils in the infiltrate and lack of heart involvement. Conditions very similar to vetch toxicosis have been reported in horses with no vetch exposure. These cases have been variably referred to as "idiopathic granulomatous disease involving the skin," "systemic granulomatous disease," "generalized granulomatous disease" or "equine sarcoidosis." Organ involvement is variable. Skin lesions include scaling, crusting and alopecia on the face or limbs that progress to a generalized exfoliative dermatitis. Histologically, *the skin has multifocal, sometimes perifollicular to deep dermal nodules of granulomatous inflammation*. Sarcoidosis in man has a genetic basis and is thought to represent a hypersensitivity response to a persistent antigen. These idiopathic conditions in the horse are fairly indistinguishable and should be considered "*vetch- like disease*" until more information is available.

Toxicity from vetch seeds is known to be due to the presence of *prussic acid*. The cause of the granulomatous diseases listed above remains unclear. Nor is it certain whether they represent one entity or a common tissue reaction to a variety of insults. One proposed pathogenesis is that ingestion of vetch or another substance leads to antigen formation in the form of a hapten or a complete antigen that sensitizes lymphocytes and evokes the cell-mediated response upon repeat exposure. Factors that support this hypothesis are the resemblance of the histologic lesions to a type IV hypersensitivity response, age incidence, low morbidity, genetic influence and possible need for repeat exposure. Lymphocyte blastogenesis and cutaneous hypersensitivity studies have not substantiated this hypothesis, however, only a few vetch antigens have been studied.

The diagnosis of vetch toxicity or vetch-like disease is a *diagnosis by exclusion*. It is made after review of the herd history, and character and distribution of the lesions. The combination of lesions is fairly distinctive.

Quassinoid toxicosis

Quassinoid compounds, such as neoquassin and quassin found in hardwood trees of the genus *Quassia (Simarouba amara)* in the family Simaroubaceae, have been reported to be associated with a *vesiculobullous dermatitis of the skin* around the eyes, nose, ears, anus and lips of horses. *Wood shavings* from these plants have been incorporated in bedding and the outbreaks have occurred in large numbers of exposed horses. Gross lesions develop within the first few days of exposure and most often resolve within a week. Systemic signs such as anorexia and icterus accompany cutaneous lesions in some cases. Hepatopathy and nephrosis have been reported. Similar symmetrical lesions of the oral mucosa, mucocutaneous junctions, and pressure points have been reported in dogs exposed to *Simarouba* shavings.

Quassinoids have been shown experimentally to have insecticidal and anthelmintic properties while their derivatives have antitumor, antiulcer, and cytotoxic activity in vitro. The mechanisms leading to toxicity are not known. Definitive diagnosis is dependent upon a compatible history, exclusion of viral diseases such as vesicular stomatitis and exposure to other toxins, and the positive identification of plants of the *Quassia* genus in the bedding material.

ACTINIC DISEASES OF SKIN

The radiant energy of the sun includes components that are potentially harmful to mammalian skin. This radiation is known as **actinic radiation** and its acute effect is the well-known *sunburn* reaction. **Photosensitization** is essentially an *exacerbated form of sunburn*, caused by the activation of photodynamic chemicals in the skin by radiation of an appropriate wavelength and is discussed under the heading Photosensitization dermatitis. **Photoallergy** is distinct from phototoxicity; *it occurs when the photoproduct of an exogenous chemical acts as an antigen*. Photoallergic reactions require prior sensitization to the drug or chemical and are more clinically diverse. Photoallergies have not been documented conclusively in animals. **Skin cancers** induced or exacerbated by actinic radiation are considered with Tumors of the epidermis.

Direct effect of solar radiation

Solar energy is a form of non-ionizing radiation comprised of ultraviolet light (100–400 nm), visible light (400–700 nm), and infrared light (700–20 000 nm) rays. *Most of the direct photobiologic reactions in the skin are induced by high energy light in the ultraviolet radiation UVB range (290–320 nm)*. Longer wavelengths of 320–400 nm constitute UVA and may augment UVB-mediated damage. The integument is normally protected against the deleterious effects of ultraviolet radiation by the hair coat, the stratum corneum and melanin pigmentation. The quantity of ozone, smog, altitude, latitude, season of the year and time of day also strongly influence the amount of UV rays reaching the skin. The greatest potential for solar-induced skin damage occurs at high altitudes and temperate latitudes during mid-summer days, and in thin, lightly pigmented, sparsely haired, sun-exposed skin. An increasing prevalence of sun-induced dermatoses and tumors has been noted in humans, coincident with *the depletion of the ozone layer and a consequent increase in the intensity of ultraviolet radiation reaching the earth's surface*. This trend may also become evident in animals. Potentially, all animals are susceptible to the acute and chronic effects of actinic radiation, but the protection afforded by the hair coat, and to a lesser extent stratum corneum and skin pigmentation, is normally sufficient to prevent solar-induced damage. The conditions described below typically affect animals whose anatomical defenses are poor, either by lacking skin pigmentation or hair cover.

UVB radiation stimulates light-absorbing molecules in the skin referred to as chromophores. *Chromophores include keratin proteins, melanin, carotene, nucleic acids, peptide bonds and some amino acids*, to name a few. Light absorbed by chromophores results in electron transfers and free radical production. *Free radical mediated cellular damage* is discussed elsewhere. Energy dissipated from electron transfers induces chemical reactions to form altered cell components referred to as *photoproducts* that include altered DNA molecules, enzymes, and hydrogen and disulfide bonds within proteins. Nucleoprotein is susceptible to ultraviolet radiation damage resulting in mitotic inhibition and, if extensive enough, cell death. Sublethal damage may promote mutagenesis or carcinogenesis by the formation of thymidine dimers between pyrimidine base pairs of DNA. Pyrimidine dimer repair mechanisms normally correct DNA damage prior to cell replication, however repeated or extensive damage may lead to failure of repair mechanisms and cell transformation. The "*sunburn cell*" associated with UV damage is a keratinocyte that has undergone apoptosis. UVB-induced keratinocyte apoptosis is a complex event that involves cytokines such as TNFα and probable p53-mediated induction of apoptosis in cells sustaining substantial DNA damage. Studies in mice have shown that UVB radiation-induced apoptotic keratinocytes are replaced by hyperproliferative keratinocytes leading to epidermal hyperplasia, suggesting apoptosis and hyperplasia are related events. Ultraviolet light also induces mutations of the p53 tumor suppressor gene in keratinocytes contributing to a proliferative advantage to mutated cells that is found in solar-induced actinic keratoses and squamous cell carcinomas in humans. These findings indicate ultraviolet radiation can serve as both a tumor initiator and promoter. UV radiation may also alter immunologic reactivity in favor of the growth of the tumor, through the induction of suppressor T cells and possible impairment of natural killer cell function. UVB radiation exposure reduces the number of Langerhans cells and impairs their antigen-presenting functions. Contact hypersensitivity responses in experimental animals are reduced following UVB irradiation.

Apoptotic keratinocytes, "sunburn cells," arranged singly or in clusters or bands in the outer stratum spinosum are a characteristic microscopic feature of acute sun-induced epithelial damage. These may be induced within 30 minutes of sun exposure. Other lesions include spongiosis, vacuolation of keratinocytes, loss of the granular layer, and, in severe burns, vesiculation. Dermal hyperemia and edema are prominent features. In mild lesions, there is a slight increase in mononuclear cells; in severe burns, there is marked vascular damage, erythrocyte extravasation and neutrophilic exocytosis. The initial lesion of UV-irradiation induced injury consists of transient erythema, probably due to a direct heating effect and the photobiologic effects of UVB acting directly on dermal capillaries. The delayed erythema reaction may be due to direct damage to endothelial cells or the release of cytokines from the radiation-damaged keratinocytes. Ultraviolet radiation has been shown to increase the production of keratinocyte-derived cytokines. Ultraviolet light also induces adaptive responses in the epidermis, in particular epidermal hyperplasia and alterations in melanin pigmentation. An immediate pigment darkening is due to changes in existing melanin, and the delayed or "tanning" reaction to stimulation of melanogenesis and proliferation of melanocytes. *Melanin both absorbs and scatters UV radiation and, being able to trap free radicals, is important in minimizing the deleterious effects of incident photons.* Basal keratinocytes with melanin granules forming protective caps over the nucleus have an increased distribution in sun-exposed skin. In chronically sun-damaged skin, pigment distribution can become irregular due to impaired transfer of melanin from melanocytes to keratinocytes, thereby weakening host defenses. *Long-term effects* of ultraviolet irradiation include variable degenerative changes in the dermis (solar elastosis and fibrosis), adnexa (comedones, cysts), and epidermis (solar keratosis). Lesions vary by species and among individuals within the species.

Solar dermatitis, or *sunburn*, occurs most frequently in *cats, dogs, pigs, cows, and goats*. The lesions in *cats* typically affect the tips of the ears, nose, eyelids, and lips of white, blue-eyed animals. The initial lesion is erythema followed by alopecia, scaling and crusting (Fig. 5.51). The ear tip may curl over. Lesions are exacerbated each summer, often eventuating in malignant transformation into squamous cell carcinoma. Primary phototoxicity in swine occurs in white or light-colored *pigs*. While any age group may be affected, the condition is most severe in suckling and weaner pigs. Occasionally, severely affected ears may slough. Light-colored *goats* and *cows* are also prone to solar dermatitis. The udders are particularly susceptible when does are turned out into strong sunlight after a winter indoors.

Solar dermatitis occurs most often in *short-haired dogs with light pigmentation*. Breeds most often affected include Bull Terriers, Whippets, Beagles, and Dalmatians. Lesions are most often present on the ventrolateral abdomen and thorax, lateral flank, hocks, and bridge of nose in nonpigmented skin. Such lesions are probably related to the basking behavior exhibited by the animals. *Early lesions of erythema and scaling evolve into thick, lichenified, erythematous, crusted patches and plaques.* Hemorrhagic bullae may develop. The most consistent histologic finding in dogs with chronic solar dermatitis is a *narrow, hypocellular, pale-staining band of collagen along the dermoepidermal junction*. This change may be present prior to clinical signs of actinic dermatitis and may be used as an indicator of solar damage if the history, anatomical site, and breed are supportive. Other changes noted in canine sun-damaged skin include epidermal acanthosis, apocrine gland ectasia, and follicular keratosis resulting in follicular cyst formation and possible furunculosis, particularly over pressure points (Fig. 5.52A). A layer of fibrosis often surrounds cystic follicles. A superficial perivascular mixed infiltrate of lymphocytes, plasma cells, monocytes, neutrophils, and rare eosinophils is usually present. Furunculosis leads to a marked foreign-body response. Follicular changes are thought to be due to loss of support of follicles, however elastin studies in dogs have not demonstrated degeneration of elastin fibers supporting the follicular wall. Advanced lesions may have epidermal dysplasia (Fig. 5.52B) or concurrent UV-light induced neoplasms such as a squamous cell carcinoma, hemangioma, or hemangiosarcoma. It is important to note that UV light-induced neoplasms may arise in skin devoid of other changes suggestive of actinic damage. *Actinic comedones* may also be present without lesions suggestive of actinic epidermal damage. *Differentials* are many and include other conditions resulting in comedone formation, acne, various allergies, bacterial or fungal infections, neoplasia or a primary keratinization disorder. Restriction of lesions to nonpigmented, sparsely haired skin and a history of sun exposure should be helpful in differentiation.

Solar elastosis, a hallmark of chronic sun exposure in humans, has been described only rarely in *dogs, cats, sheep and horses* and essentially represents *disorganization of dermal components due to*

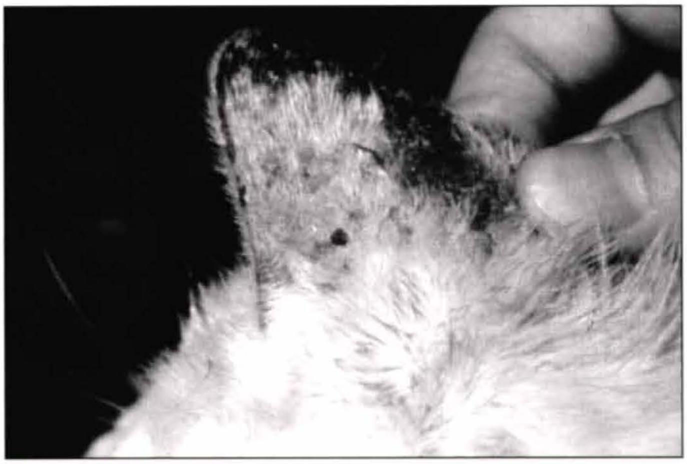

Figure 5.51 Solar dermatitis in a white cat, with erythematous, crusted patches and plaques on the pinnae.

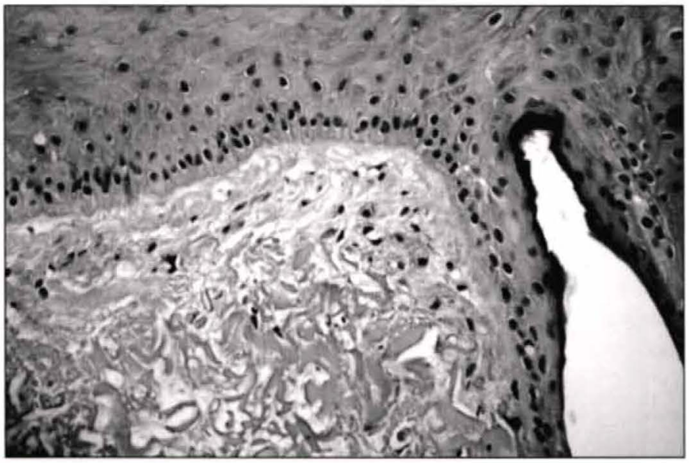

Figure 5.53 Solar elastosis. The dermis is filled with agglomerated, thick, irregular, basophilic degenerate elastic fibers.

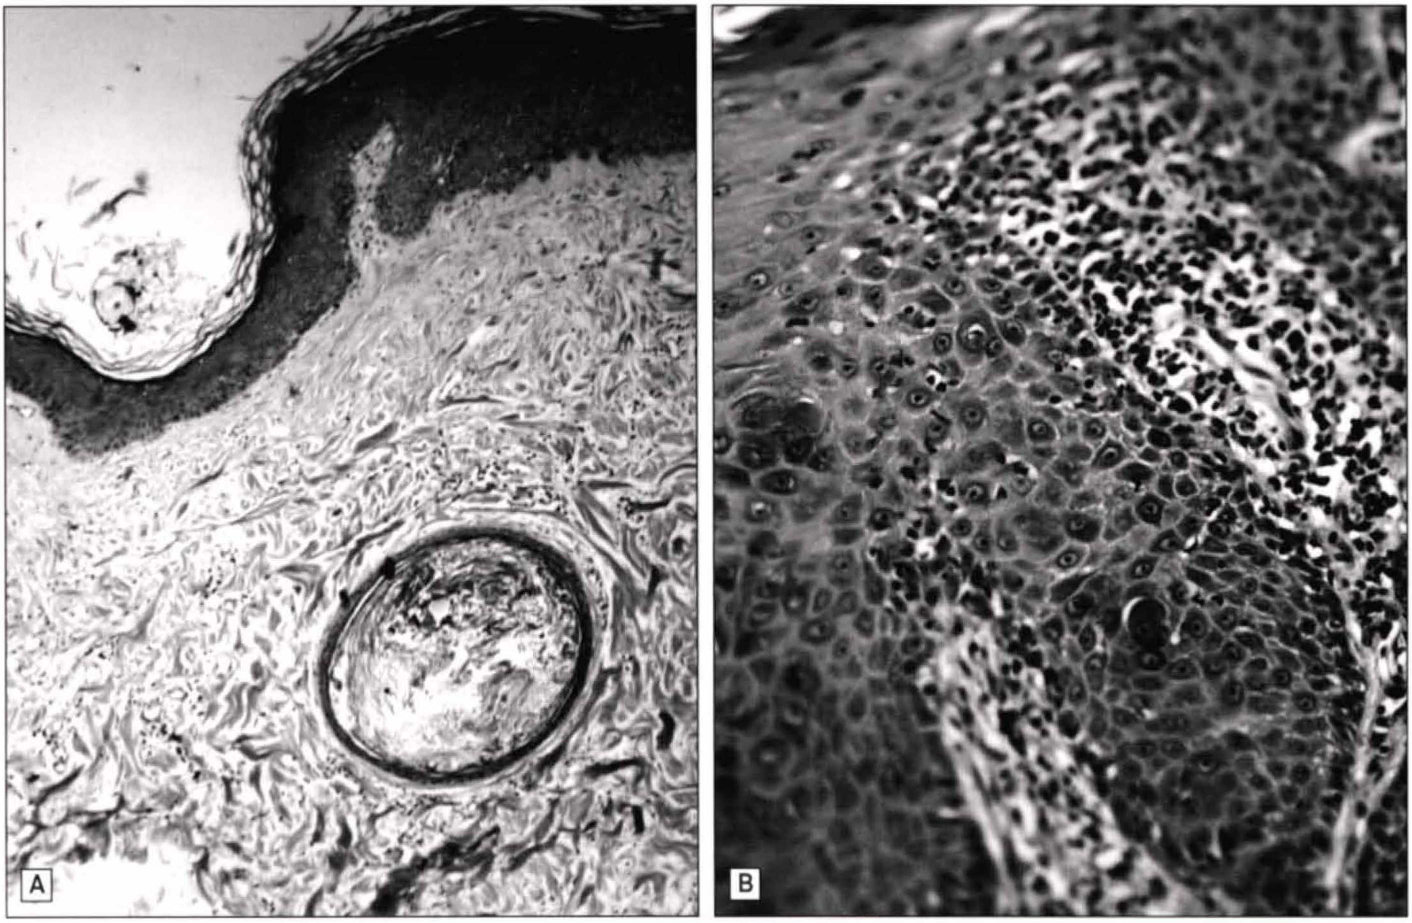

Figure 5.52 Solar dermatitis. A. Note hyperplastic epidermis, superficial layer of pale dermal collagen, and comedone formation. **B.** Hyperplastic epidermis with "**sunburn cells**" and other evidence of dysplasia.

altered fibroblast function. The lesions usually occur in conjunction with solar radiation-associated neoplasms, particularly squamous cell carcinomas. Solar elastosis appears in hematoxylin and eosin-stained sections as *scattered or agglomerated, thick, irregular, basophilic degenerate elastic fibers* (Fig. 5.53). Silver impregnation staining techniques may be needed to demonstrate elastin changes in animals. Solar dermatitis is often present without evidence of elastosis.

Solar keratoses, common *precancerous skin lesions* in humans, occur in cats, dogs and horses. The conjunctiva of horses with white eyelids is a common site. Histologically, the early lesions have many of the features of sunburn, including epidermal hyperplasia, spongiosis, acute dermal inflammation and focal necrotic keratinocytes. More chronic lesions show pronounced epidermal hyperplasia with *dysplasia*, ortho- and parakeratotic hyperkeratosis, perivascular mononuclear cell infiltrates and dermal scarring, but seldom develop significant solar elastosis, as typifies human solar keratoses. *Lesions frequently progress to invasive squamous cell carcinoma.* Solar keratoses may also develop cutaneous horns.

Photosensitization dermatitis

Photosensitization dermatitis occurs in animals when photodynamic or fluorescent pigments are deposited in sunlight exposed skin. Photodynamic pigments absorb ultraviolet light or visible light in the action spectrum and convert it to light of a longer wavelength, usually beyond the UVB range. The energy from the absorbed light leads to tissue injury by reacting directly with molecular oxygen, producing reactive oxygen intermediates such as superoxide anion, singlet oxygen and hydroxyl radical. Oxygen free radicals may also be formed indirectly, as the result of a calcium-dependent, protease-mediated activation of xanthine-oxidase in the skin. Release of reactive oxygen species initiates chain reactions which lead to mast cell degranulation and damage to cell membranes, nucleic acids, proteins and subcellular organelles, particularly lysosomes and mitochondria.

The photodynamic agent usually reaches the skin via the *systemic circulation*, although *percutaneous absorption* of some photodynamic agents can cause local contact photosensitization. The agent may originate externally or it may be an endogenous substance that has accumulated to an abnormal degree as a result of metabolic dysfunction. Sources include *plant pigments and drugs* or, in the case of metabolic dysfunction, the *by-products of hemoglobin metabolism or chlorophyll degradation products*. The three categories of photosensitization are classified according to the source of the agents.

- In *type I, or primary photosensitization*, the animal *ingests plants or drugs* containing photoreactive substances that are deposited in the skin. Most exogenous sources of photoreactive pigments are found in plants, and therefore foraging animals such as horses, sheep, cattle and goats are most frequently affected.
- In *type II photosensitization*, an inherent inability to properly metabolize heme pigments necessary for erythrocyte production leads to the build up of the photoreactive pigments, *hematoporphyrins*.
- An abnormal build up of *phylloerythrin*, a degradation product of chlorophyll, induces *type III photosensitization*. This is known also as *hepatogenous photosensitization* because it depends upon the failure of a damaged or immature liver to eliminate phylloerythrin. Type III photosensitization occurs most often in animals ingesting large amounts of green forage.
- A fourth group contains those examples of photosensitization for which the pathogenesis is presently undetermined.

The **gross lesions** are similar for all forms of photosensitization. They occur on those areas of the body most exposed to sunlight and which lack protective fleece, hair coat or skin pigmentation. In *cattle*, any area of light-colored skin is susceptible. This is best demonstrated in broken-colored animals such as Holsteins, in which the white skin is affected but the black is spared. The relatively hairless skin of the teats, udder, perineum and muzzle is also affected. The ventral surface of the tongue is frequently affected in cattle if constantly exposed during licking. In *sheep*, the susceptible sites are the ears, eyelids, face, muzzle and coronets, although the back may be affected in animals with an open fleece or which have been shorn closely. The udders and teats of dairy *goats* are predisposed. In *horses*, lesions are most common on the face, perineum, and distal extremities but may affect any white skin. Lesions in *pigs* are uncommon, and have a predilection for the ears, eyelids, udder, and back. Photosensitization is rare in *dogs* and *cats* and causative agents remain obscure.

The initial reaction in photosensitization is erythema, followed by edema, which is more prominent in sheep than in cattle. The very marked edema of the ears in sheep causes them to droop and swelling of the muzzle may cause dyspnea. The disease in sheep is appropriately known as "bighead" or geeldikkop, a South African term meaning "thick, yellow head;" the equivalent term in New Zealand is "facial eczema." The lesions are *intensely pruritic*, causing rubbing, scratching and kicking at affected parts. Vesicles or bullae may develop. There is marked exudation and extensive necrosis. Affected skin becomes dry and sloughs in desiccated sheets (Fig. 5.54). Necrosis is frequently seen on the upper surfaces of the ears

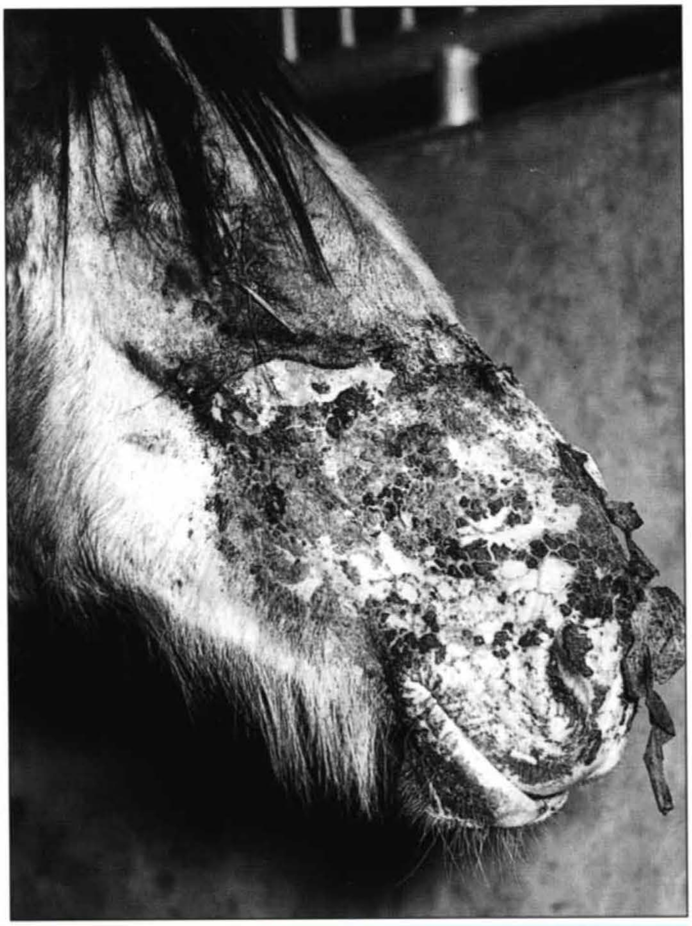

Figure 5.54 Photosensitization in a horse. Note necrosis and sloughing of skin from white areas of the face.

of sheep; the tips typically curl upwards as a result of mummification or may slough entirely. There is swelling of the eyelids and excessive lacrimation. Among the more obscure manifestations of photosensitization is the convulsive reaction of some sheep and cattle, photosensitized by ingestion of St. John's wort, on contact with cold water. *Icterus* typically is associated with hepatogenous photosensitization, but hepatogenous photosensitization may occur in its absence. Economic losses in livestock can be severe due to damaged hides, weight loss, fly-strikes, secondary infections, and reluctance of animals to let the young nurse damaged udders. In severe episodes of photosensitization, animals may die. This is more often the result of concomitant damage to other organs, particularly the liver, than to cutaneous damage alone. Injury to erythrocytes in cutaneous circulation may produce severe hemolysis.

Histologic lesions mirror the gross lesions with *coagulative necrosis of the epidermis* and possibly the follicular epithelium, adnexal glands, and superficial dermis. Subepidermal clefts or vesicles form and the *dermis is edematous*. Endothelial cells of the superficial, mid, and occasionally deep dermal vessels are often swollen or necrotic. Fibrinoid degeneration of vessel walls and thrombosis may be present. Initially, inflammation is sparse but soon the lesions are infiltrated by neutrophils. Secondary bacterial colonization is common.

Differential diagnosis should include other vesicular or necrotizing dermatopathies, including chemical or thermal burns. *Establishing the diagnosis is dependent upon anatomic distribution of lesions in nonpigmented, poorly haired, sun-exposed regions*. Lesions limited to areas of contact such as the extremities, ventrum or muzzle suggests the presence of a contact photosensitizing agent. Multiple affected animals in a herd suggest exposure to a photosensitizing agent rather than a photoallergic reaction. Types I, II, and III photosensitivities can be differentiated by signalment and concurrent clinical signs, such as evidence of liver disease combined with examination of pastures and feedstuffs, and investigating photodynamic drug or chemical exposure. The *Candida albicans* inhibition assay is a simple, inexpensive, quantitative, and relatively rapid assay for screening plants and feedstuffs for potential primary contact or systemic photosensitizers. The test does not detect all phototoxins. Thin-layer chromatography techniques may be useful in identifying phototoxic compounds. Analysis of suspect vegetation for the identification and quantification of fungal spores may be needed to establish fungal organisms and associated mycotoxins as contributing factors.

Primary photosensitization (type I photosensitization)

Plants are the most common cause of primary photosensitization; hence herbivores are most commonly affected. Additional sources include *mycotoxins, molds, chemicals and drugs. The majority of photosensitizing plants contain pigments belonging to either the helianthrone or furocoumarin family of pigments.*

The **helianthrones** include the red fluorescent pigments, *hypericin and fagopyrin*. Some of the most commonly implicated plants include St. John's wort (*Hypericum perforatum*) and buckwheat (*Fagopyrum* spp.), and the resulting diseases are referred to as *hypericism* and *fagopyrism*, respectively. Photosensitization induced by St. John's wort affects horses, cattle, sheep and goats. Hypericin is present at all stages of plant growth but significant amounts are consumed by livestock only when the plant is prolific or other feed is scarce. Other related plants that can lead to hypericism include goatweed, Tipton weed, amber, cammock, and Klamath weed. Photosensitization induced by buckwheat affects sheep, pigs, cattle, goats, and horses.

The **furocoumarin** family of pigments contains the photodynamic agents, *psoralens*. Photosensitization occurs in cattle, sheep, white chickens, and ducks as a result of ingestion of plants such as spring parsley (*Cymopterus watsonii*), bishop's weed *(Ammi majus)* and Dutchman's breeches *(Thamnosma texana)*. The furocoumarins differ from the helianthrone photosensitizing pigments by inducing, additionally, *corneal edema and keratoconjunctivitis*. Primary photodermatitis of pigs in Argentina occurred after consumption of feed contaminated with *Ammi majus* seeds containing the furocoumarin, xanthotoxin. Furocoumarins have also been documented to form *phytoallexins* in fungus-infected parsnips (*Pastinaca sativa*) and celery (*Apium graveolens*), leading to **phytophotocontact dermatitis**. *Psoralens adsorbed onto the skin react with UV light*. These have been associated with phytophotocontact dermatitis in pigs in New Zealand. Lesions were vesicular, affecting only the dorsal aspect of the snout. Rubbing the snouts and feet of white pigs with the leaves of the fungus-infected celery and parsnips before exposing the areas to UV light reproduced the lesions. *Cymopterus watsoni* causes phytophotodermatitis in sheep in Utah and Nevada. Lesions principally affected the non-wooled areas, such as the muzzle, lips and udder. High lamb mortality may be incurred from mismothering. Contact photodermatitis suspected to be caused by giant hogweed (*Heracleum* *mantegazzianum*) occurred in dogs. Giant hogweed contains psoralens and has been documented to cause photodermatitis in man, ducks, and goats.

Texas cattle and deer develop primary photosensitization after consuming moldy leaves of *Cooperia pedunculata*. In addition to skin lesions, keratitis occurs frequently and may lead to blindness.

Ingestion of alsike clover (*Trifolium hybridum*), also known as red clover hay, results in a primary photodermatitis referred to as *trifoliosis* in cattle, sheep, hogs, and some horses. Trifoliosis has been reported in the USA, Canada, Australia, and England. A second syndrome, referred to as *alsike clover poisoning*, is characterized by hepatic dysfunction and photodermatitis and has only been reported in the horse. The toxic mechanism is not known but is thought to be due to a toxin within the plant itself or to the presence of a mycotoxin. The variable presentations are speculated to be related to seasonal changes, stage of plant growth, soil and environmental conditions.

A condition clinically and histologically compatible with a primary photodermatitis occurred in 12 of 30 Harrier Hounds in a kennel in New Zealand. Lesions were limited to the nonpigmented, sun-exposed skin of the tri-colored hounds and resolved within a short period of time with supportive care. The hounds were fed a diet of horse and cattle meat. Although an ingested compound was suspected as the cause, no phototoxin could be identified. Similar cases have been reported in Foxhounds in England and Border Collie dogs in New Zealand.

Phenothiazine photosensitization is characterized by typical cutaneous lesions and in ruminants by the additional lesions of corneal edema and keratoconjunctivitis. The secretion of the ruminal metabolite, phenothiazine sulfoxide, in tears and aqueous humor, has explained the unusual location of the lesions. Phenothiazine photosensitization occurs most commonly in *calves* but also in *sheep, swine, and birds*. Pigs develop cutaneous lesions more frequently than sheep or cattle, probably because the activating radiation is more able to penetrate the integument. The greater susceptibility of calves has been ascribed to a relatively inefficient conversion of the photodynamic sulfoxide metabolite back to phenothiazine in the liver. This conversion depends on effective mixed-function oxidase enzyme activity in the liver.

Photosensitization due to defective pigment synthesis (type II photosensitization)

Photosensitization due to *endogenous pigment accumulation* is the result of a congenital enzyme deficiency causing abnormal heme synthesis with the resultant blood and tissue accumulation of photodynamic agents such as *uroporphyrin I, coproporphyrin I and protoporphyrin III*.

Bovine congenital hematopoietic porphyria *is the result of a deficiency in uroporphyrinogen III cosynthetase*, a key enzyme in heme biosynthesis. The condition is inherited as a simple recessive trait affecting many breeds including Shorthorn, Ayrshire, Holstein and Jamaican cattle. It has also been reported in crossbred cattle. The disease is known as "osteohemochromatosis" and "pink tooth," both suggested by the *red-brown coloration of porphyrin pigments in dentin and bone*. The pigment is also deposited in other tissues but the discoloration may be obvious only in lungs, spleen, and kidney in which it is deposited in the interstitial tissue and tubular epithelium. The pigments are *excreted in the urine*; hence the alternative names "porphyrinuria" and "hematoporphyrinuria." Affected urine is amber to brown, darkens on exposure to light, and fluoresces bright red on exposure to ultraviolet radiation. *Affected teeth and bones also fluoresce.* The anemia of bovine congenital erythropoietic porphyria is discussed in Vol. 3, Hematopoietic system.

The cutaneous lesions result from the photodynamic properties of the accumulated porphyrins, in particular the *uroporphyrins* that absorb UVA radiation. Reactive oxygen species directly induced by the porphyrins or, possibly, via activation of xanthine oxidase in the skin are responsible for the cell membrane damage. The gross cutaneous lesions are typical of photosensitization. The microscopic lesions closely resemble those of erythropoietic porphyrias in man. The chief lesions are subepidermal clefts, hyalinization of dermal capillary walls, and a minimal infiltrate of inflammatory cells. The basement membrane zone lines the base of the subepidermal cleft, in some instances covering small projections of dermal papillae (festoons). Festoons are a more prominent feature of the human lesion since dermal papillae are better developed in human skin.

Bovine erythropoietic protoporphyria is inherited as a *recessive trait in Limousin cattle* in the United States. It differs from bovine congenital porphyria in that photodermatitis is the sole clinical manifestation of the disease. Animals do not have discolored teeth, anemia or urine porphyrin excretion. The enzyme defect is a *deficiency of ferrochelatase*, which allows protoporphyrin IX to accumulate in blood and tissues. Heterozygotes have reduced (50%) ferrochelatase activity and are clinically normal.

Porphyria of **swine** is inherited as a *dominant characteristic.* Although it mimics certain aspects of bovine erythropoietic porphyria, *photosensitization does not occur*, even in white-skinned animals. The defect in porcine porphyria is not known.

Photosensitization occurs in Siamese **cats** with excessive accumulation of uroporphyrinogen I, coproporphyrinogen I and protoporphyrins in blood, urine, feces and tissues. The defect is presumably a *deficiency of uroporphyrinogen cosynthetase III*, as has been established in humans and cattle.

Hepatogenous photosensitization (type III photosensitization)

The most common form of photosensitization in domestic animals occurs in conjunction with primary hepatocellular damage or, less commonly, bile duct obstruction and is due to impaired capacity of the liver to excrete the potent photodynamic agent, **phylloerythrin**. Phylloerythrin is a chlorophyll catabolite formed by microbial action in the intestinal tract and transported to the liver via the portal circulation. Hepatocytes assimilate the phylloerythrin and excrete it into the bile. One of the earliest signs of liver cell damage is a reduced ability to transport and excrete phylloerythrin. Mild renal tubular damage caused by some toxins may further inhibit the excretion of phylloerythrin. The circulating phylloerythrin accumulates in tissues including the skin. *Photodermatitis occurs provided the animal is on a chlorophyll-rich diet and is exposed to sufficient solar radiation of the appropriate wavelength.* High ambient solar radiation and lack of shade are contributing factors. Photosensitization tends to occur most often when the hepatic damage is generalized, even if mild. Severe focal necrotizing lesions of the liver generally do not cause photosensitization because there is enough hepatic reserve to remove the phylloerythrin from the circulation. The cause of hepatic damage may be a plant toxin, mycotoxin, infectious agent, or chemical.

Toxic plants and mycotoxins account for most cases of hepatogenous photosensitization. A few of the many plants implicated in hepatotoxic photosensitization include lantana (*Lantana camara*), bog asphodel (*Narthecium ossifragum*), *Tribulus terrestris*, *Agave lecheguilla*, *Nolina texana*, *Cymadothea trifolii*-infested clover, *Trifolium hybridum* ("alsike clover poisoning"), and *Panicum* spp. grasses such as kleingrass (*Panicum coloratum*). Kleingrass is a perennial grass forage crop with a toxic principle suspected to be a saponin. Cases of kleingrass induced-photosensitization are sporadic, potentially related to environmental conditions and have been reported in Australia, Africa, and Texas. Some plants work in combination; black sagebrush appears to precondition sheep to photosensitization caused ultimately by *Tetradymia* spp.

A number of reports of hepatogenous photosensitization in livestock cite a variety of common forage crops such as alfalfa hay or silage, winter wheat, Bermuda grass pasture, crab grass, oat stubble, or various clover pastures. In the majority of cases, the toxicity was preceded by unusual climatic conditions of drought, increased rainfall, or temperature variations. In many cases, a specific toxic compound cannot be identified. A plausible explanation is the establishment of optimum conditions for the production of mycotoxins, hepatotoxins or photodynamic agents in the damaged plant material.

Forages containing the mycotoxin, *sporidesmin*, from spores of *Pithomyces chartarum* cause **facial eczema**, an economically important hepatogenous photosensitization of sheep and cattle in Australia, New Zealand, South Africa, and the northwestern United States. *Geeldikkop*, a disease characterized by hepatogenous photosensitization, is associated with extensive losses among sheep and goats in South Africa. A hepatogenous photosensitization, secondary to a presumed genetic defect in phylloerythrin transport, has been reported in Corriedale lambs. Hepatogenous photosensitization is discussed in more detail in Vol. 2, Liver and biliary system.

Photoaggravated dermatoses

In humans, several autoimmune dermatoses are exacerbated by exposure to UV light. These include pemphigus, lupus erythematosus, and bullous pemphigoid. A similar relationship has been proposed in the analogous canine diseases.

A poorly understood disease in the *horse*, **photoactivated vasculitis** affects only the white-haired extremities. The pathogenesis is not currently known. An immune-mediated vasculitis, in which immune complexes may be acting as photodynamic agents has been proposed. Percutaneous absorption of initiating agents has not been ruled out. Affected horses have normal liver function and no known exposure to photosensitizing compounds. In addition, lesions may be restricted to one white extremity, other white areas on the horse are unaffected and the lesions do not always regress with cessation of exposure to sunlight, all indicating the lesions are *not a form of photosensitization*. The lesions often affect the heels and must be differentiated from the other manifestations of the "greasy heel" complex. The acute lesions are well demarcated, erythematous, oozing and crusted; erosion and ulceration may occur and the affected limb may be edematous and painful. The chronic lesions are hyperkeratotic plaques. Histologically, there is intense dermal edema, vascular dilation and subtle small vessel leukocytoclastic vasculitis, affecting only the superficial plexus. Thrombi may be seen occasionally. The epidermis may be eroded or ulcerated but undergoes papillary hyperplasia over time.

NUTRITIONAL DISEASES OF SKIN

The elasticity of the skin, the orderly maturation of the epidermis and the quality and luster of the horny appendages are an indication of the state of the health of the animal as a whole. This applies equally to nutritional diseases and to diseases of other causes. Many systemic diseases result in cutaneous changes. The general metabolic transformations that take place in the skin are not qualitatively different from those in other tissues but there are some quantitative differences, such as the high requirements and turnover of sulfur-containing amino acids in the elaboration of keratin. *In most metabolic disturbances and deficiencies of essential nutrients, whether from dietary lack, malabsorption, the action of antimetabolites, or the body's inability to properly absorb or utilize nutrients, changes will be reflected in the skin*. The molecular basis for these skin lesions is, however, poorly understood. There are only a few syndromes that occur naturally and are sufficiently clearly defined to warrant discussion here. A larger number can be produced experimentally. Cutaneous manifestations of systemic disease not known to be a result of a nutritional derangement are discussed in other, more appropriate sections of this chapter such as Endocrine diseases of skin and Cutaneous paraneoplastic syndromes.

Protein–calorie deficiency

Starvation or protein–calorie malnutrition results in changes in the skin, the first being the *disappearance of subcutaneous fat*. Even though water intake may not be restricted, there is reduced hydration of the connective tissues of the subcutis and dermis, and the skin wrinkles and loses its elasticity. As hair is 95% protein, *hair growth and keratinization can require up to 25–30% of an animal's daily protein requirement*. Protein deficiencies are rare but can occur in cats fed primarily food formulated for dogs, in young dogs fed a low-protein diet, or in animals with increased nutrient requirements.

An early sign of starvation is the development of a *dull, dry and often brittle hair coat*. Hypotrichosis develops as a thinning of the hair rather than baldness, and seasonal shedding may cease or be prolonged. Lesions may be symmetrical on the head and trunk and spread to the limbs. The skin may atrophy, or hyperkeratosis, hyperpigmentation, and possibly loss of hair pigmentation develop. In pigs, the skin often becomes hyperkeratotic and assumes a dirty, dry appearance and the hair becomes long and shaggy. The skin of a malnourished animal has an increased susceptibility to bacterial infection and parasitic infestations and their effects. Under-nutrition of the pregnant ewe, between 115–135 days of gestation, decreases the number of secondary wool follicles in the developing fetus. Most experimental work on the effects of nutrition on hair growth have been performed in sheep, the purpose being either to improve wool production or to investigate chemical methods of shearing. Changing sheep from a low-protein to a high-protein diet led to a 33% increase in fleece production, due mostly to an increase in the rate of mitosis in the hair bulb. Specific amino acid deficiencies have been investigated as potential replacements for mechanical shearing as wool production is highly dependant upon levels of certain amino acids, specifically cysteine.

The effects of starvation on other organs such as liver, pancreas, bone, and bone marrow are discussed elsewhere.

Fatty acid deficiency

Fatty acid deficiency may occur in all domestic species in association with general dietary deficiency, malabsorption or liver disease. Deficiencies may be evident in animals when the fat has either leached from a diet, has become rancid from improper or prolonged storage, or when the diet was formulated with low fat content to save cost. Animals on specially formulated low-fat diets for therapeutic reasons may develop signs of fatty acid deficiency and require specific types of supplementation. Animals on antioxidant-deficient diets may also develop signs of fatty acid deficiency. Cutaneous lesions take months to develop and begin with *diffuse scaling, loss of haircoat sheen, and alopecia*. The scaliness is initially dry but over months progresses to an oily, often pruritic stage. Otitis externa may be an accompanying lesion and the skin is susceptible to secondary bacterial and yeast infection. Histologic lesions include *epidermal hyperplasia, orthokeratotic or parakeratotic hyperkeratosis and hypergranulosis*. The pathologic mechanisms underlying the epidermal hyperproliferation are not well understood. Experimental studies demonstrated an increase in epidermal DNA synthesis and a decrease in prostaglandin E and F levels in the skin of essential fatty acid-deficient mice. The lower prostaglandin levels likely reflect a lack of precursor arachidonic acid. Deficiency of prostaglandin E_2 could influence epidermal cell kinetics through its effect on ratios of cyclic AMP to GMP. Supplementation of animal diets with balanced omega-6 and omega-3 fatty acids is thought to modulate arachidonic acid metabolism and subsequent production of leukotrienes and prostaglandins that in turn may influence epidermal turnover kinetics and the inflammatory response.

A seborrheic dermatosis in **cats** characterized by dry scaly skin and alopecia is responsive to fatty acid supplementation but is not likely to be the result of a true deficiency. Experimental essential fatty acid deprivation in cats produces dry, scaly coats. Diets containing linoleic acid and linolenic acids as the sole source of essential fatty acids also induce a seborrheic dermatosis. Cats are obligate carnivores, as they lack delta-6-desaturase, the enzyme responsible for converting these 18-carbon fatty acids to longer chain fatty acids. Arachidonic acid is an essential fatty acid for the cat.

Hypovitaminoses and vitamin-responsive dermatoses

Cutaneous lesions may occur as manifestations of deficiencies of *vitamins A, C, and E, riboflavin, pantothenic acid, biotin, and niacin.* Most of these are described in experimentally induced deficiencies. Many of the naturally occurring hypovitaminoses are probably not the result of a single vitamin deficiency but represent the cumulative effect of several inadequacies of the diet.

Vitamin A deficiency

Vitamin A is a fat-soluble vitamin belonging to a group of compounds referred to as *retinoids.*Vitamin A is involved in cellular growth and differentiation, as well as in visual processes and reproduction. Vitamin A has a controlling effect on epithelial differentiation. *Cutaneous lesions of vitamin A deficiency are squamous epithelial hyperkeratosis and squamous metaplasia of secretory epithelia.*Vitamin A oversupplementation is teratogenic and can lead to toxicity if liver storage capacity is exceeded. Signs are manifest primarily in the skeletal system and liver, or as malformations of the fetus in pregnant animals.

Hypovitaminosis A has been reported in all species of domestic animals, although many accounts are anecdotal. It may be secondary to dietary deficiency, decreased intestinal absorption, liver disease or toxicities such as chlorinated naphthalene toxicity of cattle. Bile and pancreatic enzymes are needed for dietary absorption of vitamin A. The cutaneous lesions of hypovitaminosis A in *cattle* are a marked scaling and crusting dermatitis; in the *pig*, follicular hyperkeratosis; and, in *cats*, scaling, follicular plugging and alopecia. A report in the *dog* indicated thickened, hyperpigmented skin with alopecia and follicular hyperkeratosis.

Vitamin A-responsive dermatoses occur in **dogs** and almost exclusively in the Cocker Spaniel. In one syndrome, Cocker Spaniels are predisposed, probably because of a congenital abnormality of epidermopoiesis and keratinization (see Seborrhea). The lesions include hyperkeratotic plaques, follicular plugging and the formation of keratin fronds. Ventral and lateral chest and abdomen are sites of predilection. There may be accompanying otitis externa and pyoderma. Histologically, *the predominant lesion is marked follicular keratosis* (Fig. 5.55). Vertically oriented keratin casts protrude from the follicular ostia. There is mild to moderate epidermal hyperplasia and surface hyperkeratosis of the basket weave type. Dermal inflammation is mild, mononuclear and perivascular, unless secondary bacterial infection intervenes to produce neutrophilic folliculitis and/or furunculosis. There are rare reports of vitamin A-responsive dermatoses in other breeds of dogs. These diseases are not vitamin A deficiencies per se, in that plasma levels of vitamin A are within the normal range. The fact that therapy is effective can be attributed more to the "normalizing" effect of vitamin A (and retinoids) on cellular differentiation in the epidermis. Differentials include primary or secondary seborrhea and late-stage sebaceous adenitis. Oral supplementation with vitamin A may be needed to confirm the diagnosis.

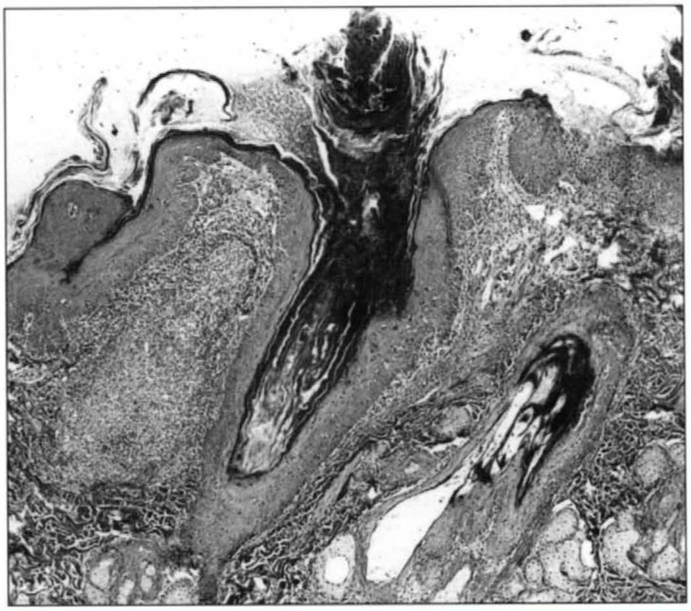

Figure 5.55 Vitamin A-responsive dermatosis. Note the marked follicular hyperkeratosis. (Courtesy of Parker WM, Hardy MH, and J Am Anim Hosp Assoc.)

Vitamin B deficiencies

The **B-vitamin complex** is essential to the maintenance and proper functioning of many important metabolic pathways. B vitamins are water soluble and not stored within the body, necessitating a constant dietary supply. These vitamins interact with each other, with vitamin C, and with fat-soluble vitamins. Single deficiencies of these vitamins are rare. *Deficiencies result in dry, flaky seborrhea with alopecia, anorexia, and weight loss.*

Riboflavin (vitamin B2) deficiency is mostly a problem in *swine and chickens* fed grain rations with borderline concentrations of the vitamin. Ruminants do not become deficient because of rumen synthesis of the B-complex vitamins. Young calves, however, may develop deficiency if deprived of milk or an appropriate replacer. Animals develop hyperemia around the lips, nose and buccal mucosa, diarrhea, weight loss and generalized alopecia. Cutaneous lesions described in hyporiboflavinosis include scaling and ulcerative dermatitis in the pig, erythema, scaling and dry hair coat on the ventral abdomen and hindlegs in the dog, and alopecia in the cat.

Pantothenic acid is a component of coenzyme A, an essential factor for entrance of acetic acid into the Krebs' cycle. Deficiency is documented in *pigs*, but may occur in dogs and calves. Pantothenic acid deficiency in pigs produces progressive alopecia with dermatitis and ulceration, in addition to the general effects of weight loss, diarrhea and neurologic signs. Young pre-ruminant calves may show dermatologic signs that include alopecia, a roughened coat and dermatitis. Leukotrichia has been described in dogs.

Biotin deficiency rarely occurs spontaneously, except in intensively reared *swine*, as the vitamin is widely distributed in feeds. Biotin is essential for proper utilization of fats, glucose, and amino acids. Feeding raw egg whites that contain avidin, a substance that renders biotin unavailable, may induce deficiencies. Cutaneous lesions reported in biotin-deficient pigs include *alopecia, pustular dermatitis and cracked hooves*, causing lameness and significant economic loss. Microscopic lesions include epidermal hyperplasia, orthokeratotic and parakeratotic hyperkeratosis, epidermal necrosis and pustules, and folliculitis. A deficiency attributed, in part, to a lack of vitamin B, probably biotin, was reported in *lambs* reared artificially on reconstituted cow's milk. Alopecia was largely due to a fleece in which individual fibers were thin, weak and straight. Histologically and ultrastructurally, the wool fibers had reduced numbers of cortical cells. Histochemical stains showed a delay in the incorporation and oxidation of sulfhydryl groups. Supplementation with B-group vitamins partially restored the fleece. Biotin deficiency reportedly causes a dry, brittle, hair coat, scaling and leukotrichia in *dogs*. Dogs deficient in biotin may develop periocular and facial alopecia resembling the clinical lesions of systemic lupus erythematosus, discoid lupus, or other dermatoses affecting the face.

Niacin is a component of the pyridine nucleotides NAD+ and NADP+ needed for the function of a number of enzymes involved in nutrient metabolism. Deficiency occurs spontaneously in animals fed diets low in pyridoxine (vitamin B6) and tryptophan as all of these components are needed for pyridine nucleotide synthesis. *Pigs* fed a low animal protein diet that is also high in corn renders niacin unavailable to the animal due to low tryptophan levels. Cutaneous lesions include alopecia and a crusting dermatitis. Niacin deficiency in *dogs* induces reddening and ulceration of the oral mucous membranes, resembling human hyponiacinosis, known as "*pellagra*." Reports of canine cases from the first quarter of the 20th century indicate severe necrotizing glossitis and stomatitis leading to the term "*black tongue*."

Pyridoxine (vitamin B_6) serves as coenzyme in amino acid and protein metabolism. Deficiency produced experimentally in *cats* resulted in a dull, unkempt coat with scaliness and alopecia of the head and extremities. Histologically, hair follicles were in telogen and there was epidermal and follicular hyperkeratosis. Since pyridoxine may be indirectly involved in zinc transport, through its effect on tryptophan metabolism, these effects might be due to alteration in the levels of zinc. Isoniazid has been reported to inactivate pyridoxine.

Vitamin C deficiency

Vitamin C (ascorbic acid) is required for the proper synthesis and structural maintenance of collagen and as a component of a number of essential enzymes. Almost all mammals synthesize vitamin C with the exception of humans, nonhuman primates, guinea pigs, Indian fruit bats, and Indian pipistrels. Insects, invertebrates, and fish also cannot synthesize vitamin C. *Deficiencies (scurvy or scorbutus) are limited to these species of animals*, and signs are related to the inability of fibroblasts to form collagen or osteoid and are discussed in Vol. 1, Bones and joints.

Vitamin E deficiency

Vitamin E deficiency is discussed primarily in Vol. 1, Bones and joints and Vol. 2, Liver and biliary system. Steatitis or "*yellow-fat disease*" involves subcutaneous fat and may be seen clinically as a skin disease. The yellowness of the fat is due to the *deposition of ceroid*. Vitamin E acts as an antioxidant to prevent lipid peroxidation. Dietary requirements vary by species and individual and with the other components of the diet. Naturally occurring vitamin E deficiency has not been reported in the dog.

Nutritional panniculitis occurs in *cats, mink, foals and swine*. The disease is associated with the feeding of *fishmeal, fish offal or other products with a high concentration of unsaturated fatty acids*. Diets with a high content of oily fish such as tuna, white fish and sardines are most often implicated, however, the condition in cats also has been associated with diets containing primarily liver, diets with only a small fish content, or improperly stored or outdated commercial cat food. The practice of feeding high-fish diets to cats is reported to be common in Greece. Destruction of vitamin E also occurs in food that, through improper processing or storage, becomes rancid. The disease is not, however, the result of a simple deficiency, since cats fed diets deficient in vitamin E but also lacking in unsaturated fatty acids, do not develop panniculitis. In *mink and foals*, it may be associated with degeneration of muscles, and in *swine* it may occur alone or be associated with any one or combination of ulceration of the squamous mucosa of the stomach, muscle degeneration, and hepatosis dietetica. The disease has variable mortality in *cats* after a short clinical course in which there is progressive depression, possible fever, hyperesthesia, reluctance to move, palpable thickening and increased firmness of the subcutaneous fat, easiest to detect in the inguinal region. The changes are not confined to the subcutaneous tissues but affect all fat depots. Biopsy reveals fat that varies from gray to lemon yellow to orange and is indurated and sometimes edematous. Hematological changes may include neutrophilic leukocytosis and anemia.

The initial histologic change is deposition of globules of ceroid in the interstitial tissue. This, together with a fishy odor, may be all that is observed in swine in which the fat is soft and gray rather than yellow. In most affected cats, *fat necrosis stimulates inflammation, which is initially neutrophilic but becomes granulomatous*. Numerous macrophages, and occasionally giant cells, ingest the ceroid pigment. Mineralization may be present. Ceroid may be found also in macrophages of the liver, spleen and lymph nodes. In cats, the initial differential should include infectious steatitis, sterile nodular panniculitis, lupus panniculitis, or other noncutaneous diseases such as feline infectious peritonitis, ascites of various causes, and other causes of hyperesthesia. *The clinical signs and the demonstration of ceroid, a variant of lipofuscin, which is acid fast and autofluorescent, should establish the diagnosis*.

Vitamin E-responsive dermatosis has been described in **goats**. Kids and adults, on a selenium-deficient diet, developed periorbital alopecia and generalized seborrhea. The haircoat was dull and brittle. Histologically, the lesions were orthokeratotic hyperkeratosis and mild superficial perivascular dermatitis, in which mononuclear cells predominated.

In **dogs**, a variety of conditions including dermatomyositis, acanthosis nigricans, demodicosis, and discoid lupus erythematosus are variably responsive to topical or systemic vitamin E therapy. Improvement in condition is thought to be due to the antioxidant properties of vitamin E leading to the stabilization of cell membranes and modulation of the inflammatory response through arachidonic acid and prostaglandin metabolism and actions on leukocytes.

Alopecia in **calves** associated with the feeding of milk substitute was attributed, in part, to vitamin E deficiency. The calves had low levels of serum vitamin E and the hair regrew after vitamin E therapy was initiated for concurrent nutritional myopathy.

Mineral deficiency and mineral-responsive dermatoses

Iodine, cobalt, copper, and zinc deficiencies may lead to integumentary lesions. Iodine deficiency is discussed in Vol. 3, Endocrine glands. The effects of copper deficiency on wool and hair are referred to under Disorders of pigmentation. Cobalt deficiency causes a progressive, wasting disease in ruminants. There are nonspecific changes in the wool or hair coat including lack of growth and increased fragility.

Zinc deficiency

Zinc is an essential trace element. Zinc is a component of many important metalloenzymes and is a cofactor for many others. It exerts its primary effect through zinc-dependent enzymes that regulate RNA and DNA metabolism. Zinc thus plays a role in all metabolic processes involved with tissue growth, maturation and repair, and is involved in vitamin A metabolism and in enzymes needed for free radical scavenging. Zinc also modulates many aspects of the immune and inflammatory responses. The relationship between the changes in particular tissue enzyme activities brought about by zinc deficiency and clinical manifestations of the deficiency syndrome are not, however, well understood. In the integument, a substantial proportion of zinc is in the wool or the hair coat. Naturally occurring true zinc deficiency is extremely rare in cats, and not reported in horses, or dogs. On the other hand, zinc-responsive dermatoses are described in the dog in the following sections.

Zinc deficiency causes anorexia, alterations in food utilization, growth retardation, reproductive disorders, depression of the immune response, hematologic abnormalities, depression of central nervous system development, decreased wound healing, and keratinization defects in epidermis, hair, wool, and horny appendages. True zinc deficiency is of most significance in the pig.

Parakeratosis in swine

Zinc-responsive dermatosis in swine (parakeratosis) became an important clinical entity in the 1950s, coincident with and related to the widespread introduction of dry meal feeding. *The cause is not a simple deficiency.* The availability of dietary zinc is adversely affected by the presence of phytic acid in plant protein rations, a high concentration of calcium, a low concentration of free fatty acids, alterations in intestinal flora, and the presence of bacterial and viral enteric pathogens such as transmissible gastroenteritis virus. Zinc deficiency may induce secondary vitamin A deficiency as a result of its effect on appetite and food utilization. Economic losses are due to depression of growth rate, but, with improved management techniques, *parakeratosis is no longer a major problem.* Parakeratosis occurs in young, growing pigs, 2–4 months of age. The initial gross lesions are erythematous macules on the ventral abdomen and medial surface of the thigh. The lesions develop into papules, which become covered with a gray-brown, dry, roughened scale-crust that may reach 5–7 mm in thickness. Deep fissures penetrate the crust and are filled with brown-black detritus, which is composed of sebum, sweat, soil and other debris. These areas are susceptible to secondary bacterial infection, often leading to pyoderma or subcutaneous abscessation. *Lesions are roughly symmetrical and have a predilection for the lower limbs, particularly over the joints, around the eyes, ears, snout, scrotum and tail.* In severely affected animals, lesions may become generalized. Pruritus is not a feature of parakeratosis. The dorsal surface of the tongue is "furred" and the esophageal mucosa loses its normal smooth sheen and becomes dull and white.

The microscopic lesion in the skin is marked hyperplastic dermatitis with diffuse parakeratotic hyperkeratosis (Fig. 5.56A, B). The oral mucous membranes also demonstrate hyperplastic epithelium. Acanthosis, elongation of rete ridges, and mitotic figures in the basal keratinocytes are regular features of the hyperplastic response of the epidermis. The dermal lesions in uncomplicated parakeratosis include variable vasodilation and a mild to moderate, predominantly mononuclear cell, perivascular infiltrate. With bacterial infection, there may be nodular or diffuse neutrophilic dermatitis, folliculitis, perifolliculitis or furunculosis.

Parakeratosis in swine must be differentiated grossly from sarcoptic mange and exudative epidermitis. The former is usually intensely pruritic, and the latter usually occurs in a younger age group and the scale-crust is greasy rather than dry. Parakeratosis is rarely fatal unless toxemia or septicemia secondary to cutaneous bacterial infection develops or because of exacerbation of intercurrent infections such as pneumonia. Affected pigs recover rapidly upon zinc supplementation.

Zinc deficiency in ruminants

The clinical signs and gross lesions of zinc deficiency in ruminants are similar to those described in pigs. Hyperkeratosis also affects the forestomachs. Naturally occurring zinc-deficiency dermatoses are uncommon in **cattle**, but have been reported, for example, in grazing cattle from Guyana and housed dairy cows in Finland. The

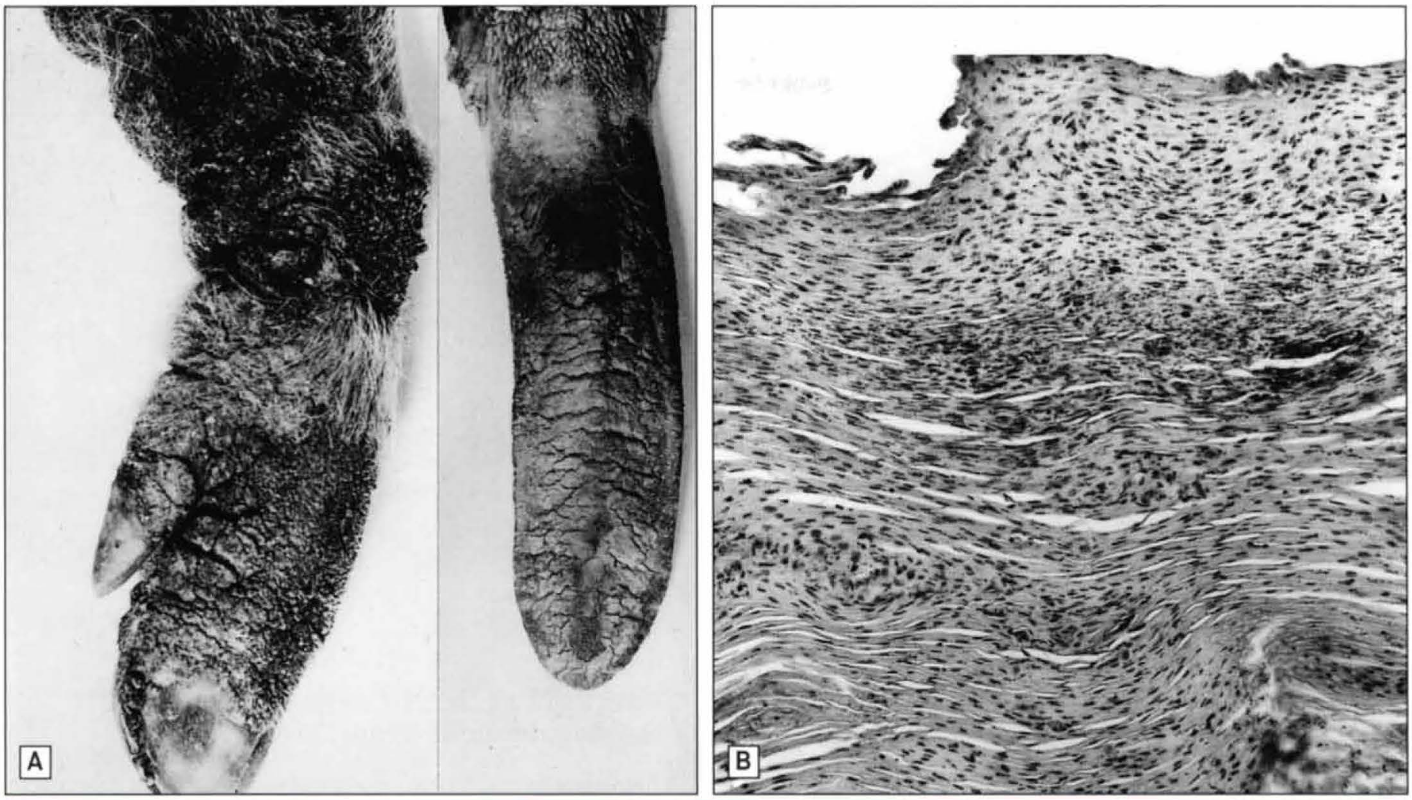

Figure 5.56 Zinc-responsive dermatosis in a pig. **A.** Marked hyperkeratosis of the skin of the foreleg and tongue epithelium. **B.** Marked parakeratotic hyperkeratosis.

hereditary zinc deficiencies of cattle are discussed under Congenital and hereditary diseases of skin.

In **sheep** with naturally occurring deficiency, histologically the hyperkeratosis is predominantly of the orthokeratotic rather than the parakeratotic type. Sheep also have thin, easily epilated, red-brown stained wool and loss of fleece. Wool eating and drooling are prominent clinical signs. Crusting and scaling lesions develop around the eyes, nose, hooves, and scrotum and on pressure points. The normal ringed structure of the horns is lost and the horns are shed. Abnormal growth of the hooves may lead to soreness and the adoption of a kyphotic stance.

Zinc-responsive dermatoses in **goats** are reported from the USA, Europe and Australia, sometimes associated with depressed reproductive efficiency. Experimental zinc deficiency of goats produces the typical weight loss, alopecia and parakeratotic scaling dermatosis described in other ruminant species.

Canine zinc-responsive dermatoses

Naturally occurring zinc-responsive dermatoses in the dog fall under two syndromes:

- **Syndrome 1** *affects primarily Siberian Huskies and Alaskan Malamutes*, and rarely other breeds not of Arctic origin, such as Great Danes. The cutaneous lesions usually become manifest before the dogs are 1 yr of age. Older dogs may develop lesions during times of stress such as pregnancy, lactation or intercurrent disease. Lesions comprise *scaling and crusting dermatitis* with a predilection for the face, particularly around the eyes, lips and nose, pressure points and footpads (Fig. 5.57A). Lesions may be unilateral initially and progress to a bilateral distribution. Pruritus may be present. Secondary pyoderma is not uncommon. *The pathogenesis of the syndrome is not well established.* Alaskan Malamutes with chondrodysplasia have zinc-responsive spermatozoal defects and reduced zinc absorption from the intestinal tract; possibly malabsorption is responsible for the dermatological disease. Lifetime supplementation of zinc is necessary to alleviate signs.
- **Syndrome 2** *occurs in puppies of any breed and is associated with a relative deficiency of zinc, probably secondary to excessively high levels of calcium and/or phytates in the diet in rapidly growing animals.* In the USA, this disease has been associated with the feeding of *generic dog food*, in Britain and Sweden with the feeding of soy- and/or cereal-based diets. Recovery quickly follows restoration of a diet meeting the National Research Council standards for canine nutrition or zinc supplementation of cereal diets. Now that dog food manufacturers are aware of the problem, *the disease is less common.* The gross

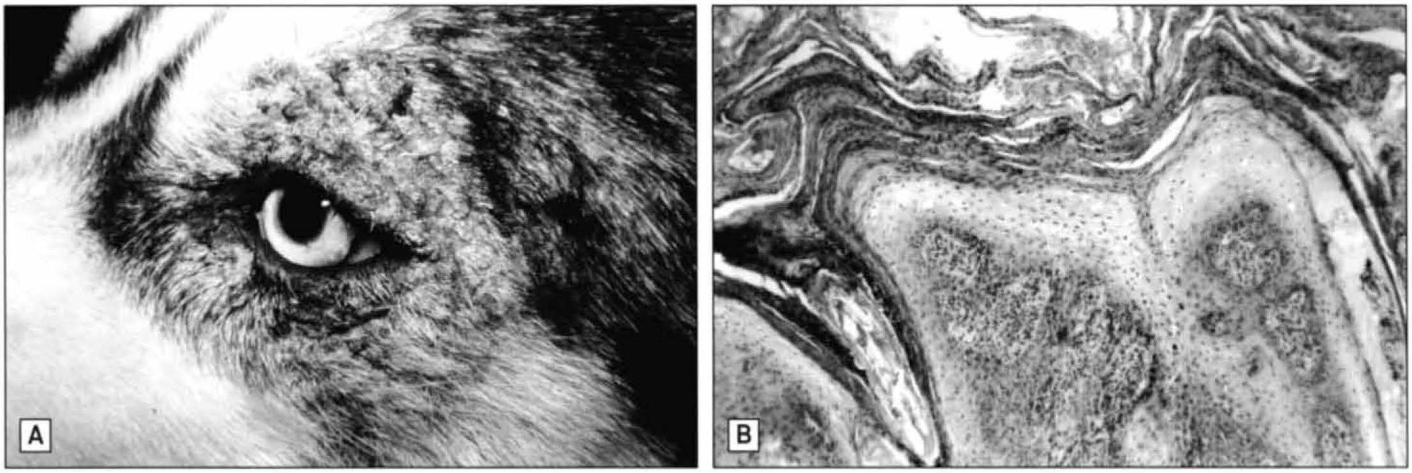

Figure 5.57 Zinc-responsive dermatitis in a dog. **A.** Scaling and crusting dermatitis of the face. (Courtesy of B Dunstan.) **B.** Papillary epidermal hyperplasia, marked epidermal edema and parakeratotic hyperkeratosis affecting the epithelium of the skin surface and follicular ostia.

lesions are multiple, scaling and crusted plaques, particularly affecting the muzzle, pressure points, distal extremities and trunk. There is extreme thickening and fissuring of the footpads and, sometimes, the planum nasale. Secondary pyoderma may develop and puppies often show a local lymphadenopathy.

The histologic lesions of both syndromes are usually typical of zinc deficiency, with papillary epidermal hyperplasia, marked spongiotic parakeratotic hyperkeratosis affecting the epithelium of the skin surface and follicular ostia, and multifocal neutrophilic crusts (Fig. 5.57B). Mild to moderate superficial perivascular mononuclear or eosinophil-rich dermatitis is present. Some reports indicate that the keratinization defect was sufficiently severe to induce dyskeratotic changes at all levels of the epidermis, while in others orthokeratotic hyperkeratosis alone was found.

Differential diagnoses include superficial necrolytic dermatitis, thallium toxicity and chronic hypersensitivity dermatitis that may look very similar histologically. Dermatophytosis, demodicosis, and pyoderma should be considered based upon gross lesions. *The signalment, history, lesion distribution, and pathologic changes should help to establish the diagnosis.* In some cases, response to dietary changes and/or zinc supplementation may be needed for confirmation of the suspected diagnosis. Serum and plasma zinc levels are not an accurate method of assessing zinc status. Values, even in a normal animal, are subject to marked variation according to sex, age, stress, concurrent disease, and collection methods. It is possible that dietary factors other than zinc are involved in some of these diseases, particularly those responding to dietary changes and not just to zinc supplementation.

Superficial necrolytic dermatitis (hepatocutaneous syndrome)

A histologically distinct cutaneous reaction pattern characterized by the so called "red, white, and blue" *epidermal changes of parakeratosis, epidermal necrolysis or laminar intra-epidermal edema, and basilar hyperplasia* has been recognized most often in the *dog*, and occasionally in the *cat*. The condition resembles necrolytic migratory erythema, a human paraneoplastic syndrome most often associated with alpha cell neoplasms of the pancreas. *The pathogenesis of superficial necrolytic dermatitis (SND) is unknown, but hepatic dysfunction and derangement of glucose and amino acid metabolism are clearly involved.* Elevated glucagon levels alone are unlikely to be directly responsible for the skin lesions, as both dogs and humans may develop the disease in their absence and dermatitis is not an inevitable result of the hyperglucagonemic state. Hypoaminoacidemia, due to sustained gluconeogenesis and increased hepatic catabolism, is documented in both canine and human patients and it has been postulated that it may deplete epidermal proteins and induce epidermal necrosis. Zinc and fatty acid metabolism may also be deranged. *The most likely pathogenesis of abnormal or impaired ability to properly utilize nutrients and the clinical and histologic similarities of this entity to zinc-responsive dermatoses* warrant discussion of SND in this section.

In dogs, SND has been reported to occur in association with a variety of systemic diseases including *glucagon-secreting tumors of the pancreas, hyperglucagonemia, diabetes mellitus, and liver disease.* Over 90% of the reported canine cases are associated with *severe hepatopathy*. The variety of concurrent diseases and the histologic appearance have led to terms for the characteristic cutaneous reaction pattern in dogs. These include superficial necrolytic dermatitis, hepatocutaneous syndrome, diabetic dermatopathy, metabolic epidermal necrosis, and necrolytic migratory erythema. Diabetes and hyperglucagonemia in some cases could be secondary to the hepatic degeneration. A feline case was associated with a pancreatic carcinoma presumably of endocrine origin.

Lesions have a roughly bilaterally symmetrical distribution. The muzzle, lips, periocular skin, edges of the pinnae, distal extremities,

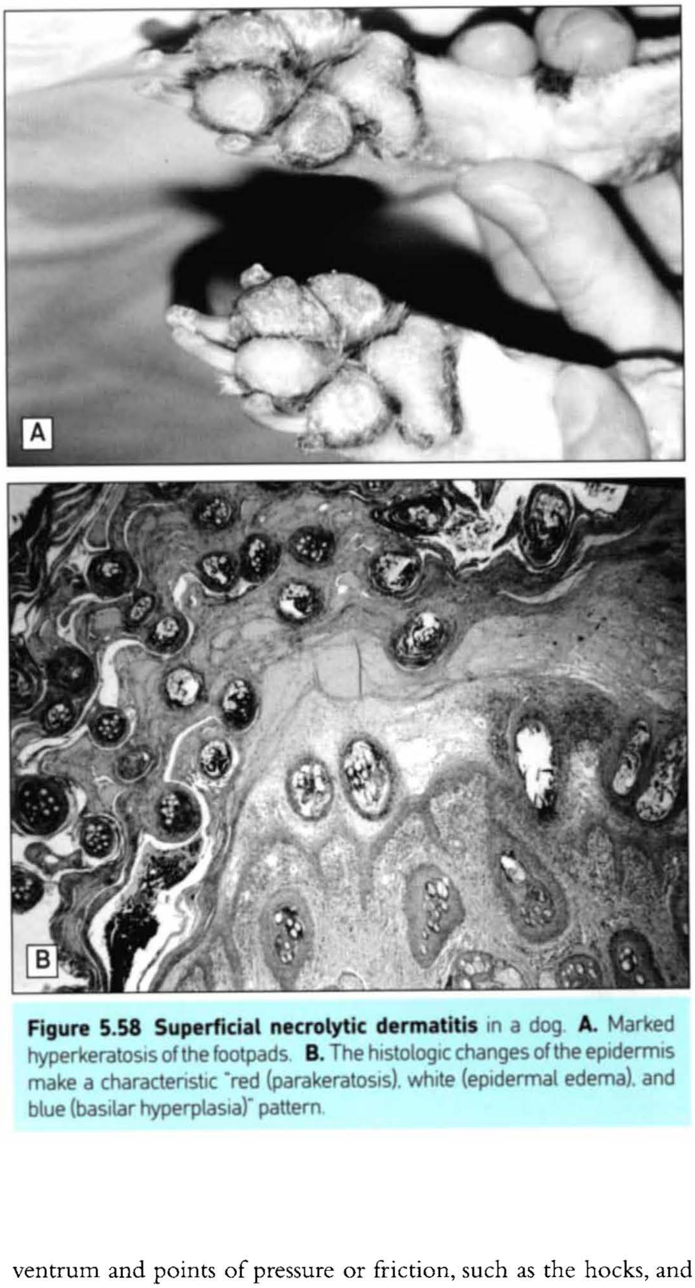

Figure 5.58 Superficial necrolytic dermatitis in a dog. **A.** Marked hyperkeratosis of the footpads. **B.** The histologic changes of the epidermis make a characteristic "red (parakeratosis), white (epidermal edema), and blue (basilar hyperplasia)" pattern.

ventrum and points of pressure or friction, such as the hocks, and the external genitalia are typically affected. Oral and mucocutaneous lesions are occasionally reported. Lesions are erythematous, erosive, ulcerative and crusted. The footpads are markedly hyperkeratotic (Fig. 5.58A). Footpad lesions were not a feature of SND in the cat. *The histologic lesions of the "red, white and blue" epidermis are virtually pathognomonic - the distinctive feature is a band of hydropic, pale-staining keratinocytes in the upper half of a usually acanthotic stratum spinosum* (Fig. 5.58B). Both intra- and intercellular edema contribute to the epidermal pallor. As these cells degenerate, clefts and vesicles may form in the outer stratum spinosum. Neutrophils may accumulate to form subcorneal pustules. The stratum corneum is diffusely and markedly parakeratotic and appears hypereosinophilic in comparison to the subjacent pale-staining stratum spinosum of the epidermis. The epithelium of the follicular infundibulum can also be affected. The basal cell layer is basophilic and hyperplastic, forming small rete ridges. Dermal inflammation is minimal, and predominantly mononuclear and perivascular. In eroded lesions, neutrophilic exocytosis is prominent and inflammatory crust covers the surface.

In cases associated with liver disease, the most commonly associated gross lesion is a *nodular liver with intervening firm, collapsed parenchyma*. Histologically, there is loss of parenchyma and minimal inflammation. Hepatocytes are markedly vacuolated due partially to fatty degeneration. The nodules have been interpreted in some cases to represent regeneration and in others to be comprised of nodular remnants of atrophic hepatic parenchyma.

The diagnosis is based on typical histologic findings. However, the pathognomonic epidermal edema may not be present in every biopsy. *Differential diagnoses* include other parakeratotic, hyperplastic dermatitides, such as the zinc-responsive dermatoses, lethal acrodermatitis of bull terriers, and thallium toxicity. The clinical differential is the same as listed for zinc-responsive dermatoses. The prognosis is generally considered poor since most cases have advanced liver disease. Cases associated with a pancreatic neoplasm may have resolution of skin lesions following tumor excision.

ENDOCRINE DISEASES OF SKIN

Endocrine disorders frequently manifest clinically as skin disease, but these dermatoses are rarely specific for any one endocrinopathy. While these dermatopathies are more common in dogs, they can occur in any species. **Clinical features** of many endocrine dermatoses include *a dry, coarse, brittle, dull, easily epilated haircoat that fails to regrow after clipping, hypotrichosis and hyperpigmentation, and alopecia that is frequently bilaterally symmetrical.* Secondary pyoderma and seborrhea are common. In addition, endocrine dermatoses share many **histologic features**, *including orthokeratotic hyperkeratosis, follicular keratosis, dilation of follicular ostia and infundibula, hair follicle atrophy, absence of hair shafts in follicles, increased numbers of telogen follicles, variably increased trichilemmal keratinization (flame follicles) of follicles, and epidermal hyperpigmentation.* These histologic changes suggest an endocrine dermatosis but frequently are not pathognomonic for a specific endocrinopathy. *A combination of clinical and histologic features together with clinical testing to demonstrate hormonal deficiency or excess is required for confirmation.*

Hypothyroidism

Hypothyroidism is the most common endocrine dermatopathy in **dogs**, and almost all cases are due to primary hypothyroidism. The most common cause is thought to be *lymphocytic thyroiditis*, an immune-mediated condition similar to Hashimoto's thyroiditis in humans. *Idiopathic thyroid atrophy* is also a common cause and may represent the end stage of lymphocytic thyroiditis. *Other causes* include developmental defects of the thyroid gland and rarely iodine deficiency. Pituitary neoplasia, or hypopituitarism, resulting in decreased secretion of TSH can cause secondary hypothyroidism. It is a disease of middle-aged dogs and there is no sex predilection, although the incidence is increased in neutered males and ovariohysterectomized females. Breeds that are predisposed include the Doberman Pinscher, Golden Retriever, Chow Chow, Great Dane, Irish Wolfhound, Boxer, English Bulldog, Dachshund, Afghan Hound, Newfoundland, Alaskan Malamute, Brittany Spaniel, Poodle, Irish Setter, and Miniature Schnauzer. *Clinical cutaneous changes* include secondary seborrhea, dry, coarse, brittle hair, hair that does not regrow after clipping, hypotrichosis with fine retained hairs, hyperpigmentation and alopecia that tends to develop first in areas of friction and can progress to become bilaterally symmetrical. Pruritus is not a feature unless there is secondary pyoderma or seborrhea. Histologic changes can be nonspecific and simply suggest an endocrinopathy. The most common changes are orthokeratotic hyperkeratosis with follicular keratosis, epidermal hyperplasia, and hair follicles in telogen or atrophied. Changes that are more specific but less common are myxedema, and dermal thickening.

Hypothyroidism occurs less frequently in other domestic animals, and usually in association with iodine deficiency and goiter. In **Merino sheep** and **Afrikander cattle**, a hereditary defect in the biosynthesis of thyroid hormone produces symmetric hypotrichosis and thick, myxedematous, wrinkled skin. In **goats**, hypothyroidism occurs in a mixed strain of Saanen and dwarf goats in association with a hereditary congenital thyroglobulin deficiency. Gross cutaneous changes include bilaterally symmetrical hypotrichosis and thick, myxedematous, scaly skin. Histologic findings include orthokeratotic hyperkeratosis, follicular keratosis, diffuse dermal mucinous degeneration (myxedema) and dermal thickening.

Hyperadrenocorticism

Hyperadrenocorticism is common in **dogs** and can be caused by bilateral adrenocortical hyperplasia resulting from a *pituitary tumor* (pituitary-dependent hyperadrenocorticism), a *neoplasm of the adrenal cortex* (usually unilateral), or exogenously administered glucocorticoids resulting in *iatrogenic hyperglucocorticism*. Of the naturally occurring forms, the pituitary-dependent form is considerably more common. The disease is seen most commonly in middle-aged or older dogs, and the Boxer, Boston Terrier, Dachshund, and Poodle are predisposed. Clinical cutaneous changes can include *bilaterally symmetric hypotrichosis or alopecia affecting primarily skin of the trunk, pendulous abdomen, thin skin that has decreased elasticity, slow wound healing, hyperpigmentation, telangiectasia, scaling, comedones, and calcinosis cutis* (Figs 5.59, 5.60A). Lesions of calcinosis cutis occur most commonly in the axilla, groin, or dorsal neck region and appear as erythematous papules that frequently ulcerate and exude a white, chalky material. Calcinosis cutis is almost always the result of iatrogenic hyperadrenocorticism. Other causes of mineral deposits in the skin are discussed under Physical injury to skin.

Histologically, canine hyperadrenocorticism is characterized by thin epidermal and follicular epithelium, which can be between 1–3 cell layers (Fig. 5.60B). If calcinosis cutis is present, the epidermis is frequently hyperplastic and can be ulcerated. Other changes can include orthokeratotic hyperkeratosis, marked follicular keratosis sometimes with comedone formation, thin dermis, hair follicles

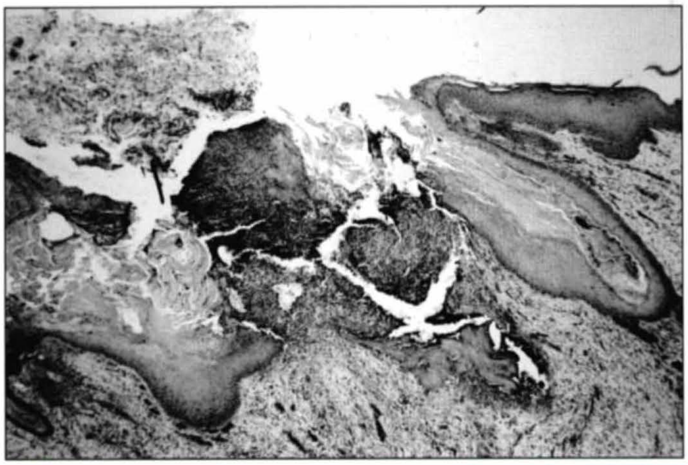

Figure 5.61 Calcinosis cutis in hyperadrenocorticism in a dog. The epidermis is hyperplastic. A large area of mineralized dermal collagen accompanied by granulomatous inflammation is undergoing transepidermal elimination.

that are frequently in telogen or catagen, sebaceous gland atrophy, and variable hyperpigmentation. Phlebectasia has been reported in dogs. *The presence of calcinosis cutis* (Fig. 5.61), *which can occasionally result in osseous metaplasia, is virtually pathognomonic for hyperadrenocorticism*, bearing in mind that mineralization of the external root sheath can be seen in normal old dogs, and in Poodles. Cutaneous histologic lesions of hyperadrenocorticism can occur focally at the site of topical glucocorticoid application.

Hyperadrenocorticism is considerably less common in **cats**. As in dogs, the condition is more commonly pituitary dependent than adrenal dependent or iatrogenic. The clinical presentation in cats is similar to that in the dog, however in addition there is often concurrent diabetes mellitus, and marked skin fragility and friability in which dermal collagen is reduced. This can result in tearing and lacerations of the skin (*feline skin fragility syndrome*). Histologic lesions in the cat are similar to those in the dog, however calcinosis cutis and telangiectasia have not been reported.

Hyperadrenocorticism occurs in **horses** and is almost always seen in association with *hypertrophy, adenomatous hyperplasia, or functional neoplasms of the pars intermedia of the pituitary*. The disease affects primarily aged horses and has no breed or sex predilection. Gross cutaneous changes may include a coarse, brittle, long, shaggy hair coat (hirsutism), an abnormal shedding pattern, episodic hyperhidrosis, poor wound healing, decreased muscle tone, weight loss, and susceptibility to secondary skin infections.

Hyposomatotropism and hypersomatotropism

Hyposomatotropism occurs in young **dogs** with *congenital pituitary dwarfism usually due to pituitary cysts*. In the German Shepherd Dog and Carnelian Bear Dog, pituitary dwarfism is thought to be inherited as a simple autosomal recessive condition and is usually associated with a cystic Rathke's cleft. The pituitary deficiency is often accompanied by deficiencies in thyroid, adrenal and sex hormones. The growth retardation due to the pituitary defect can be accompanied by a puppy coat that fails to shed and the development of endocrine alopecia with typical histologic changes.

Hypersomatotropism (*acromegaly*) is very rare in **dogs**. Excessive somatotropin (growth hormone) production is associated with administration of progestins or with the metestrus (luteal) phase of the estrous cycle in intact female dogs. Cutaneous changes include thick, folded, myxedematous skin, especially on the head, neck and distal extremities. The haircoat may be long and thick and the nails may exhibit rapid overgrowth. Histologic findings in canine hypersomatotropism include thickened dermis due to increased production of glycosaminoglycans and collagen by dermal fibroblasts. Myxedema is present in about a third of cases.

Hyperestrogenism

Hyperestrogenism can occur in male or female **dogs**. In middle-aged to older intact male dogs it is associated with *functional testicular neoplasms*, primarily Sertoli cell neoplasms, and occasionally functional interstitial cell tumors and seminomas. The Boxer, Shetland Sheepdog, Cairn Terrier, Pekingese, Collie and Weimaraners are predisposed. Hyperestrogenism is also seen in middle-aged to older intact female dogs with *polycystic ovaries or functional ovarian neoplasms*. It can also occur in male or female dogs following estrogen administration.

Gross cutaneous changes include *symmetrical hypotrichosis or alopecia*, which typically originates at the perineum and genital region and progresses cranially on the trunk. The hair is dry and dull, is easily epilated, can fail to regrow after clipping, and can be accompanied by hyperpigmentation, especially macular pigmentation. Male dogs may develop a pendulous prepuce, gynecomastia, or prostatomegaly with squamous metaplasia of the prostatic ducts. Females may develop an enlarged vulva. Histologic changes include hair follicles that are primarily in telogen, orthokeratotic hyperkeratosis, and follicular keratosis.

Alopecia X

Growth hormone/castration-responsive dermatosis has many synonyms, including hyposomatotropism of the adult dog, sex-hormone alopecia, pseudo-Cushing's syndrome, testosterone-responsive dermatosis, estrogen-responsive dermatosis, congenital adrenal hyperplasia like-syndrome. This diversity in nomenclature reflects the differences in endocrine values and responses to various treatments and the fact that the pathogenesis of this condition has not been fully characterized. *To simplify the nomenclature, the condition is now being referred to as* **alopecia X**. These dogs have normal thyroid function and adrenal function, and most theories involve a deficiency or imbalance in sex hormones and/or growth hormone deficiency. There may be partial deficiency of 21-hydroxylase or other adrenocortical enzymes necessary for adrenal steroidogenesis.

Alopecia X occurs most often in *plush-coated Nordic breeds*, such as the Pomeranian, Keeshond, Chow Chow, Samoyed, Siberian Husky, Alaskan Malamute, Norwegian Elkhound, American Eskimo Dog, and occasionally in other breeds. Affected dogs have *symmetrical alopecia* of the trunk, perineum, caudal thighs, and neck, sparing the head and distal extremities (Fig. 5.62). Hyperpigmentation is common. Alopecia X usually develops between one and two years of age and either sex can be affected. Initial histologic changes are characterized by *follicular atrophy*; trichilemmal keratinization in primary hairs can be quite prominent. Caution is warranted in making the diagnosis of

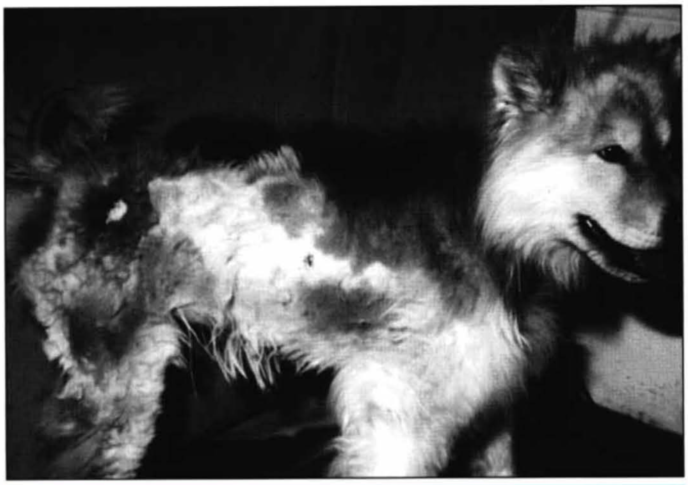

Figure 5.62 Alopecia X in a dog. (Courtesy of B Dunstan.)

Alopecia X based exclusively on this feature as normal primary hair follicles of Nordic breeds can have increased trichilemmal keratinization.

Canine recurrent flank alopecia

Canine recurrent flank alopecia (seasonal flank alopecia, cyclical flank alopecia) is a condition seen most commonly in the Boxer, English Bulldog, Airedale Terrier, Schnauzer, and Griffon Korthal, but can occur in many breeds. It is characterized by alopecia of the skin of the flank that is usually bilaterally symmetrical, rarely unilateral, and occurs recurrently or seasonally. The first episode occurs at approximately 4 years of age but can be variable. In the northern hemisphere, the onset of alopecia is usually between November and March. There is spontaneous hair regrowth after 3–8 months, however occasional dogs have progressively less hair regrowth after each episode. Rare dogs fail to regrow hair after the first episode; and some dogs have one episode of alopecia that never recurs.

Clinically, the bilaterally symmetrical lesions are usually confined to the thoracolumbar regions, have well demarcated margins with abrupt transition from affected to unaffected skin, and are usually hyperpigmented. Histologic changes are those of *non-inflammatory, non-scarring follicular atrophy*. Follicular infundibula are dilated and filled with keratin that can extend into the openings of the primary and secondary atrophic follicles, giving the appearance of an inverted footprint over the remnants of the follicular epithelium (Fig. 5.63).

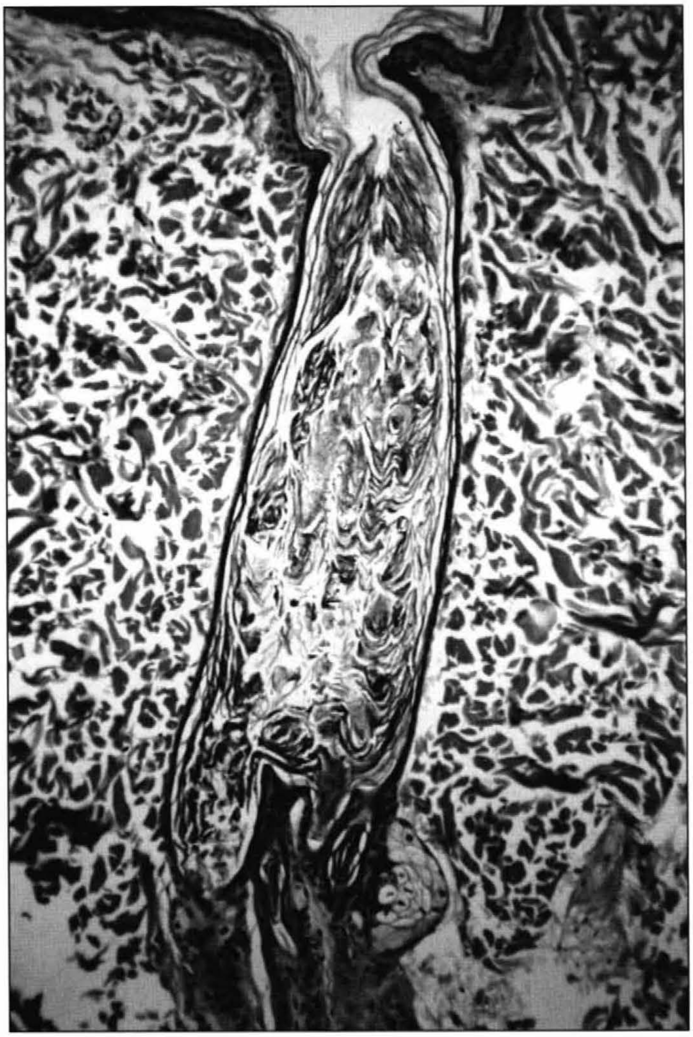

Figure 5.63 Recurrent flank alopecia in a dog. Follicular infundibula are dilated and filled with keratin that extends into the openings of the primary and secondary atrophic follicles, giving the appearance of an inverted footprint. (Courtesy of B Dunstan.)

IMMUNE-MEDIATED DERMATOSES

Hypersensitivity dermatoses

Contact with exogenous antigens usually leads to induction of a protective response, but when the immune response causes damage to tissues, it is called *hypersensitivity or allergy*. Compounds such as dust, pollens, food, drugs, microbiologic agents, insect components, and various chemicals contain antigens that are normally innocuous but may induce allergic reactions in predisposed individuals. Most cutaneous hypersensitivity reactions are mediated by type I (immediate) hypersensitivity, type IV (cell-mediated or delayed) hypersensitivity, or by a combination of the two types. Hypersensitivity reactions cause a variety of dermatoses that range from annoying and uncomfortable to severely debilitating or life-threatening. Allergic dermatoses are common and important in dogs, cats, and horses and are rarely reported in food animals.

Urticaria and angioedema

Urticaria (hives, heat bumps) and **angioedema** (angioneurotic edema) *are variably pruritic, edematous skin lesions produced by mediators released by basophils and dermal mast cells.* Urticaria and angioedema are most common in horses, uncommon in dogs, and rare in ruminants, pigs, and cats. A wide variety of immunologic and nonimmunologic causes have been implicated, but frequently the specific causative agent cannot be determined for a particular individual. Immunologic causes of urticaria/angioedema are thought to involve type I hypersensitivity reactions primarily; type III hypersensitivity is involved occasionally. *Recognized initiators* in all species include foods and food additives, drugs, biologic agents, stinging and biting arthropods, intestinal parasites, inhalant and contact allergens, and bacterial, fungal, and viral infections. *Nonimmunologic factors* associated with urticaria/angioedema include physical factors such as heat, cold, or pressure; mast cell degranulating agents such as radiocontrast media; and agents that result in perturbation of arachidonic acid metabolism. Deficiency of C1 esterase inhibitor is a genetic cause of chronic urticaria in humans. Aspirin and other nonsteroidal anti-inflammatory drugs, psychological stress, and concurrent febrile illness may be *exacerbating factors*, if not causative ones, in humans with chronic urticaria. Another cause of chronic urticaria identified in humans is IgG autoantibody directed against the IgE receptor of cutaneous mast cells and circulating basophils. Binding of the autoantibody to this receptor induces release of histamine. Irrespective of cause, the *final common pathway is increased vascular permeability and resultant edema produced by histamine, the major mediator, and possibly also by kinins, eicosanoids, and neuropeptides.*

Drugs are probably the most frequent cause of urticaria in **horses**. A wide variety of systemic drugs and biological products have been implicated in initiating urticaria. *Wheals* frequently develop in minutes to hours after exposure to the offending drug and usually subside within several hours. *Cholinergic or heat-reflex urticaria*, induced by exercise or a hot bath, has been reported in a horse. Pruritus in this horse appeared to be exacerbated by pelleted feed. An unusual form of urticaria called *dermatographism*, which is induced by blunt pressure to the skin, has also been described in the horse. In some instances, urticaria is thought to be caused by *overfeeding of grains*, especially those high in protein content ("protein bumps," "feed bumps"). Lesions occur anywhere on the body but are most common on the face, neck, and thorax. In **cattle**, a unique form of urticaria has been described in high-producing dairy cows, especially Jerseys and Guernseys, that become sensitized to casein in their own milk (*milk allergy*). Foods, drugs, biologic agents, and venomous stings are reported most frequently as causes of urticaria and angioedema in **dogs** and **cats**.

Urticaria is characterized by *wheals (hives), which are discrete, well-circumscribed, erythematous, edematous plaques with a flat-top and steep sides* (Fig. 5.64). They are cool and pit upon digital pressure. They vary in size and may coalesce to measure many centimeters in diameter. Wheals are usually round; but in some instances they assume bizarre and irregular serpentine shapes. The overlying hair may stand erect, giving the impression of a follicular disease. The lesions may be localized to a single body region, e.g., lateral neck, head, or thorax, or they may involve the entire body. The individual lesions usually last less than 12–24 hours and disappear leaving no residual skin changes unless pruritus results in self-mutilation. Although individual lesions are transient, new ones may erupt over a period of days or weeks. *Angioedema consists of larger, less well demarcated swellings* that originate subcutaneously. With time, the swellings may gravitate ventrally. Angioedema is a potentially serious condition since involvement of perilaryngeal tissues may cause asphyxiation. Approximately 50% of affected humans develop both lesions concurrently but development of both wheals and angioedema does not seem to be as common in animals.

Microscopic lesions are variable and nonspecific. The epidermis is usually normal in nontraumatized lesions. Urticaria is characterized by *dermal edema,* which is visualized as widening of spaces between collagen fibers in the superficial and middle dermis. The change may be very subtle and can be missed. Edema is typically more severe and involves the deep dermis and subcutaneous tissue in angioedema. Small vessels are congested and lymphatics are dilated. Inflammation is inconsistent. When present, it usually consists of perivascular granulocytes, mast cells, and fewer lymphocytes and macrophages. The reaction involves the upper and middle dermis in urticaria and the deep dermis and subcutis in angioedema. Vasculitis is not a typical feature of urticaria and angioedema.

Diagnosis is usually based on the history and appearance and transitory nature of the clinical lesions. Biopsy is performed to rule out other conditions when the lesions are recurrent or chronic and the diagnosis is uncertain. Identification of a particular inciting

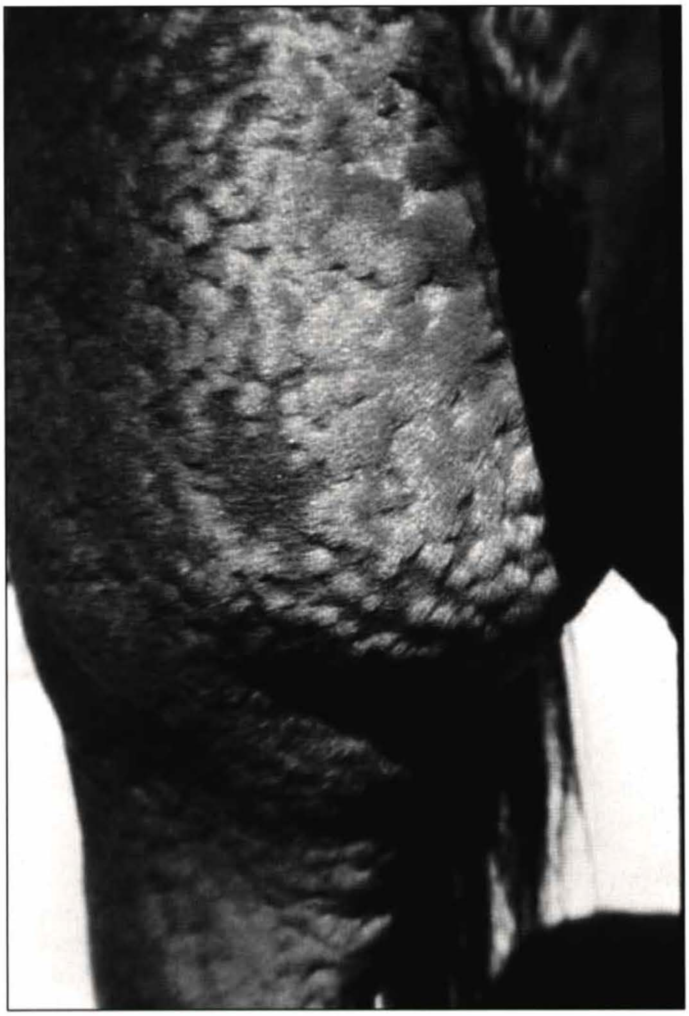

Figure 5.64 Urticaria in a horse. Discrete, well-circumscribed, erythematous, edematous plaques with a flat-top and steep sides. (Courtesy of B Dunstan.)

cause relies on history and a combination of elimination trials, environmental alterations, intradermal skin testing, and insect control measures.

Atopic dermatitis

Atopy is an inherited tendency to produce IgE antibodies and develop clinical allergy to pollens and other innocuous environmental antigens. Clinical disease can involve the respiratory tract, and consist of allergic rhinitis and asthma, or the skin, and manifest as atopic dermatitis. In animals, atopic dermatitis is much more common than the respiratory manifestations of atopy. Allergic rhinitis occurs in cattle, however.

Atopic dermatitis is a multifactorial skin disease in which there is a complex interrelationship between genetic, environmental, skin barrier, pharmacologic, psychologic, and immunologic factors that contribute to the development and severity of the disease. Although clearly a *genetic disorder*, the genetic mapping of atopic dermatitis is not simple and more than one gene appears to be involved. The *pathogenesis* of atopic dermatitis is incompletely understood but it is thought to be caused by an *underlying immunoregulatory imbalance* producing activation of a subpopulation of T helper type 2 lymphocytes (Th2 cells) that release cytokines important to the pathogenesis of atopic dermatitis. Th2 cells produce IL-4, IL-5, and IL-13 and are associated with IgE-mediated reactions. IL-4 is a critical cytokine in the development of allergic diseases. It signals T cells to become Th2 cells, which are the major source of IL-4 production, thereby initiating a self-amplifying process. IL-4 induces expression of IgE receptors on Langerhans cells, resulting in enhanced antigen presentation capability. IL-4 and IL-13 induce the antibody isotype switch from IgM to IgE. They also up-regulate expression of vascular cell adhesion molecule–1 (VCAM-1), an adhesion molecule expressed by cutaneous endothelial cells and involved in migration of eosinophils and mononuclear cells into sites of allergic inflammation. IL-5 promotes differentiation, vascular endothelial adhesion, and survival of eosinophils. In contrast, Th1 cells produce IFN-γ, which inhibits IgE synthesis and differentiation of Th2 cells. The balance between Th1 and Th2 cells may be modulated by biochemical defects in monocytes. Peripheral blood mononuclear cells of individuals with atopic dermatitis have been shown to have increased activity of phosphodiesterase, which results in increased monocyte prostaglandin E_2 (PGE_2) production. PGE_2 tends to inhibit Th1 production of IFN-γ and accentuate IL-4 secretion by Th2 cells.

IgE appears to have a multifunctional role in the pathogenesis of atopic dermatitis. An immediate type hypersensitivity reaction develops within minutes of allergen exposure when mast cells bearing allergen-specific IgE bind allergen and release a variety of preformed mediators, most notably histamine. The skin histamine content has been found to be increased in humans and dogs with atopic dermatitis. *Activated mast cells* also release cytokines such as IL-4, IL-5, IL-6, TNF-α, and platelet activating factor (PAF) that further promote inflammation. An IgE-dependent late-phase reaction develops subsequently when expression of leukocyte adhesion molecules on postcapillary venule endothelium promotes influx of eosinophils, neutrophils, and mononuclear cells into the skin. Eosinophils release various mediators including PAF, eosinophil major basic protein (MBP), eosinophil cationic protein (ECP), and cytokines that promote inflammation and cause tissue damage. Antigen-specific IgE antibodies also appear to be involved in a non-classical role in antigen uptake and processing. IgE-bearing antigen-presenting cells (APCs), particularly Langerhans cells and dermal dendritic cells, bind, process, and present specific antigen locally to allergen-specific indeterminate T cells (Th0) thereby directing them to the Th2 cell phenotype. Moreover, IgE-mediated antigen presentation increases the presenting capacity of these APCs up to 100-fold, a mechanism known as "*facilitated antigen presentation*." Ultimately, B cells are stimulated to produce more allergen-specific IgE, which is bound to antigen-presenting cells, and a vicious cycle of facilitated antigen presentation is perpetuated.

Atopic dermatitis traditionally has been thought to be triggered by inhaled aeroallergens, hence the synonym **allergic inhalant dermatitis**. However, there is evidence both in humans and animals suggesting that *a transepidermal route of exposure may be involved instead or as well*. In the dog, such a route of antigen presentation is suggested by the typical distribution of skin lesions primarily to ventral, sparsely haired areas. Immunohistochemical studies of lesional skin from humans, dogs, and cats with atopic dermatitis have found increased numbers and focal aggregation of activated Langerhans cells within the epidermis. *These findings are interpreted to represent antigen capture within the epidermis*. Increased numbers of T cells are also seen in the epidermis. Clustering of dendritic cells is also evident in the superficial dermis, suggesting increased local antigen capture and/or antigen presentation to T cells. Furthermore, both the aggregated epidermal Langerhans cells and dermal dendritic cells are positive for surface IgE, findings consistent with the theory that cutaneous allergen capture or presentation is mediated by IgE. In lesional skin of atopic dogs, epidermal eosinophil exocytosis, subcorneal eosinophilic micropustule formation, and eosinophil degranulation have been observed and interpreted to indicate that the interaction between allergen and immunocompetent cells occurs in the epidermis and results in the release of eosinophil chemotactic factors by keratinocytes or epidermal Langerhans cells. In addition, increased expression of adhesion molecules by dermal endothelial cells has been found. Increased numbers of CD4+ and CD8+ T cells are seen in lesional atopic skin of humans, cats, and dogs. Tissue-selective homing of T cells is thought to be regulated at the level of T cell recognition of vascular endothelial cells via interaction of differentially expressed T lymphocyte homing receptors, such as cutaneous lymphocyte antigen (CLA), and their endothelial cell ligands. Therefore, *increased expression of endothelial adhesion molecules promotes migration of increased numbers of CLA+ T cells into the skin*. The tendency to develop atopic dermatitis as opposed to asthma or allergic rhinitis may depend on differences in skin-versus lung-seeking propensity of the memory/effector T lymphocytes.

The characteristic feature of atopic dermatitis is intense pruritus but the pathogenesis is not well understood. It is thought to be driven by local release of pharmacologic mediators, including histamine, neuropeptides, and eicosanoids; however, it does not appear that histamine is a major pruritogen in atopic dermatitis. Of the various chemical mediators, *neuropeptides* may be particularly important in the pathophysiology of itching in the atopic individual. In addition, atopic dermatitis appears to be associated with a decreased threshold for pruritus. The development of clinical lesions is also partially dependent on skin trauma caused by scratching. Once the itch-scratch cycle is initiated, mechanical trauma to the keratinocytes results in release of various proinflammatory cytokines that can maintain and promote inflammation. These include IL-1, TNF-α, and IL-4. It is unclear whether there is also an intrinsic keratinocyte defect. Keratinocytes from humans with atopic dermatitis exhibit enhanced production of GM-CSF in response to IL-1, which can contribute to increased numbers and enhanced antigen-presenting function of dendritic cells.

Atopic dermatitis is associated with a cell-mediated immunodeficiency that appears to be confined to the skin. Consequently, patients with atopic dermatitis have an increased tendency to develop skin infections, which are generally superficial. Superficial infection with *Malassezia* is common in humans and dogs with atopic dermatitis. Lesional skin of humans and dogs with atopic dermatitis has a high incidence of colonization with pathogenic strains of staphylococci. Besides causing superficial pyoderma, *S. aureus* in humans is believed to augment allergen-induced skin inflammation in atopic dermatitis by secreting exotoxins that act as *superantigens*. Superantigens have the capacity to activate large classes of T cells nonspecifically by virtue of their ability to bridge the linkage between the class II major histocompatibility complex molecule on the APC and the T cell receptor without having to be processed and presented by the APC. IgE antibodies directed against these exotoxins have been identified in individuals with atopic dermatitis and the severity of disease correlates with these IgE antibodies, presumably because the locally produced exotoxins are absorbed through the skin surface and cause IgE-dependent mast cell degranulation within the dermis. Other toxins secreted by *S. aureus* organisms have been found to induce release of TNF-α by keratinocytes and cause inflammation by nonspecific mechanisms.

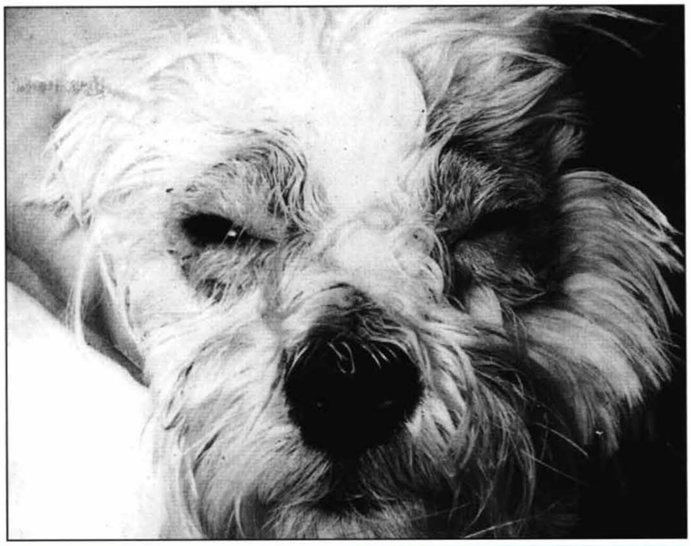

Figure 5.65 Atopy in a dog.

Atopic dermatitis is a common condition in **dogs** and is estimated to affect 10–15% of the population. It is second only to flea-bite hypersensitivity in those geographical areas with fleas. It has a *familial pattern* but the mode of inheritance is unknown. No relationship between dog leukocyte-antigen (DL-A) and canine atopy could be found. Breeds thought to be predisposed include the Chinese Shar-Pei, Cairn Terrier, West Highland White Terrier, Scottish Terrier, Lhasa Apso, Shih Tzu, Wire-haired Fox Terrier, Dalmatian, Pug, Irish Setter, Boston Terrier, Golden Retriever, Boxer, English Setter, Labrador Retriever, Miniature Schnauzer, Belgian Tervuren, and Beauceron. Females are affected more commonly in some studies, while in others no sex predilection has been found. The age of onset is variable but disease usually is apparent between 1 and 3 years of age. It is rare in dogs less than 6 months, except in Chinese Shar-Peis which may develop disease as early as 3 months of age; and, unless there is a change in the environment, most dogs develop clinical signs by 6 years.

The *primary clinical sign is pruritus*, which frequently begins seasonally but eventually becomes perennial. Pruritus most commonly affects the face (Fig. 5.65), paws, distal extremities, and ventrum and is manifested typically as face-rubbing and foot-chewing and licking. Skin lesions are usually due to self-trauma, secondary bacterial pyoderma, *Malassezia*-dermatitis, and secondary seborrhea. Secondary skin changes include variable alopecia, salivary staining of the hair, excoriations, papules, pustules, crusts, hyperpigmentation, lichenification, and pyotraumatic dermatitis. Eventually cutaneous involvement may become generalized. Atopic dogs characteristically have an unpleasant odor that results from a combination of seborrhea, secondary bacterial or yeast infection, and hyperhidrosis. Atopic otitis externa is common. Noncutaneous clinical signs are rare and may include conjunctivitis, rhinitis, asthma, and gastrointestinal disorders.

No breed or sex predilection is apparent in **cats** with atopic dermatitis; and it is uncertain whether there is an inherited predisposition. Clinical signs usually develop at 6 months to 2 years of age. *Pruritus* is the primary clinical sign but it may not be obvious because of the secretive nature of cats. Instead, hair loss, secondary to covert licking and chewing, may be the only abnormality and the skin may appear normal. *Clinical lesions of atopic dermatitis in cats are extremely variable.* They may include, in addition to self-induced alopecia, eosinophilic granuloma complex lesions, miliary dermatitis, recurrent swelling of the lower lip, otitis externa, and pruritus of the face, pinnae, and neck. *Miliary dermatitis is a clinical reaction pattern of cats* that consists of numerous small erythematous crust-covered papules. It is not specific for atopic dermatitis and may also occur in ectoparasite, food, and drug hypersensitivities. Noncutaneous signs associated with atopy in cats include sneezing, conjunctivitis, coughing, and asthma. Lymphadenopathy may be present in cats with miliary dermatitis or eosinophilic granulomas.

Pruritus is the primary clinical sign in **horses** with atopy. Some cases are manifested as recurrent pruritic urticaria. Onset is usually between 1.5 and 4 years of age. Skin lesions usually develop secondarily in response to self-trauma and include alopecia, excoriations, lichenification, and hyperpigmentation. The face, ears, ventrum, and legs are most commonly affected. Arabians and Thoroughbreds may be predisposed. A seasonal pruritic dermatosis typical of atopic dermatitis has been described in two **Suffolk ewes**.

Microscopic changes associated with atopic dermatitis have been considered nonspecific and usually consist of perivascular to interstitial dermatitis. In *dogs*, the epidermis is variably hyperplastic and may have mild, patchy intercellular edema, focal parakeratosis, and crusting. Erosion and ulceration may be present from self-trauma. Exocytosis of lymphocytes or eosinophils and small subcorneal accumulations of eosinophils may be seen. Dermal inflammation is superficial perivascular to interstitial, and consists of lymphocytes and macrophages primarily. Mast cells are in increased numbers and may be numerous. Eosinophils and neutrophils are usually in low numbers, but eosinophils may be missed because of degranulation. Sebaceous glands are hyperplastic and apocrine sweat glands may be dilated in chronic lesions. Superficial dermal blood vessels may be congested and the superficial dermis may be mildly edematous.

Histologic changes in the skin of *cats* with atopic dermatitis vary according to the lesions biopsied. The epidermis varies from normal to variably hyperplastic. Serocellular crusts, foci of intercellular edema and epidermal necrosis, and exocytosis of small numbers of eosinophils are usually present in lesions of miliary dermatitis. The dermis contains a superficial perivascular to interstitial infiltrate of mixed cells. Mast cells, eosinophils, lymphocytes, and neutrophils are typically present but vary in their proportions. Neutrophils are most numerous in areas of erosion or ulceration. In some cases, the lesions are those of an eosinophilic plaque. The microscopic lesion in *atopic horses and sheep* is hyperplastic perivascular dermatitis with a predominance of eosinophils.

Diagnosis of atopic dermatitis is based on compatible history and physical examination findings coupled with demonstration of allergen-specific IgE antibodies. In dogs, measurement of total serum IgE has not been found to be useful because there is no significant difference in IgE concentrations between atopic and clinically normal dogs. *Intradermal skin testing* (IDST) has been considered to be the most reliable method of identifying clinically relevant allergens. In vitro tests that measure concentrations of allergen-specific IgE are commercially available but generally have been found to correlate poorly with IDST results. However, newer procedures for measurement of allergen-specific IgE may be more accurate in identifying clinically relevant allergens. Diagnosis may be complicated by the presence of concurrent hypersensitivity conditions such as flea-bite allergy or food allergy.

Food hypersensitivity (allergy)

Food hypersensitivity refers to an exaggerated, immunologically mediated reaction to specific food allergens resulting in disease. This hypersensitivity reaction may be mediated by IgE (type I hypersensitivity) and by non-IgE-mediated mechanisms. Food-induced allergic reactions are responsible for a variety of signs involving the skin, gastrointestinal tract, and respiratory tract. The skin may represent the second most frequent target organ, after the gastrointestinal tract, in food hypersensitivity reactions.

Food allergy in humans is thought to develop as a consequence of physiologic and immunologic immaturity resulting in increased absorption of food antigens during the first few months to years of life in association with the inherited tendency for increased production of IgE antibody. Absorption of intact food proteins appears to be limited normally by the intestinal mucosal barrier and by combination of the proteins with food allergen-specific IgA secreted into the gut. However, adult levels of IgA are not generally produced until puberty and this relative IgA deficiency may contribute to increased permeability of the gastrointestinal barrier during childhood. Gastrointestinal infections and parasitism may also contribute to disruption of the mucosal barrier to increase absorption of food antigens. The majority of food allergens are *glycoproteins* with molecular weight between 10 000 and 80 000 daltons, which tend to be resistant to proteolysis and are heat-stable and water-soluble. Even in the mature intestine, approximately 2% of ingested food antigens are absorbed into the circulation in an immunologic form. However, these immunologically recognizable proteins do not normally cause adverse reactions despite being transported throughout the body because tolerance develops in most individuals. Tolerance is thought to involve activation of CD8+ T suppressor cells in GALT to suppress an immune response. The development of tolerance to food appears to have little effect on B cells since antibody production to food proteins is a universal phenomenon; although low concentrations of serum IgG, IgM, and IgA food-specific antibodies are found in normal individuals, they are of no clinical consequence. In genetically predisposed infants, however, ingested antigens result in excessive production of IgE antibodies. These food-specific antibodies bind high affinity receptors on mast cells, dendritic cells, and macrophages in tissues and basophils in circulation. When food allergens penetrate mucosal barriers and reach the IgE bound to mast cells and basophils, mediators are released that induce the signs of immediate hypersensitivity. Activated mast cells also generate various mediators (such as IL-4, tumor necrosis factor α, and platelet activating factor) that may induce an IgE-mediated late-phase response in which eosinophils, lymphocytes, and monocytes are attracted to the site of reaction and release additional inflammatory mediators and cytokines. Mononuclear cells can be induced to secrete "histamine-releasing factors" that interact with IgE bound to basophils and possibly other cells to increase releasibility of these cells. In addition, IgE antibodies bound to Langerhans cells lead to more efficient capture of antigens and preferential activation of Th2 lymphocytes that promote allergic inflammatory reactions. The development of dermatitis rather than respiratory signs in individuals with food allergy may relate to homing of allergen-specific T cells to the skin by way of cutaneous lymphocyte-associated antigen (CLA), a homing molecule that directs these cells to the skin.

The pathomechanism of food hypersensitivity in animals is unknown, but it is assumed to be an IgE-mediated hypersensitivity reaction as in humans. It is not known when the gastrointestinal tract of companion animals becomes mature. Since gastrointestinal parasitism and viral enteritides are relatively common in animals, disruption of the intestinal mucosal barrier may be an important factor in the development of food hypersensitivity. Food allergy, as recognized in animals, is clinically different from the condition in humans, however. In humans, food hypersensitivity is most commonly seen in infants and young children; and in many cases, a loss of clinical sensitivity develops after 1–3 years of an appropriate food elimination diet. Although signs may initially develop in young animals, food hypersensitivity is typically a disease of adult animals and no loss of clinical sensitivity has been observed in affected animals. Furthermore, laboratory and clinical evidence suggests that food-specific IgE antibody directly contributes to the pathogenesis of atopic dermatitis in humans. In animals, food allergy is currently considered a separate entity from atopic dermatitis, although the two conditions may coexist.

Food allergy is thought to be the third most common hypersensitivity in **dogs** after flea-bite allergy and atopic dermatitis. The prevalence is unknown but food hypersensitivity has been suggested to account for 10–15% of canine allergic dermatoses. A significant number of dogs with food allergy, ranging from 23% to 45% in various studies, have concurrent hypersensitivity conditions such as atopic dermatitis, flea-bite allergy, or both. The most common allergens identified are *beef, wheat, dairy products, chicken, eggs, corn, and soy*. Some dogs, up to 64% in one study of 25 dogs with food allergy, react to two or more dog food ingredients, suggesting that multiple food hypersensitivities are not uncommon. Signs of food allergy may develop at any age; but in approximately 50% of dogs, signs are seen before 1 year of age and may occur as early as 4 months. No sex predisposition has been found. Breed predilection is uncertain. None has been found in some studies, while different breeds have been found to be at increased risk in various studies, no doubt reflecting regional differences in genetic pools.

Clinical signs in dogs are extremely variable. *The most consistent sign is pruritus* that is usually nonseasonal and may be generalized or localized to the feet, face and ears; inguinal and axillary regions; or lumbosacral and perineal area. Depending on the location of the pruritus, food allergy may mimic sarcoptic mange, flea allergy dermatitis, or atopic dermatitis. The pruritus may be unresponsive or poorly responsive to glucocorticoid therapy. Primary skin lesions may include erythema, papules, or pruritic urticaria-angioedema but they are frequently obscured by self-trauma as a consequence of chronic pruritus. More commonly, only secondary lesions are seen and these typically include excoriation, alopecia, hyperpigmentation, lichenification, scales, crusts, ulceration, and seborrhea. In a small number of cases, pruritic otitis externa or recurrent superficial pyoderma may occur in the absence of any other clinical signs of food allergy. Bacterial pyoderma and *Malassezia* infection are common secondary complications. Some dogs also exhibit *concurrent gastrointestinal signs*, which include increased frequency of defecation most commonly, and mucus and/or blood in feces, tenesmus, vomiting, or diarrhea less frequently. Neurologic signs, such as malaise and seizures, and respiratory signs have been reported rarely in conjunction with skin lesions in dogs with food allergy.

The prevalence of food allergy in **cats** is unknown. No breed or sex predilection is apparent. Most cases are recognized in young adult cats. The major complaint is *severe pruritus* that is usually nonseasonal and frequently poorly responsive to glucocorticoid therapy. The face, ears, and neck are most commonly involved but pruritus may be generalized (Fig. 5.66). Allergens identified include

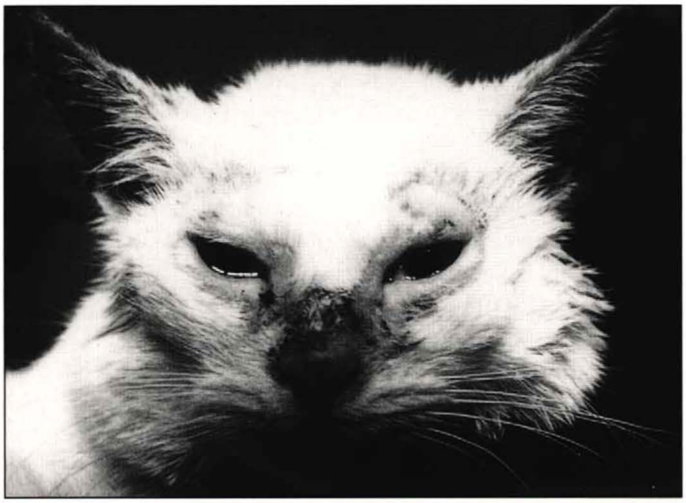

Figure 5.66 Food allergy in a kitten. Periocular and nasal alopecia, crusting, and erythema.

fish, lamb, milk, whale meat, beef, chicken, rabbit, eggs, and pork. Food allergic cats may also have other hypersensitivity conditions such as atopic dermatitis or flea-bite allergy. Skin lesions are extremely variable and include erythema, angioedema-urticaria, self-induced alopecia and excoriations, crusting, seborrhea, or miliary dermatitis. They may be localized to the face and head or generalized in distribution. Eosinophilic granuloma complex lesions may be a manifestation of food allergy. Concurrent gastrointestinal or respiratory signs are uncommon.

Food hypersensitivity has been reported rarely in **horses, cattle**, and **pigs**. Substances that have been incriminated include wheat, barley, bran, oats, concentrates, and tonics in horses; wheat, bran, corn, clover hay, rice bran, and soybeans in cattle; and clover pasture in pigs. Clinical signs in horses and cattle are pruritic papular eruptions, pruritic urticaria, and tail rubbing. A condition described as food allergy in white hogs on new clover pasture consisted of generalized erythema and skin pain, depression, and reluctance to move. The description of this condition is more suggestive of an adverse food reaction, such as photosensitization, than of food hypersensitivity, however.

The microscopic lesions associated with food allergy are variable and are not diagnostic. The epidermis is variably acanthotic and may be multifocally spongiotic. Crusting, erosion, and ulceration may be present. The superficial dermis is mildly to moderately edematous and inflammation is variable. In dogs, inflammation may be perivascular, interstitial, or diffuse. The cells are mixed and include lymphocytes, macrophages, eosinophils, and mast cells. Neutrophils and plasma cells are present in numbers proportional to the degree of self-trauma. Sebaceous and apocrine glands may be hyperplastic in chronic lesions. In cats, dermal inflammation may be a superficial perivascular mononuclear dermatitis but more commonly is characterized by eosinophilic inflammation that is perivascular to diffuse and extends into the subcutis. Mast cell numbers are commonly moderately to markedly increased throughout the dermis. Collagen degeneration may occur in areas of intense eosinophilic inflammation. Eosinophilic folliculitis and furunculosis and lesions of eosinophilic plaque are present in some cases of food allergy in cats. The microscopic lesion ascribed to food allergy in large animals is superficial perivascular dermatitis, with eosinophils comprising a significant proportion of the inflammatory cells.

The *diagnosis* of food allergy is made by a combination of appropriate clinical history, exclusion of other pruritic conditions, and resolution of pruritus with feeding of a hypoallergenic diet. Intradermal skin testing and measurement of serum allergen-specific IgE levels have been found to be unreliable for diagnosis of food allergy in animals.

Allergic contact dermatitis

Allergic contact dermatitis is an uncommon hypersensitivity condition in domestic animals. Although considered a typical delayed (type IV) hypersensitivity reaction, *there is considerable overlap in pathogenesis between allergic contact dermatitis and primary irritant dermatitis and the rigid distinction between the two conditions is becoming blurred.* It has been estimated to account for 1–10% of dermatoses in dogs. The low incidence, as compared to that in humans, is thought to be due to the natural protection afforded by the hair coat of most animals and by the decreased exposure to potential allergens in cosmetics and industrial chemicals.

Allergic contact dermatitis is caused by contact with a nonirritating concentration of a substance to which an individual has previously become sensitized. The compounds involved are usually lipid-soluble haptens (low-molecular-weight substances) that become immunogenic only after penetrating the epidermis and binding covalently to an autologous structural or cell surface protein to form a complete antigen. This antigen is subsequently internalized and processed by Langerhans cells and presented to CD4+ T cells. Langerhans cells are crucial to development of allergic contact dermatitis as depletion of these cells results in a decreased ability to induce contact sensitization. During the induction phase of the reaction, Langerhans cells present antigen to CD4+ cells in the paracortical region of regional lymph nodes where the specifically sensitized T cells undergo clonal expansion and then circulate as memory cells in blood and home to skin by virtue of adhesion molecules that bind to addressins on endothelial cells. Development of allergic contact dermatitis depends on the nature of the allergen, frequency of contact, and state of the skin. *Factors that damage the integrity of the protective barrier of the skin predispose to development of allergic contact dermatitis.* The induction phase is typically a prolonged process, estimated to require 6 months to 2 years to develop. While strong immunogens can elicit sensitivity after as short a period of contact as 7 to 21 days, most contact allergens are weaker immunogens and require chronic repeated exposure for sensitization to develop. Upon subsequent exposure to the contact allergen, specifically sensitized T cells in skin and circulation are presented the antigen by Langerhans cells (*elicitation phase*), become activated, and elaborate various cytokines that attract and activate other inflammatory cells and stimulate proliferation of the epidermis. Only a very small fraction (<1%) of the infiltrating T cells are specific for a relevant antigen. Thus, various amplification and recruitment mechanisms are involved in induction of the reactions. The activated T cells secrete a Th1 profile of cytokines, including IFNγ and TNFβ, which recruit and activate a wide variety of inflammatory cells, affect keratinocyte function and differentiation, and induce expression of adhesion molecules on endothelial cells and keratinocytes. TNFβ and IFNγ induce expression of ICAM-1 on keratinocytes and endothelium, which promotes homing of T cells to the dermis and epidermis. Unlike the delayed-type hypersensitivity reaction that develops in response to antigen injected into the dermis which primarily involves CD4+ cells, the response to hapten painted on the epidermis involves both CD4+ and CD8+ T cells. Local production of cytokines induces arrival of more T cells and further amplification of proinflammatory mechanisms. Irritated keratinocytes also release a variety of cytokines that induce or augment the inflammatory response.

Allergic contact dermatitis has been reported most frequently in *dogs and horses*, although most cases have not been confirmed by patch testing. Numerous *plants and chemicals* have been suspected or shown to cause allergic contact dermatitis in animals. In dogs, wandering Jew (*Tradescantia fluminensis*), spreading dayflower (*Cornelina diffusa*), doveweed (*Murdannia nudiflora*), leaves and bulbs of plants in the family Amaryllidaceae, dandelion leaves, cedar wood, and Asian jasmine have been implicated in cases of allergic contact dermatitis. Cobalt and nickel ions, pine oil resin found in cleaning products, topical medications such as neomycin, rubber, cement, and various fragrances such as those in shampoos and carpet deodorizers are a few of the chemical causes of allergic contact dermatitis in dogs and cats. In horses, pasture plants, insecticides, various dyes and preservatives of tack items, soaps, and bedding materials have been suggested as causes of allergic contact dermatitis.

The *clinical course* is typically prolonged and lesions in dogs are usually confined to sparsely haired areas of the body such as the lips, chin, ventral cervical and thoracic areas, abdomen, scrotum, perineum, and ventral interdigital skin. Foot pads are usually protected by the thick stratum corneum; however, cracking of foot pads of all four feet was a feature described in a cat with suspected allergic contact dermatitis to carpet deodorizer. Lesion distribution is also dependent on the contactant involved. *Primary lesions include erythema, papules, plaques, and vesicles*, but these are very transient and thus rarely seen. *Pruritus is variable*, ranging from mild to severe. *Chronic secondary lesions are more commonly seen and include alopecia, lichenification, scaling, crusting, excoriations, and pigmentary changes.* Secondary bacterial or fungal infection may complicate lesions.

Microscopic changes described in various reports of allergic contact dermatitis in animals have been conflicting. *Differences in histologic lesions no doubt reflect, at least in part, differences in stage of the reaction.* While neutrophils have been the predominant cell type seen in some cases, lymphocytes or eosinophils predominated in others. The epidermis may be variably spongiotic and may develop vesicles in some areas. In allergic contact dermatitis produced experimentally in dogs by topical application of 1-chloro-2,4-dinitrochlorobenzene (DNCB), histologic changes at 48 and 72 hours post-challenge included mild acanthosis, mild dermal edema, and perivascular and perifollicular infiltrations of lymphocytes and macrophages. Mild and focal to widespread and marked epidermal necrosis may occur, both in patch test reaction sites as well as in spontaneous lesions. Exocytosis of inflammatory cells is a common feature but the cells vary and may be neutrophils, lymphocytes, eosinophils or a combination thereof. The superficial dermis may be edematous and the predominant inflammatory cells may be lymphocytes, neutrophils, or eosinophils. Inflammation may be perivascular, diffuse interstitial, or lichenoid and frequently perifollicular. *The histologic changes of allergic contact dermatitis are frequently indistinguishable from those caused by irritant contact dermatitis.*

The list of *differential diagnoses* is extensive and includes a wide variety of allergic and parasitic conditions, bacterial and fungal infections, and irritant contact dermatitis. When a single animal of a group is affected, allergic contact dermatitis is considered more likely than irritant dermatitis. *Diagnosis is based on history, physical examination findings, exclusion of other dermatoses, and is confirmed by restriction followed by provocative exposure to the suspected allergen or patch testing.*

Insect hypersensitivity

Insects are cosmopolitan in their distribution and virtually all animals are exposed to them. Many insects are capable of inducing allergic reactions, including various dermatoses. *Antigens of insect* *origin that produce hypersensitivity are usually proteins and sources include venom, saliva, whole bodies, shed skins, egg capsules, feces, and insect hemoglobin.* These antigens can be introduced via the bite or sting of insects or by inhalation, ingestion, or percutaneous absorption. In general, lesions associated with insect hypersensitivity are *seasonal* or seasonally more severe and *involve short- or sparsely haired regions,* such as the nose, muzzle, pinnae, inguinal area, and distal extremities. *Lesions typically consist of pruritic crusted papules and are characterized histologically by eosinophilic inflammation.*

The most well known insect hypersensitivities of veterinary significance are those caused by an allergic reaction to salivary antigens and these are *flea-bite hypersensitivity of dogs and cats* and *Culicoides hypersensitivity of horses.* More recently, a *hypersensitivity to mosquito bites has been recognized in cats* and an *eosinophilic furunculosis of the face of dogs* is suspected to be a hypersensitivity response to the sting or bite of various insects. The first three of these conditions will be discussed in this section. Canine eosinophilic furunculosis of the face is discussed under Eosinophilic and collagenolytic dermatitides.

Flea-bite hypersensitivity is a pruritic dermatitis caused by hypersensitivity to allergens in the saliva of fleas. *It is the most common allergic dermatosis of dogs and cats in flea-endemic regions.* The cat flea, *Ctenocephalides felis felis*, is the major initiator of the condition. Since many animals harbor large numbers of fleas without any apparent skin abnormalities, it is likely that animals develop skin disease as a result of flea infestation only if they are allergic to fleas.

Both type I and type IV hypersensitivity reactions are believed to be involved in the pathogenesis of flea-bite hypersensitivity. Participation of immediate hypersensitivity is supported by the fact that clinically allergic animals develop immediate skin reactions in response to intradermal injection of flea antigen and that IgE antibodies to flea antigen are demonstrable in sera from allergic animals. Histologic evidence also supports a role for immediate hypersensitivity and suggests that cell mediated/delayed hypersensitivity is involved in the pathogenesis of flea allergy as well. Many flea allergic animals also have delayed skin test reactions, further support for a type IV hypersensitivity component. Upregulation of mast cell proteases has been demonstrated during sensitization, with selective release of mast cell tryptase after exposure to flea antigen.

No breed or sex predilections have been reported in flea-bite hypersensitivity; and in cats, no age predilection has been recognized. In dogs, disease occurs most commonly between 3 and 5 years, unless naive dogs are moved to a flea-endemic area at a later age. Disease is rare prior to 6 months. Signs tend to be more severe in summer and fall in animals living in areas with cold winters but are year-round in those living in warm regions or where indoor infestation persists. Affected individuals may have other hypersensitivity conditions, such as atopic dermatitis or food allergy.

Flea-bite hypersensitivity in **dogs** is characterized by pruritus, erythema, wheals, and papules that may become crusted. *Primary lesions are usually obscured by secondary lesions that develop in response to chronic pruritus.* These may include hyperkeratosis, lichenification, hyperpigmentation, alopecia, excoriations, redundant skin folds on the rump and caudal thighs, and seborrhea. Lesions typically involve the dorsal lumbosacral area, flanks, caudal and medial aspect of the thighs, and ventral abdomen. In severely hypersensitive dogs, lesions may become generalized. Pyotraumatic dermatitis ("hot spots") and bacterial pyoderma are common secondary complications. Firm alopecic nodules ("fibropruritic nodules") may develop on the dorsal lumbosacral region secondary to self-trauma in chronically affected dogs. Differential diagnoses include other hypersensitivity conditions (atopic dermatitis, food allergy), sarcoptic mange, cheyletiellosis, and bacterial or yeast infection.

The lesions of flea-bite hypersensitivity in **cats** are extremely variable. The most common manifestation is multiple erythematous pruritic papules covered by brown crust ("*miliary dermatitis*") on the dorsal lumbosacral area, flanks, caudal and medial aspect of the thighs, ventral abdomen, and neck. In some cats, the condition may be manifested as over-zealous grooming rather than scratching, producing alopecia that may be ventral abdominal, bilaterally symmetrical along the lateral aspect of the trunk, or dorsal lumbosacral. The skin may appear completely normal grossly or excoriations, crusts, scales, and hyperpigmented macules may be seen. Fleas or flea dirt may not be evident because of the fastidious grooming behavior typical of most cats. Eosinophilic granuloma complex lesions have also been associated with flea-bite hypersensitivity in cats. Secondary bacterial pyoderma is uncommon. Differential diagnosis is extensive because the manifestations of flea allergy are so varied in cats. *The most common differentials for miliary dermatitis include other hypersensitivity conditions (atopic dermatitis, food hypersensitivity), dermatophytosis, and cheyletiellosis.* Cases characterized by self-induced alopecia with normal appearing skin may resemble an endocrinopathy.

Histopathology is useful in confirming the suspected diagnosis of a hypersensitivity condition, but *the microscopic changes associated with flea-bite hypersensitivity are similar to those seen in other hypersensitivities and the specific diagnosis cannot be made histologically.* The epidermis is variably acanthotic and foci of spongiosis and serocellular crusting are commonly seen. Mixed orthokeratotic and parakeratotic hyperkeratosis and self-induced erosion or ulceration may be present. Foci of epidermal necrosis and intraepidermal eosinophilic pustules may be evident. The superficial dermis is mildly to moderately edematous and a perivascular to interstitial infiltration of eosinophils, lymphocytes, fewer macrophages, and mast cells is present in the superficial to mid-dermis in dogs and may extend into the subcutis in cats. The proportion of eosinophils in relation to mononuclear cells varies, with eosinophils being most numerous in early lesions and mononuclear cells predominating in more chronic reactions. Melanophages are in variable numbers and may be numerous in chronic cases with prominent lichenification. Sebaceous and apocrine glands may be hyperplastic in chronic lesions. Neutrophils are numerous in association with ulceration or bacterial infection. In cats, eosinophilic mural folliculitis and furunculosis have been seen in flea bites as have histologic lesions of eosinophilic granuloma complex.

***Culicoides* (insect) hypersensitivity** *is the most common allergic dermatosis of horses.* It occurs worldwide and *Culicoides* spp. gnats are the most common cause. The condition is known by a variety of colloquial names worldwide, including Queensland itch, kasen, dhobie itch, sweet itch, muck itch, summer itch, and summer eczema. It is a major annoyance to horse and owner and substantial economic losses can be incurred from treatment, prevention, and damage caused by scratching horses. *Culicoides* hypersensitivity is an *intensely pruritic dermatosis* that can render affected animals too restless and anxious to perform.

The insects are also called biting midges, punkies, and "no-see-ums." Hundreds of different species exist throughout the world and they vary in their favored feeding sites and time of activity. They are most active when the ambient temperature is greater than

10°C (50°F), when humidity is high, and when there is no breeze since they are weak fliers. The insects are in highest numbers in wetlands and swampy areas.

The hypersensitivity to salivary antigens of *Culicoides* gnats is thought to be mediated by *both type I and type IV hypersensitivity reactions*. Support for immediate hypersensitivity is provided by immediate skin test reactivity to *Culicoides* antigens, presence of specific IgE in affected horses, and peripheral eosinophilia and increased blood histamine concentrations during periods of insect activity. The presence of increased numbers of primarily CD4+ T lymphocytes and eosinophils in skin test reactions is also consistent with immediate hypersensitivity. Also, sulfidoleukotriene generation from peripheral blood leukocytes in response to *Culicoides* extract was increased in horses with insect hypersensitivity, indicating involvement of IgE-mediated hypersensitivity in the pathogenesis of *Culicoides* hypersensitivity. Delayed reactions (up to 48 hr) to intradermal skin tests suggest that type IV hypersensitivity may also be involved in the pathogenesis of the condition.

Culicoides hypersensitivity is typically a seasonal disease but in warm climates it may be a problem virtually year-round. Horses of any breed and either sex are affected; pedigree studies suggest there may be a genetic basis. Lesions are uncommon in horses less than 2 years old; however, in tropical and subtropical climates with a long insect season, sensitization and mild clinical disease may develop within the first year of exposure. The favored feeding sites vary with the species of *Culicoides* endemic to a particular environment, accounting for the varied distribution of skin lesions. Distribution may be dorsal and involve the head, ears, neck, withers, back, and tailhead; or it may be primarily ventral and involve the intermandibular space, legs, and ventral midline. In some areas, such as Florida in the USA, multiple species of *Culicoides* are active at different times and have different favored feeding sites such that disease may be generalized. The *primary lesions are pruritic papules* that may be recognized initially by clusters of erect hairs and commonly become encrusted. Because of severe pruritus, however, self-mutilation obscures the primary lesions and results in *more commonly observed secondary lesions such as excoriations, crusts, lichenification, pigmentary changes, broken hairs, alopecia, and a short stubbled tail ("rat tail")* (Fig. 5.67). The mane may be rubbed off and the skin over the neck and withers may become thickened and rugose. Lesions typically heal during winter and recur in spring or summer and commonly worsen with age. Affected horses may scratch and bite themselves and rub objects in their environment, thereby causing damage to themselves, their riders, and environmental objects. Constant anxiety and restlessness may prevent severely affected animals from performing as riding or show animals. Also, since sweating exacerbates pruritus, affected horses cannot be worked vigorously. The differential diagnoses include ectoparasitism and other hypersensitivity dermatoses. The *diagnosis* is based on seasonality of the condition, location and appearance of lesions, sporadic occurrence of the condition in a group, eliminating other diseases, and response to therapy.

The *histologic lesions* of *Culicoides* hypersensitivity are typically *superficial or superficial and deep perivascular dermatitis consisting of eosinophils and lymphocytes primarily*. The epidermis is variably acanthotic, spongiotic, and hyperkeratotic with foci of parakeratosis, and may be focally necrotic. Increased numbers of T lymphocytes and Langerhans cells are present in the basal portion of the epidermis. Erosions and ulceration may be present as a result of self-trauma and are associated with neutrophilic inflammation. The dermis is variably edematous and increased numbers of mast cells, which may be degranulated, are present. In some cases, eosinophilic inflammation is diffuse and collagen degeneration or eosinophilic folliculitis may also be seen.

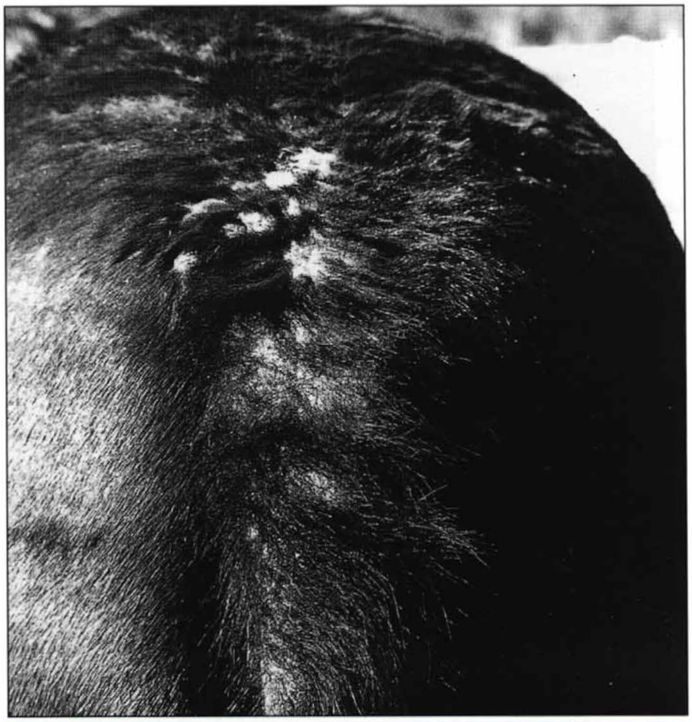

Figure 5.67 ***Culicoides* hypersensitivity** in a horse. Alopecia, crusting and scaling at the tail head ("rat tail").

A seasonal pruritic dermatosis attributed to *Culicoides* hypersensitivity has also been described in *cattle, sheep, and donkeys*. Affected sheep were 2–5 years of age and had an intensely pruritic, exudative dermatitis with loss of wool and marked skin thickening of the abdomen, udder, teats, and legs. Lesions in adult dairy cattle consisted of marked thickening and folding of the skin of the head, ears, and neck. Donkeys developed exudative dermatitis, alopecia, crusting, and skin thickening of the legs and head. Affected animals were restless and often bit at themselves, suggesting that they were intensely pruritic. Histologic examination of biopsies from affected sheep and cows showed primarily an eosinophilic dermal infiltrate.

Mosquito-bite hypersensitivity dermatitis has been documented in the Mosquito-bite dermatitis section.

Hormonal hypersensitivity

Pruritic dermatitis resulting from hypersensitivity to endogenous sex hormones is recognized in women ("autoimmune progesterone dermatitis") and is *very rare in dogs*. Results of intradermal skin tests with aqueous progesterone in women indicate that type I (immediate) and/or type IV hypersensitivity are involved. *Most canine cases are in intact females, frequently with a history of irregular estrus or recurrent pseudopregnancy*. The condition is characterized by *intense pruritus* that develops or is exacerbated near the time of estrus or pseudopregnancy but tends to become more severe and protracted with each episode; pruritus is generally perennial in male dogs. Bilaterally symmetric erythema and crusted papules typically begin in the dorsal lumbosacral, perineal, genital, and caudomedial thigh areas and progress cranially. In chronic cases the condition is generalized and the skin becomes alopecic and lichenified. Pruritus is usually unresponsive to glucocorticoid treatment. Differential diagnoses include other allergic conditions and sarcoptic mange. The microscopic lesion is a hyperplastic superficial perivascular dermatitis in which neutrophils, mononuclear cells, or eosinophils may predominate. *Diagnostic clues include poor response to glucocorticoid therapy and development or exacerbation of cutaneous signs coincident with estrus or pseudopregnancy*. Gonadectomy is curative.

Intestinal parasite hypersensitivity

Hypersensitivity to intestinal parasites has been suspected of causing pruritic dermatoses in *dogs, cats, horses, and humans*. The pathomechanism is unknown but a type I hypersensitivity reaction has been proposed. *Ascarids, coccidia, hookworms, tapeworms, and whipworms have rarely been associated with pruritic dermatoses that resolve with elimination of the intestinal parasites*. Lesions that have been attributed to intestinal parasite hypersensitivity include multifocal or generalized papulocrustous eruptions, pruritic seborrheic disease, pruritic urticaria, and pruritus without skin lesions. The histologic changes described are superficial perivascular dermatitis with variable numbers of eosinophils, ranging from few to many. Diagnosis is based on fecal examination and resolution of the skin lesions following appropriate parasiticidal therapy.

Autoimmune dermatoses

The autoimmune skin diseases are *uncommon to rare* but merit detailed consideration as many are debilitating to life-threatening and require specific therapy. *Their characteristic microscopic lesions combined with clinical information and careful interpretation of ancillary studies often enables a specific diagnosis to be made*. In the vast majority of cases, the stimulus triggering the aberrant T or B cell responses against self-antigens is unknown. Drug therapy, underlying neoplasia (see Paraneoplastic pemphigus, p. 652), tissue injury, infectious diseases, other autoimmune diseases, and genetic makeup are all factors known to be associated with the occurrence of autoimmune diseases. Penicillinamine, for example, may precipitate clinically, histologically and immunologically classical cases of pemphigus in humans, which regress when the drug is withdrawn. Drug-induced forms of pemphigus are thought to be the result of haptenization of keratinocyte antigens rendering them immunogenic. One theory suggests environmental agents, such as drugs, influence T cells by causing DNA methylation abnormalities that, in turn, alter gene expression. Exposure to ultraviolet light is known to exacerbate cutaneous autoimmune disease perhaps by inducing keratinocyte ICAM-1 expression and keratinocyte production of pro-inflammatory cytokines. Still another theory suggests that the structural similarities of peptide fragments of some infectious agents to host proteins may trigger post-infectious autosensitization.

The recognition that one autoimmune disease, tissue injury, inflammatory or neoplastic process in an individual may precede the onset of cutaneous autoimmune disease led to investigation of the phenomenon termed "*epitope spreading*." Epitope spreading refers to the process by which the targets of the autoimmune response do not remain fixed but drift to include other epitopes on the same protein or nearby proteins of the same tissue. This may account for regional variations in pemphigus antigen expression and the clinical variation of cutaneous autoimmune diseases. Epitope spreading may also account for aberrant immune responses developing to tissue antigens after the tissue has been injured, possibly leading to the release or exposure of a previously sequestered antigen.

Selection of fresh lesions is crucial to diagnosis. Demonstration of tissue-bound or circulating autoantibody using appropriate immunological tests may be helpful in confirming the diagnosis of an autoimmune skin disease. However, such tests (e.g., direct and indirect immunofluorescence testing, immunohistochemistry) are fraught with interpretation pitfalls (false-positive or false-negative test results) and should

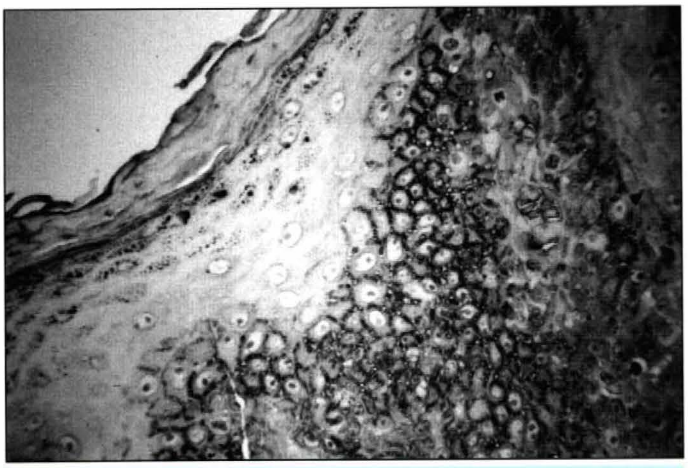

Figure 5.68 Immunoperoxidase stain of **pemphigus complex**. Note diffuse intense labeling of intercellular bridges.

never be interpreted in the absence of histologic examination. Demonstration of autoantibodies does not necessarily confirm causative roles for these antibodies, just as negative results do not necessarily exclude the diagnosis of a cutaneous autoimmune disease. For example, the various entities of the pemphigus complex are characterized by the deposition of immunoglobulin, with or without complement, on the surface of keratinocytes or at the basement membrane zone using the techniques of direct immunofluorescence (IF) testing or immunohistochemistry (IHC) (Fig. 5.68). Unfortunately, false-negative (poor lesion selection, prior glucocorticoid therapy) and false positive (any dermatosis in which spongiosis or numerous lymphocytes and plasma cells are present) reactions are frequent. In addition, normal epithelium of the canine nasal planum and footpad often label nonspecifically. Hence, *these immunopathological tests can only be interpreted in the light of clinical and histopathological findings*. Indirect immunofluorescence testing has variable usefulness in domestic animals with pemphigus as results may be falsely negative or "pemphigus-like" antibodies can be occasionally found in non-pemphigus diseases. Recent studies indicate indirect IF testing for canine PF is useful provided the appropriate substrate (bovine esophagus) is used. In many of the putative cases of autoimmune skin disease in animals, the criteria for autoimmunity have not been met fully.

Autoimmune diseases characterized by vesicles, pustules, or bullae as the primary lesion

The pemphigus complex

Pemphigus refers to *a group of autoimmune skin diseases characterized clinically by pustules, vesicles, bullae, erosions and ulcers and histologically by loss of adhesion between cells (acantholysis)*. Autoantibodies directed against antigens within various stratified squamous epithelia, including skin, mucocutaneous junctions, oral mucosa, esophagus, and vagina, develop and can be detected via immunologic assays. *Different types of pemphigus are recognized based on the level at which acantholysis occurs within the epidermis, and the clinical and immunological findings*. Autoantibodies are directed against components of keratinocyte transmembrane glycoproteins responsible for keratinocyte cell-to-cell adhesion (desmosomes) or cell-to-substrate adhesion (hemidesmosomes). Desmosomes are more numerous in the more superficial layers of the epidermis and vary in protein subunit composition. Hemidesmosomes are present on the basal surface of the basal layer of the epidermis. Vesicles, pustules, or bullae form within the various layers of the epidermis or at the basement membrane zone according to the location of the target antigen. Severity of clinical disease is related to the depth of vesicle or bullae formation, with the more severe lesions associated with separations deep within or below the epidermis. The mechanisms leading to acantholysis are not completely understood. Antigen-antibody binding may result in a type II immune reaction or promote proinflammatory cytokine release from keratinocytes. The binding of pemphigus autoantibodies to keratinocyte antigens is associated with the synthesis and secretion of urokinase-type plasminogen activator (uPA), a serine protease that activates plasminogen. Activation of plasminogen may indirectly induce the cleaving of intercellular contacts. Anti-uPA antibodies or the specific inhibitor of uPA, plasminogen activator inhibitor type-2, inhibit lesion formation in vitro. Another hypothesis proposes that the binding of autoantibodies to keratinocyte antigens may disrupt the structural integrity of the adhesion molecule. Experimental studies in mice have demonstrated that acantholysis in pemphigus foliaceus (PF) can occur with passive transfer of PF IgG autoantibody as well as with transfer of Fab fragments and $F(ab')_2$ fragments in both complement-sufficient and complement-deficient mice.

Pemphigus foliaceus (PF) is the *most common form of pemphigus in domestic animals* and has been reported in the *dog, cat, horse, and goat*. In humans, PF autoantibodies recognize the desmosomal protein, *desmoglein 1*. Desmoglein 1 autoantibodies have also been identified in dogs, but autoantibodies to other keratinocyte antigens and to the basement membrane have also been identified, indicating that PF, at least in the dog, may be an immunologically heterogeneous disease. Desmoglein 1 belongs to the cadherin family of cell-adhesion molecules, and is found primarily in the upper layers of the epidermis and in only small amounts in the oral mucosa. In PF, the acantholytic process occurs at a superficial level in the epidermis producing clinical lesions that are *typically exfoliative rather than obviously erosive or ulcerative.* There is no sex predilection in **dogs**, but Akitas, Chow Chows, Bearded Collies, Collies, Chinese Shar-Peis, Dachshunds, Newfoundlands, Doberman Pinschers, Schipperkes, English Springer Spaniels, and Appaloosa horses appear predisposed. In dogs, most cases occur prior to 5 years of age. The gross lesions are similar in all species and are usually cutaneous and involve mucosa only rarely, as mucosal epithelium has desmoglein 3 as a prominent superficial adhesion molecule rather than desmoglein 1. Lesions may wax and wane. Erythematous macules give rise to transient pustules that rupture to form very shallow erosions that become covered by thick crust and scale. Alopecia is often marked. *Lesions in the dog and cat tend to appear first on the nose and spread to periorbital areas, the ears, neck and ventral abdomen.* Involvement of the feet may produce marked papillary hyperkeratosis and crusting of the footpads, and there is a *predilection for the nail beds*, occasionally leading to sloughing of nails. In **cats**, lesions are often seen around the nipples in addition to lesions on the face and ears (Fig. 5.69A). PF is the most common autoimmune skin disease in **horses;** lesions often begin on the face or distal extremities, or may be localized to coronets. In any species, the lesions may become generalized (Fig. 5.69B, C). Foals may also be affected with a benign form of PF that responds rapidly to treatment or may resolve spontaneously. Pain and pruritus may be present.

The histologic pattern of pemphigus foliaceus is an acantholytic subcorneal (see Figs. 5.1 and 5.17) *or intragranular pustular dermatitis.* Either neutrophils or eosinophils may predominate. At the base of the pustule, acantholytic keratinocytes continue to detach and enter the pustule. Ruptured pustules form a thick inflammatory crust in which acantholytic cells are prominent. The external root sheath of the hair follicle undergoes a similar acantholytic process. Dermal infiltrates consist of mild perivascular to interstitial neutrophils or eosinophils. There is dermal edema, vascular congestion and occasionally, hemorrhage. Rarely, a lichenoid inflammatory infiltrate is seen. *Deposition of IgG at intercellular bridges in all layers of the suprabasilar epidermis or in the superficial epidermis demonstrated by IF or IHC is characteristic, but not specific, for PF.* Secondary bacterial infection may complicate lesions. *The primary differential for PF is superficial bacterial folliculitis.* Acantholytic cells are more numerous and can more often be found in rafts in PF than in superficial folliculitis. *The "cling-on" stratum granulosum cells are only present in PF.* In PF, pustules also span the interfollicular epidermis encompassing multiple follicles whereas in superficial folliculitis pustules are more likely to be centered on single follicles. Evidence of recornification and reformation of pustules is often prominent in PF. Dermatophytosis and superficial pyoderma (impetigo) can also have similar gross and histologic lesions. Careful examination of skin sections with fungal and bacterial stains and possibly cultures may be needed for differentiation. Impetigo does not involve hair follicles whereas PF may.

Panepidermal pustular pemphigus (PPP) refers to a form of pemphigus in the dog that encompasses some of the features of **pemphigus foliaceus, pemphigus vegetans,** and **pemphigus erythematosus**, previously thought to be distinct entities. It is similar to pemphigus foliaceus in that lesions develop in the superficial epidermis, however, lesions are not restricted to the superficial layers of the epidermis so it does not neatly fit the same criteria as PF. Immunological studies have not definitively documented the presence of autoantibodies to desmosomal or hemidesmosomal proteins in PPP, but studies evaluating autoantibody epidermal binding patterns in dogs with PF have identified four main IgG intercellular epidermal patterns. One pattern indicates that antibodies to desmoglein 1 are present as they are in PF. Other IgG autoantibodies have been detected against intracellular keratinocyte antigens in

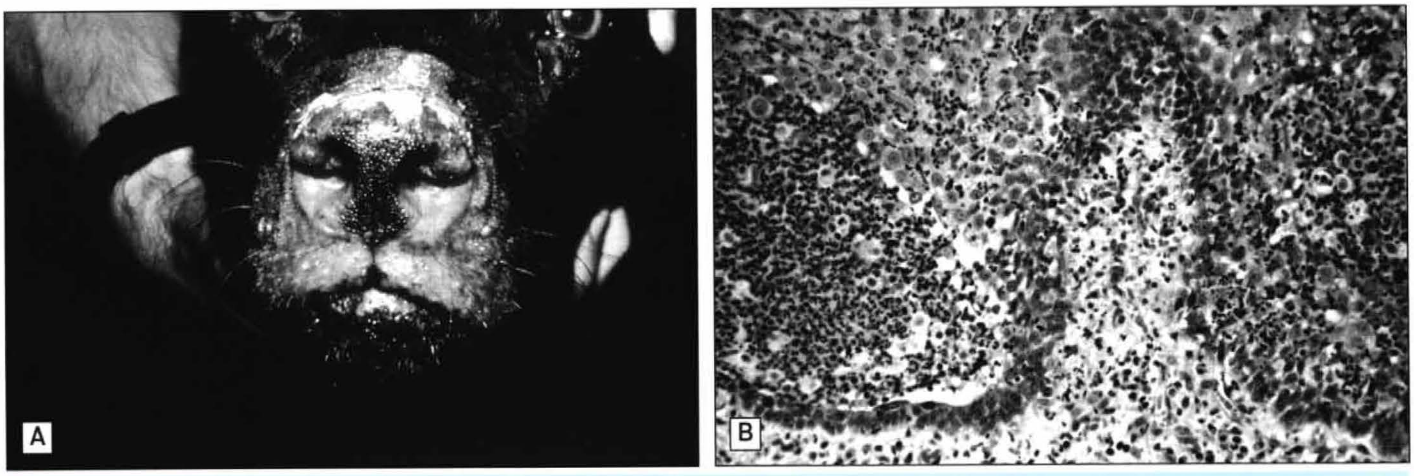

Figure 5.70 Panepidermal pustular pemphigus. (Courtesy of B Dunstan.) **A.** Scaly and crusted plaques and papules of the skin of the face and nasal planum. **B.** Pustules are present at several levels of the surface epithelium, including the suprabasal layers.

the stratum basale, spinosum, granulosum, and corneum, and basement membrane, substantiating the immunologically heterogeneous characteristics of pemphigus subtypes in the dog. These autoantibody binding patterns help to explain the variable location of epidermal pustules in subtypes of canine PF. *Original designations of pemphigus vegetans and pemphigus erythematosus in animals were based on similarities to the human conditions. Further studies suggest the conditions are not directly comparable.* Pemphigus erythematosus was considered to be a variant of PF with a facial or "lupus" lesion distribution occurring in dogs and cats. Criteria for diagnosis and differentiation from PF were dependant upon the immunological demonstration of both a diffuse cell surface IF or IHC pattern typical of the pemphigus group and a linear band of immunoglobulin, with or without complement, deposited at the basement membrane zone. For reasons previously stated, IF and IHC are not dependable. Reported cases of pemphigus vegetans in veterinary patients are very limited and originally thought to be benign variants of pemphigus vulgaris. The lack of clear clinical or histologic distinction between pemphigus vegetans and pemphigus erythematosus in the dog has led to the new inclusive entity of PPP by some veterinary dermatopathologists; however, *classification is controversial.* Some veterinary dermatopathologists also consider PPP to be a subtype of PF. Differentiation of PPP from typical cases of PF is discussed below.

PPP is less common than PF, but more common than PV. Akitas and Chow Chows are predisposed to develop both PPP and PF. In most cases, lesions first appear on the head in a symmetrical distribution involving the medial canthi of the eyes ("lupus distribution") and inner surfaces of the pinnae and nasal planum (Fig. 5.70A). The condition may remain localized to the head or proceed to the prepuce, abdomen, nail beds, and footpads. Some cases become generalized. *Gross lesions* are characterized initially by *erythematous macules* leading to *vesiculopustular lesions* resembling those of PF. Over time however, *the lesions progress to proliferative, scaly and crusted plaques or papules. Verrucous vegetations studded with small pustules are characteristic.* Depigmentation of the nasal planum may develop. The predominant *histologic lesions* are *numerous large, intraepithelial pustules composed of eosinophils, neutrophils and a few to large numbers of acantholytic epithelial cells.* These pustules occur at several levels through the surface epithelium, down to the suprabasal layers and also involve the infundibular outer root sheath (Fig. 5.70B). An eosinophilic to neutrophilic intra-infundibular mural folliculitis may be present. In mature lesions, there is papillated epidermal hyperplasia. The dermis has a perivascular to interstitial mixed infiltrate with eosinophils. Biopsies from the mucocutaneous junction or the nasal planum may be intensely plasmacytic and lichenoid. IFA or IHC may demonstrate immunoglobulin at intercellular bridges and/or the basement membrane zone, however results can be variable. *Histologic differentials* include *predominantly facial PF, discoid or systemic lupus, mycosis fungoides, pyoderma or bacterial folliculitis, dermatophytosis, and the uveodermatologic syndrome.* In PF, pustules are restricted to the stratum granulosum and stratum spinosum; in PPP, they occur in the deeper layers of the epidermis. PPP is also very proliferative compared to PF.

Pemphigus vulgaris *is the most severe and the more rare form of pemphigus in animals.* This life-threatening disease has been reported in the *dog, cat, horse, goat, monkey, and llama.* There are no apparent breed or sex predilections. Middle-aged **dogs** are most commonly affected. In humans and dogs, pemphigus vulgaris autoantibodies recognize the desmosomal protein, desmoglein 3. Desmoglein 3 also belongs to the cadherin family of cell-adhesion molecules and is most prominent in the area of the basal layer of keratinocytes of the epidermis and mucosal epithelium, hence lesions occur deeper in the epidermis and in the oral mucosa.. Desmoglein 3 is not a component of hemidesmosomes. The *fragile vesicles or bullae in the epidermis are extremely transient and readily rupture* to leave the more common presenting lesion of a roughly circular, shallow, flat-based erosion or ulcer. The margins often develop epidermal collarettes. Firm sliding pressure to adjacent unaffected skin may induce fresh vesicle formation or dislodge the skin (*the Nikolsky sign*). Lesions involve mucous membranes (Fig. 5.71A), mucocutaneous junctions and skin in the mechanically stressed areas such as the inguinal and axillary regions. Oral involvement is present in 90% of cases, and in 50% of cases the lesions commence in the mouth. Involvement of the nailbeds occurs also and corneal ulceration may be present. Animals may be febrile, depressed, and anorectic and have leukocytosis. Drooling is often a presenting complaint.

a variant of PV with IgG autoantibodies directed against plakin proteins and desmogleins 1 and 3 has been documented in the dog. Previously, autoantibodies to plakin proteins were thought to be unique to pemphigus associated with occult neoplasia (see Paraneoplastic pemphigus, p. 652).

Clinical differentials include bullous pemphigoid, erythema multiforme, toxic epidermal necrolysis, systemic lupus erythematosus, idiopathic ulcerative dermatosis of Collies and Shetland Sheepdogs, mycosis fungoides, and other diseases resulting in oral ulcers. Histopathologic findings of primary lesions in PV are diagnostic.

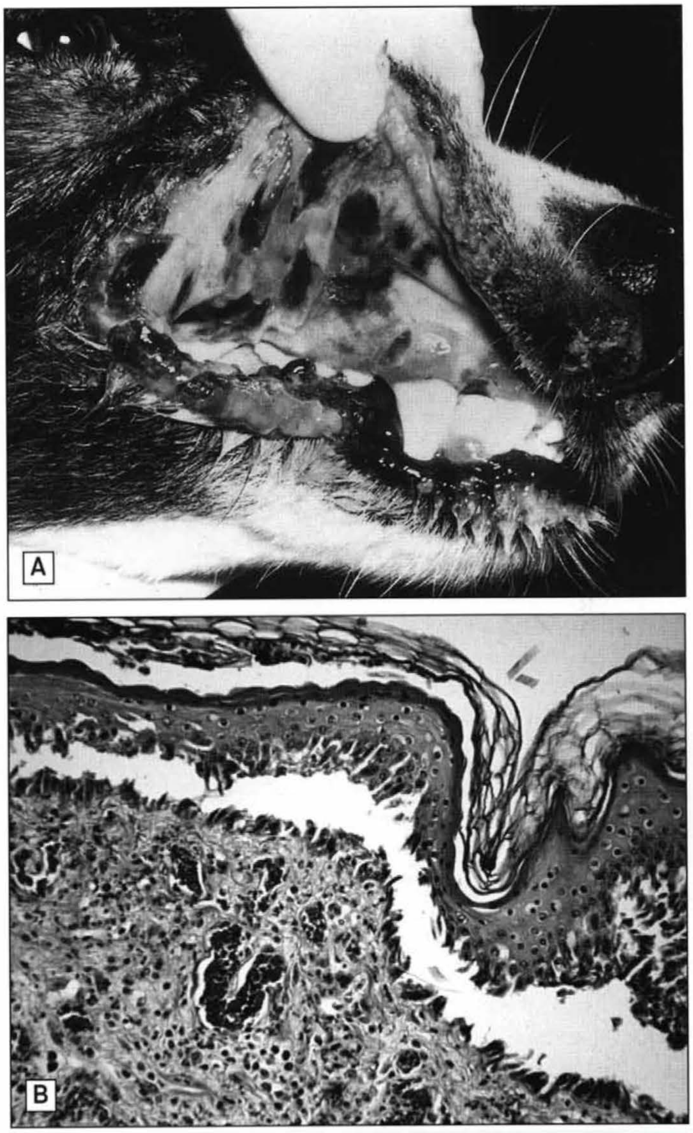

Figure 5.71 Pemphigus vulgaris. A. Flaccid bullae in oral mucosa. (Courtesy of Parker WM. and Can Vet J.) **B.** Separation of the epidermis occurs between the stratum spinosum and stratum basale. Basal keratinocytes also lose intercellular contact leaving the basal layer arranged to resemble a "row of tombstones." (Courtesy of B Dunstan.)

Microscopically, *the earliest lesions consist of spongiosis and vacuolation of the suprabasilar epidermis progressing to suprabasilar acantholysis with intraepidermal clefts, vesicles or bullae between the stratum basale and the stratum spinosum* (Fig. 5.71B). The basal keratinocytes, although separated from each other following disruption of intercellular contacts, are anchored to the basal lamina resembling a "row of tombstones." The outer layers of the epidermis form the roof of the vesicle that may contain a few acantholytic keratinocytes, singly or in clumps, but few or no inflammatory cells. The process may extend into the hair follicle epithelium. The dermal reaction in haired skin varies from a mild superficial perivascular to interstitial accumulation of mononuclear cells and eosinophils. A moderately intense lymphocytic-plasmacytic interface infiltrate may be present in mucosal lesions. The immunological pattern of labeling for autoantibodies with IFA or IHC is similar as that for PF. Recently,

Bullous pemphigoid

Bullous pemphigoid is *a chronic, autoimmune skin disease characterized clinically by vesicles, bullae and ulcers, and histologically by subepidermal vesicles/bullae containing eosinophils or other leukocytes*. In humans, the autoantibodies are directed against bullous pemphigoid antigen 1 (BPAG1, a 230-kDa intercellular antigen) and bullous pemphigoid antigen 2 (BPAG2, also called type XVII collagen, a 180-kDa hemidesmosomal transmembrane molecule). In animals, only BPAG2 has been identified. The mechanism of dermoepidermal separation is thought to be the result of the release of proinflammatory cytokines IL-1, IL-5, IL-6, IL-8 and others by keratinocytes altered by antigen-antibody interactions. Cytokines recruit neutrophils and eosinophils leading to the release of damaging proteases. Separation of basal cells from the underlying dermis may also be the direct result of

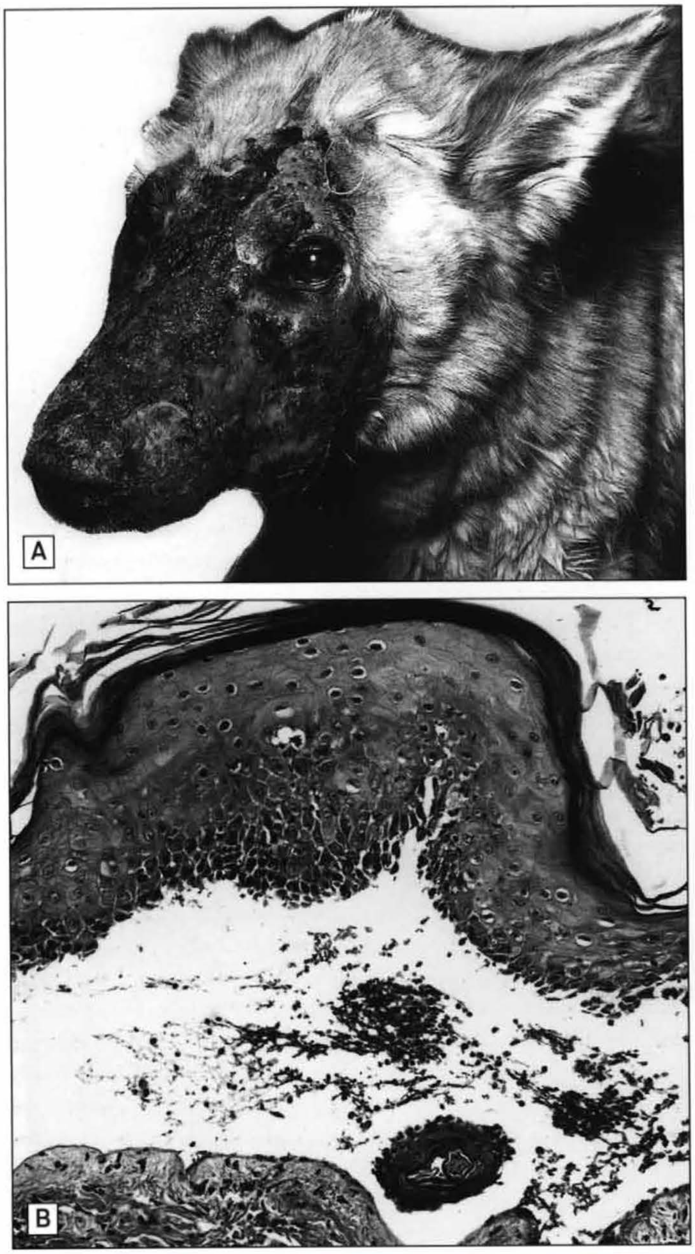

Figure 5.72 Bullous pemphigoid in a dog. **A.** Severe ulcerative facial lesion. **B.** Subepidermal vesiculation. The basement membrane zone forms the floor of the vesicle. Note the lack of acantholysis.

disorganization or internalization of components of the hemidesmosomes. In almost all cases, the stimulus triggering the immune response is unknown, although drugs may precipitate clinically, histologically and immunopathologically classical cases of pemphigoid that regress when the drug is withdrawn. Exposure to ultraviolet light is known to exacerbate bullous pemphigoid.

Bullous pemphigoid occurs in *dogs, cats, pigs, and horses*, with no apparent age or sex predilection. *Collies* appear predisposed. The gross lesions are vesiculobullous, ulcerative and crusted in nature. Grossly, bullous pemphigoid is usually indistinguishable from pemphigus vulgaris. In **dogs**, the lesions affect mucous membranes, particularly of the oral cavity, mucocutaneous junctions, and skin of the face, ears, axilla, groin, and paws (Fig. 5.72A). In **cats**, lesions may be more commonly present on the commissures of the lips, oral mucosa, and hairless regions of the concave aspect of the pinnae. In **horses**, the lesions are often generalized with marked sloughing of the oral mucosa and signs of systemic illness. Lesions on the rump and back characterize the disease in **Yucatan mini-pigs**. Mucosal lesions in pigs have not been described.

Histologically, there is *a subepidermal bulla filled with fibrin and variable numbers of neutrophils, eosinophils and mononuclear cells* (Fig. 5.72B). Eosinophils are not always present as they are in lesions of humans. *Acantholytic keratinocytes are not present.* The basal cells that line the roof of the bulla are not initially degenerate. The basement membrane zone lines the floor of the bulla as separation occurs within the lamina lucida. There is often marked subepidermal vacuolar alteration. The dermis is usually markedly edematous, capillaries are dilated and lined with swollen endothelial cells, and there is perivascular accumulation of neutrophils, eosinophils and mononuclear cells. Mild to moderate lichenoid interface dermatitis may be present, particularly in mucocutaneous regions. *Histologic differential diagnoses* include pemphigus vulgaris, systemic lupus erythematosus, epidermolysis bullosa, toxic epidermal necrolysis, and thermal burns.

Classically, bullous pemphigoid is characterized by the presence of *immunoglobulin (IgG, M, or A) and/or complement deposited at the basement membrane zone* within skin lesions. The BP180 antigen extends to the lateral and apical aspects of basal keratinocytes and labeling may extend to these areas. Serum autoantibodies may be detected in some cases.

Linear IgA disease in dogs

Linear IgA disease (LAD) *is an acquired autoimmune subepidermal blistering disease occurring in humans and recently characterized in the dog.* IgG and/or IgA autoantibodies against LAD-1, defined as the processed extracellular domain of type XVII collagen, are demonstrable at the basement membrane zone of lesional skin and in the serum of affected dogs and humans. It is interesting to note the bullous pemphigoid (BP) antigen is also type XVII collagen, however in BP, antibodies recognize the transmembrane form of type XVII collagen. Clinically, LAD is characterized by erosions, ulcers, and crusts on the face, extremities, and in the oral cavity. Histologically, dermoepidermal clefting with little or no neutrophilic infiltration is present. *Differential diagnoses are similar to those listed for BP and TEN.* Differentiation of LAD from other subepidermal blistering diseases requires demonstration of linear IgA deposits at the basement membrane zone of skin lesions as well as identification of circulating autoantibodies against the target antigen, LAD-1. Too few cases have been documented in the dog to define the prognosis.

Epidermolysis bullosa acquisita in the dog

Epidermolysis bullosa acquisita (EBA) is a subepidermal blistering disease characterized by vesicle formation in areas of concurrent neutrophilic superficial dermatitis. The condition has been reported in dogs and humans. Circulating and tissue-bound autoantibodies targeting the distal end of anchoring fibrils in the sub-lamina densa of the lower basement membrane zone have been demonstrated using immunofluorescence and immunoelectron microscopy. The actual target antigen has been shown to be the amino-terminal globular noncollagenous domain of type VII collagen. Clinical lesions in the dog are characterized by erythematous and urticarial eruption with vesicles, bullae, or ulcerations arising in areas subject to friction, including oral ulcerations. Histologically, dermoepidermal separation is present in association with marked neutrophilic inflammation in the superficial dermis and within the vesicles and bullae. Too few cases have been documented to provide information regarding triggering events or clinical outcome. Differentials include those listed for BP.

Paraneoplastic pemphigus

Paraneoplastic pemphigus (PNP) is an aggressive form of pemphigus most often associated with solid or hematopoietic neoplasia. One case in a dog could not be associated with an underlying neoplasm, so it is possible for the condition to occur in the absence of underlying neoplasia. PNP has been documented in *humans and dogs*. Cutaneous lesions may precede detection of the neoplastic process. The condition is resistant to treatment.

Lesions consist of *severe mucosal and mucocutaneous blistering and erosions*. Histologically, lesions have a combined pattern of erythema multiforme and suprabasilar acantholysis characteristic of pemphigus vulgaris. Lymphohistiocytic, lichenoid interface dermatitis and apoptosis of keratinocytes with lymphocytic satellitosis throughout the epidermis are characteristic. Immunologically, labeling of intercellular bridges and/or basement membrane is detected by IHC or IFA staining. Direct immunofluorescence studies implicate autoantibodies to a 190 kDa protein, the 210 and 250 kDa desmoplakin proteins, and to the 230 kDa BPAGI, one of the bullous pemphigoid antigens. Not all cases with the above described lesions and autoantibodies have underlying neoplasia. Histologic differentials include PPP and those listed for PV and BP.

Lupus erythematosus

Lupus erythematosus occurs in two forms: *systemic lupus erythematosus*, affecting multiple tissues including the skin, and *discoid lupus erythematosus* that is localized to the skin. While the two conditions share cutaneous lesions and certain immunological abnormalities, it is not certain that the one is a localized form of the other. Progression of discoid lupus to systemic lupus rarely, if ever, occurs.

Systemic lupus erythematosus (SLE) is a multisystem disease characterized by abnormalities in both the humoral and cellular immune systems. In the active state in the dog, lymphopenia with a marked decrease in percentage and absolute numbers of CD8+ cells and a decrease in absolute numbers of CD4+ cells occurs. The resulting CD4+:CD8+ ratio is increased from approximately 2.3 in the normal dog to almost 6 in dogs with active SLE. This ratio corrects with response to appropriate therapy. T-cell subset imbalances result in altered immune regulation and B cell hyperactivity. General failure of immune autoregulation, including defects of suppressor T-cell function and dysregulation of endogenous cytokines such as IL-6, results in the *production of antibodies against a variety of membrane and soluble antigens*. The most characteristic of these are the antinuclear antibodies directed against double-stranded DNA, RNA, nucleoprotein and histone-related antigens. Antibodies are also detected against erythrocytes, leukocytes, platelets, organ-specific antigens, clotting factors and IgG (rheumatoid factor). While some of these antibodies may be responsible for tissue injury, *the main tissue damage is effected by the antigen-antibody complexes that deposit at various sites throughout the body and incite a type III hypersensitivity reaction*. In the skin, the antigen-antibody complexes are located under the basement membrane zone of the epidermis and to a lesser extent in the walls of the dermal blood vessels. *Ultraviolet light exacerbates lesions* presumably by inducing the translocation of antigens normally expressed only intracellularly, such as extractable nuclear antigens, to the keratinocyte cell membrane. Specific autoantibodies to these antigens attach to keratinocytes and induce keratinocyte death by antibody-dependent cellular cytotoxicity mediated by lymphocytes or monocytes. Injured keratinocytes then release a plethora of cytokines including IL-1, IL-2, IL-6, and TNFβ with the resultant localization of the lymphohistiocytic infiltrate and increased B-cell activity. Other studies suggest ultraviolet radiation induces ICAM-1 expression, which in turn promotes release of TNFα. ICAM-1 is the major ligand for LFA-1, an adhesion molecule found on all leukocytes.

Canine and **feline** SLE occurs without clear age or sex predilections. Most dogs are middle-aged at the time of diagnosis. In humans, there is a clear preponderance of SLE in females, whereas one canine study found male dogs were more commonly affected. Collies, Shetland Sheepdogs, German Shepherd Dogs, and Siamese, Persian, and Himalayan cats appear predisposed. SLE is a chronic condition that *may wax and wane*, and clinical signs may appear sequentially rather than simultaneously, confounding the diagnosis. Sex hormones and nutrition are known to modulate disease activity. Drug administration, pregnancy, prolonged exposure to extreme heat or cold, and excessive exposures to UV radiation have been known to trigger onset of SLE. *Polyarthritis, fever of unknown origin, anemia, thrombocytopenia, stomatitis, glomerulonephritis, and dermatitis are the most common manifestations.* Polymyositis, lymphedema, and neurological signs may also be present. Dermatological signs occur in $\sim 1/3$ of affected dogs and cats. Skin lesions tend to occur in areas exposed to sunlight such as the face, ears, nose, lips, and sparsely haired, lightly pigmented, thin skin of other body regions (Fig. 5.73A). Footpads may be hyperkeratotic or ulcerated. Nail beds may be involved. *Gross skin lesions are extremely variable*, from a mucocutaneous, ulcerative dermatitis resembling pemphigus vulgaris and bullous pemphigoid to erythema, scaling and alopecia of little specificity. A bullous form of SLE with IgG autoantibody against collagen VII has been reported in the dog and found to be similar to the condition in humans. Secondary bacterial pyodermas are common. Occasionally, dogs develop a symmetrical scaling, erythematous and alopecic maculopapular lesion extending over the bridge of the nose onto the cheeks, resembling in distribution the classical malar rash of human systemic lupus.

The most common presenting sign in **horses** with SLE is *a sharply demarcated zone of depigmentation of the skin around the eyes, lips, nostrils, genitalia and skin of the perianal and perineal regions.* Depigmentation may be gradual or rapid and may be accompanied by erythema and scaling. Additional lesions reported have included lymphedema of the extremities, panniculitis, alopecia, and scaling of the face, neck, and trunk, and generalized exfoliative dermatitis. Systemic signs such as polyarthritis, anemia, thrombocytopenia, proteinuria, fever and weight loss may also occur in the horse, but are not common.

The microscopic lesions of SLE are variable. The critical diagnostic pattern is lichenoid interface dermatitis with hydropic degeneration of basal cells and a lymphohistiocytic to plasmacytic infiltrate at the dermoepidermal junction (Fig. 5.73B). Lymphocytes predominate. *Apoptosis of basal keratinocytes and pigmentary incontinence, a consequence of the basal cell degeneration, are diagnostically helpful histologic lesions, as is marked subepidermal vacuolar change* (Fig. 5.73C). Occasionally, this change or a leukocytoclastic vasculitis may lead to cleft or bulla formation between the dermis and epidermis. The same changes often affect follicular epithelia. A *subepidermal bullous form of SLE* with documented circulating IgG autoantibodies to type VII collagen as well as IgG deposits at the basement membrane zone has also been reported in a dog. In the acute cutaneous lesions of SLE, there is moderate to marked dermal edema, capillary dilation, extravasation of leukocytes and erythrocytes and variable lymphohistiocytic infiltrates around vessels of superficial and deep capillary plexuses. Mucinous degeneration may be prominent. As the lesion becomes chronic, there is focal thickening of the basement membrane zone reflecting accumulation of antigen-antibody complexes. Fibrinoid deposits may also occur around superficial blood vessels. Occasionally leukocytoclastic vasculitis develops. Other lesions include ortho- or parakeratotic hyperkeratosis, epidermal hyperplasia, dyskeratosis, adnexal atrophy and dermal fibrosis. Although some follicles may atrophy over time, other follicles in anagen are typically present. Immunoglobulin and complement deposition at the basement membrane zone may be detectable by IF or IHC staining. An ANA titer of >256 is present in 97–100% of dogs with SLE but is not

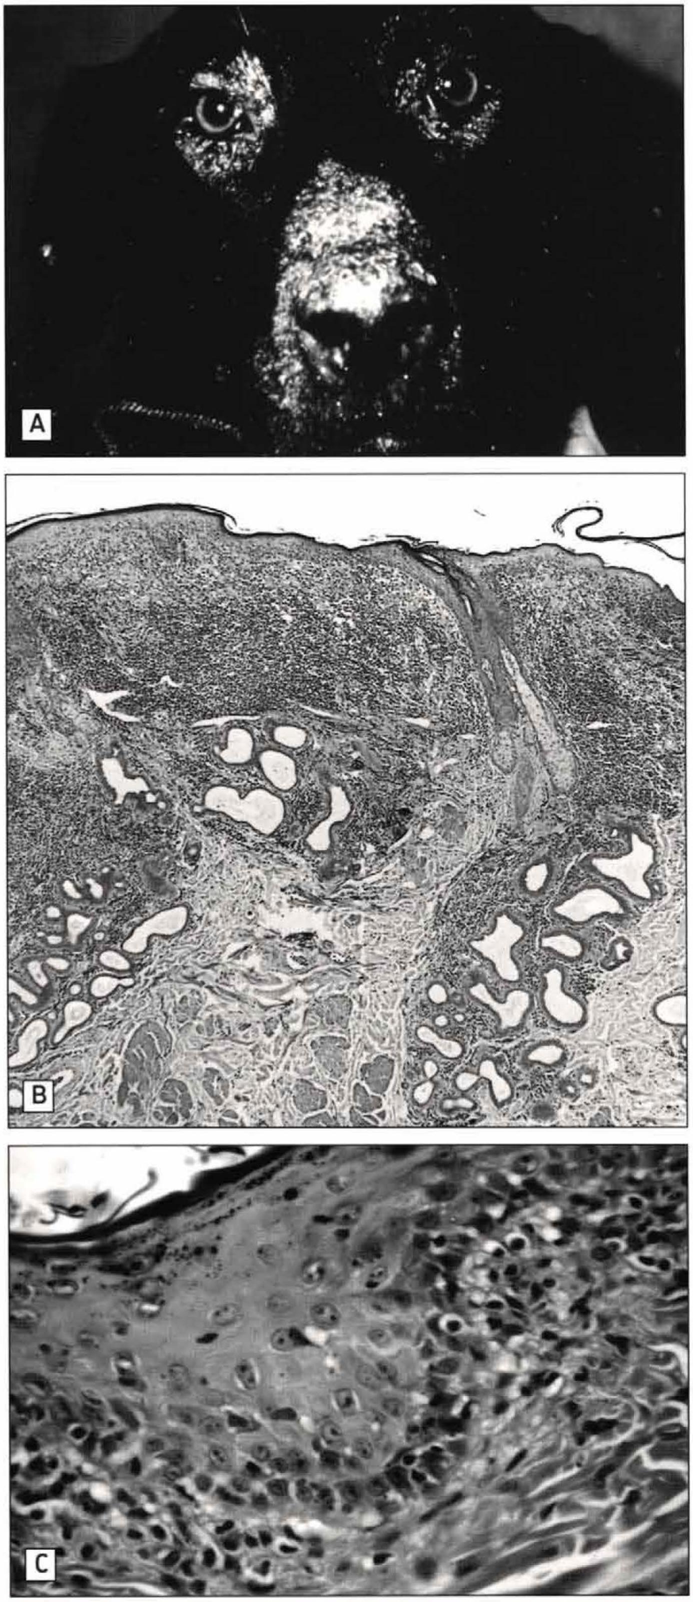

Figure 5.73 Systemic lupus erythematosus (SLE). **A. Symmetrical facial lesions** in SLE. (Courtesy of K Beale.) **B. Lichenoid interface dermatitis** in SLE. **C.** Hydropic degeneration of basal cells, apoptosis, and a lymphohistiocytic-to-plasmacytic infiltrate at the dermoepidermal junction in SLE.

entirely specific for the disease. *Differential diagnoses* vary with the type of lesions present but may include other autoimmune skin diseases, drug eruption, vasculitis, mycosis fungoides, dermatomyositis, demodicosis, dermatophytosis, and seborrhea. In the horse, other depigmenting conditions such as idiopathic leukoderma and the breed-specific, juvenile Arabian leukoderma should be considered.

The localized cutaneous form or **discoid** form of **lupus erythematosus** (DLE) is described most commonly in the *dog*, and rarely in *horses and cats*. DLE as a distinct entity in animals is currently under close scrutiny, and terminology for this clinicopathologic condition is likely to change as the pathogenesis becomes understood and may be found to be different from SLE. The relationship of DLE to SLE is obscure, as DLE does not progress to SLE. The human form of DLE is not comparable to the current condition referred to as DLE in animals. **Photosensitive nasal dermatitis** *is a more general term proposed for use for these conditions in animals until the pathogenesis can be determined.* In **dogs**, the disease is more prevalent in bitches and there is a marked breed predilection in Collies, Shetland Sheepdogs, Siberian Huskies, and German Shepherds. *Sunlight exacerbates the lesions*, which typically affect the nasal planum in dogs and cats, and the face and neck in horses. In the dog, perioral, periocular, and pinnal skin may also be affected. The lesions include erythema, depigmentation, scaling, crusting, alopecia and occasionally ulceration. Rarely, dogs are presented with only nasodigital hyperkeratosis. *Histologic findings are very similar as previously described for systemic lupus.* The epidermis may be more hyperplastic and the infiltrate is predominantly comprised of lymphocytes and macrophages with fewer plasma cells, and is often denser than in SLE. If a secondary mucocutaneous pyoderma is present, plasma cells may be more numerous. IF or IHC staining may reveal IgM, IgG, IgA, and/or complement at the basement membrane zone, however false-positives of the nasal planum are common. *Clinical differential diagnoses* include nasal solar dermatitis, PF, PPP, uveodermatologic syndrome, contact dermatitis, SLE, trauma, mycosis fungoides, drug eruption, dermatomyositis, and vitiligo. *A major histologic differential is a mucocutaneous pyoderma.* Mucocutaneous pyodermas lack evidence of basal cell damage and are predominantly plasmacytic. Both conditions may be present simultaneously.

Vesicular cutaneous lupus erythematosus is a disorder formerly known as *ulcerative dermatosis of the Collie and Shetland Sheepdog*. This condition was originally thought to be a variant of dermatomyositis, but recent immunological studies indicate the presence of autoantibodies that target nuclear antigens similar to that seen in cutaneous lupus erythematosus. Antinuclear antibody testing is negative. Lesions develop in middle-aged to older dogs. The Shetland Sheepdog and Collie appear predisposed to lesion development. Clinical lesions consist of vesicles and bullae that evolve into erosions and ulcers. The inguinal and axillary regions are most commonly involved, but lesions may also occur on mucocutaneous junctions. Histologic changes consist of interface lymphocytic dermatitis with hydropic degeneration of basal cells, keratinocyte apoptosis, and extensive vesicles and bullae at the epidermal–dermal junction.

Exfoliative cutaneous lupus erythematosus, formerly known as *lupoid dermatosis of the German shorthair pointer*, occurs in young (3 months to 3 years) German Shorthair Pointers. Gross lesions consist of scaling and crusting commencing on the head and back but becoming generalized. The most severe lesions are often present at pressure points and the scrotum. Pyrexia, peripheral lymphadenopathy and lethargy may be present. Histologic changes mimic cutaneous lesions of systemic lupus erythematosus. Some affected dogs may have a positive antinuclear antibody test.

Lupus panniculitis (lupus profundus) is *characterized by well-circumscribed subcutaneous nodules over the trunk and proximal extremities.* It is reported rarely in dogs. Histologically, it is initially a septal panniculitis with dense nodular infiltrates of lymphocytes and plasma cells and fewer macrophages. The fat lobules may undergo necrosis, often represented by hyalinization without mineralization. Usually *the dermis and epidermis show the typical microscopic features of lupus*, including hydropic degeneration of basal cells, pigmentary incontinence, thickened basement membrane zone and sclerosis of the dermis. Abundant mucinous degeneration is usually prominent. Leukocytoclastic vasculitis may be present in the interlobular septa. Histologically, lupus panniculitis is distinctive, but a rabies vaccine-induced lymphocytic panniculitis, that is virtually indistinguishable histologically, occurs in dogs.

Other immune-mediated dermatoses

Drug eruptions

Drug eruptions are occasionally reported in *dogs, cats, and horses* and rarely in other domestic animals. Drugs responsible for skin eruptions may be administered *orally, topically, or by injection or inhalation.* Any drug may cause an eruption, and any one drug consistently produces no specific type of reaction. Thus, *drug eruption can mimic virtually any dermatosis. Erythema multiforme, toxic epidermal necrolysis, and vasculitis are well-recognized dermatoses that can be manifestations of cutaneous drug eruptions* and are described individually later in this section. *Criteria* for establishing a cutaneous reaction as a confirmed drug eruption include: (1) elimination of other causes of the skin lesions, (2) timing of onset of reaction with administration of a suspect drug, (3) improvement upon drug withdrawal, (4) recognition that the suspect drug has been associated with similar reactions in other animals or species in the past, and (5) recurrence of lesions upon rechallenge of the patient with the drug. Understandably, all five of these criteria are not often met, particularly rechallenge as this can be associated with high morbidity or mortality. Time period between drug administration and onset of an adverse reaction varies widely from hours to months and lesions can result from a single or repeated administration. *Drug-induced gross and histologic lesions are not pathognomonic* for an adverse cutaneous drug eruption although histopathological changes may often point to a limited list of differentials. *Histologic patterns that have been recognized as forms of adverse drug reactions include: urticaria; perivascular dermatitis (allergy-like); hydropic and/or lichenoid interface dermatitis (erythema multiforme, toxic epidermal necrolysis, lupus erythematosus-like); perforating folliculitis; vasculitis; intraepidermal vesiculopustular dermatitis (pemphigus-like); and subepidermal bullous reactions (pemphigoid-like).* The pathogenesis of lesion formation in many types of drug eruptions is not known with certainty. Drug hypersensitivities are believed to involve all four types of hypersensitivity reactions, and in some cases are not thought to be immunologically mediated.

The most common drugs recognized to produce hypersensitivity reactions in domestic animals are the *sulfonamides (especially trimethoprim-potentiated) and penicillins.* Erythema multiforme and toxic epidermal necrolysis (discussed later in this section) have been seen most commonly with trimethoprim-potentiated *sulfonamides, cephalosporins and levamisole. Diethylcarbamazine* and *5-fluorocytosine* have been associated with fixed drug eruption on the scrotum of dogs. The ulcerative lesions healed with hyperpigmentation when the drug was withdrawn but recrudescence at the same site, with vesiculation, occurred when the dog was rechallenged. *The mechanism underlying fixed drug eruption is unknown.* In people, the epidermal invasion of T cells in fixed drug eruptions is associated with the expression of the intracellular adhesion molecule ICAM-1 on the surface of lesional keratinocytes. *Cyclosporin* has been reported to cause a lymphoplasmacytoid dermatitis with malignant features, usually manifest as a solitary plaque or nodule. *Urticaria and angioedema* have been associated with levamisole, barbiturates and some antibiotics. Drug eruptions manifesting as *exfoliative erythroderma* have been seen in dogs treated with levamisole and lincomycin. Drug eruptions resembling bullous pemphigoid clinically, histologically and immunohistochemically have been associated with *triamcinolone.* It is quite possible that some cases described as bullous pemphigoid actually represent drug eruptions. Pemphigus foliaceus-like drug eruptions have been described in cats treated with ampicillin or cimetidine and dogs receiving trimethoprim-sulfonamide. Lesions consisted of classical subcorneal pustules with acantholytic cells, with an additional feature of vasculitis in some cases. Systemic lupus-like drug reactions have been reported in dogs and in cats. Cutaneous vasculitis caused by immune complex deposition may be initiated by drug administration. Sulfadiazine administration in Doberman Pinschers causes a poorly defined skin rash as well as ocular, joint, kidney, and hematological abnormalities suggestive of systemic vasculitis.

Cryopathies

Cryopathies are cold-related hypersensitivity syndromes that include **cold agglutinin disease**, *a condition in which erythrocyte autoantibodies react at lower temperatures to produce microvascular thrombosis in superficial dermal vessels.* Other cryopathies are small vessel vasculopathies associated with abnormal serum proteins (paraproteins) that precipitate out of the serum at cooler temperatures and redissolve upon warming. *Paraproteins include cryofibrinogens, cryoglobulins, macroglobulins, and gamma heavy chains.* Cryoglobulins may be monoclonal IgG or IgM (type I cryoglobulinemia), or mixed mono- and polyclonal with one antibody directed against the other, in which case, immune complexes are in the circulation (type II cryoglobulinemia). In type III cryoglobulinemia, the immunoglobulins are polyclonal. Type I cryoglobulinemia is often associated with underlying disease such as multiple myeloma, leukemia, or lymphoma where as in type II or III, connective tissue disease such as SLE, or a systemic infection is present. Type II and III may also be idiopathic. *Most cases reported in* *dogs and cats are the result of cold-reacting anti-erythrocyte antibodies.* Cold agglutinin disease has been reported rarely to cause skin disease in dogs and cats. Cold agglutinin disease as a post-infectious event has been reported in sheep, horses, and pigs. One report in Birman cats occurred in association with neonatal isoerythrolysis and suggested that group B blood group cats may be predisposed. Lead exposure and hemobartonellosis have also been implicated as predisposing factors in dogs and cats. Cryopathy due to cryofibrinogens and cryoglobulins has also been reported in the dog. A monoclonal cryoglobulinemia associated with multiple myeloma has been reported in a cat.

Cutaneous signs associated with cryopathies result from vascular insufficiency (obstruction, stasis, spasm, and thrombosis). Lesions include erythema, purpura, cyanosis, necrosis, ulceration, and occasionally sloughing of extremities, and are precipitated or exacerbated by exposure to cold. The paws, pinnae, nose and tip of the tail are typically involved. Skin biopsy usually reveals necrosis, ulceration and often secondary suppurative changes. *Microvascular thrombosis* may be evident in cold agglutinin disease. In other types of cryopathies, paraproteins are precipitated out and deposited throughout vessel walls and within vascular lumens. The proteins stain pink with HE and bright red with PAS. *Hemorrhage* may be present. In type I cryopathies, inflammation is usually absent, whereas a leukocytoclastic vasculitis is often present in types II and III. *Diagnosis requires a test for cryoprecipitates and analysis of serum proteins.* Erythrocyte agglutination on a cooled slide that reverses upon warming and a positive Coombs' test at 4°C should be present in cases of cold agglutinating anti-erythrocyte antibodies. *Differential diagnoses include frostbites, disseminated intravascular coagulation, SLE, dermatomyositis, and other causes of vasculitis.*

Graft-versus-host disease

Graft-versus-host disease (GVH) occurs as a complication of bone marrow transplantation. It has been recorded in *humans, dogs, cats, and horses.* The disease results from donor T-lymphocyte responses to recipient histocompatibility antigens in the *acute phase*, and from immunocompetent recipient lymphocyte responses to transplantation antigens in the *chronic phase*. Principal target organs are the *skin, liver and intestinal tract.* GVH is considered the *classic example of cell-mediated attack upon the epidermis.* Proposed target cells in the skin include basal keratinocytes, follicular stem cells, and/or Langerhans cells. Studies indicate both CD8+ and CD4+ lymphocytes are active in the disease process, with CD8+ T cells found more often in the epidermis and CD4+ T cells in the dermal infiltrate. NK cells may also play a role. T cell production of IFNγ results in keratinocyte expression of ICAM-1, the binding molecule for LFA-1 found on infiltrating T cells. TNFα production by activated keratinocytes and Langerhans cells and IFNγ lead to keratinocyte production of IL-8 attracting more lymphocytes.

Skin lesions in the acute phase include generalized erythematous macules, multifocal alopecia, and ulcerative dermatitis. Oral lesions, epidermal detachment and follicular papules may be present. In the chronic phase, erythema, irregular hyperpigmentation, dermal fibrosis, cutaneous atrophy, and cicatricial alopecia from chronic ulceration may occur. *Histologic findings* include various degrees of hydropic and/or lichenoid interface dermatitis with marked lymphocytic satellitosis of necrotic keratinocytes in all layers of the epidermis and the follicular epithelium. There are lymphocytic exocytosis and spongiosis. Dermal lymphocytic infiltrate is variable. Dermal–epidermal cleft or ulceration may also be present. Over time, epidermal atrophy and dermal sclerosis with loss of adnexa may occur. Basal layer vacuolation and inflammation persist. *Differential diagnoses* include erythema multiforme, toxic epidermal necrolysis or other drug eruption, alopecia areata, and radiation dermatitis. *The history and the triad of cutaneous, hepatic and intestinal signs should lead to the proper diagnosis of GVH.*

Erythema multiforme

Erythema multiforme (EM) is an uncommon cutaneous reaction reported in the *dog, cat, horse, and cow.* EM is *usually triggered by drug therapy or infection* (viral, fungal, or bacterial), but may also occur in conjunction with underlying *neoplasia*, or may be *idiopathic*, particularly in older dogs. A few of the drugs reported to trigger EM in animals include *d-limonene-based dips, levamisole, cephalexin, trimethoprim-sulfa, gentamicin, and penicillin.* The pathogenesis is not completely understood, however studies support a *combined type III and IV immune reaction* as the mechanism of lesion formation. The possibility also exists that a drug or infectious agent may induce keratinocytes to undergo apoptosis without involvement of the immune system. The *histologic lesions*, cellular infiltrates and types of lymphocytes present mirror that of GVH disease, lending further support for a cell-mediated immune response. IF or IHC results are variable but may show deposits of immunoglobulin and/or complement in the dermal microvasculature or at the dermoepidermal junction. Circulating immune-complexes may also be present. It is unclear whether these findings indicate a role for humoral immunity in skin lesions or are epiphenomena. Antibodies to the desmosomal proteins, desmoplakin I and II have been documented in cases of EM major (see below) in humans but it is not yet determined whether antibodies formed secondary to keratinocyte damage and antigen exposure or as a primary event.

EM occurs in *two forms* that may overlap one another and with toxic epidermal necrolysis. **EM minor** *is characterized chiefly by an acute onset of symmetric erythematous macules and papules* (Fig. 5.74A). These spread peripherally and clear centrally to produce annular, serpiginous to arciform and polycyclic patterns (Fig. 5.74B). *Classic "target" lesions may be present* (5.74C).

Urticarial plaques with similar configurations and vesiculobullous lesions also occur. Lesions tend to involve mucocutaneous junctions,

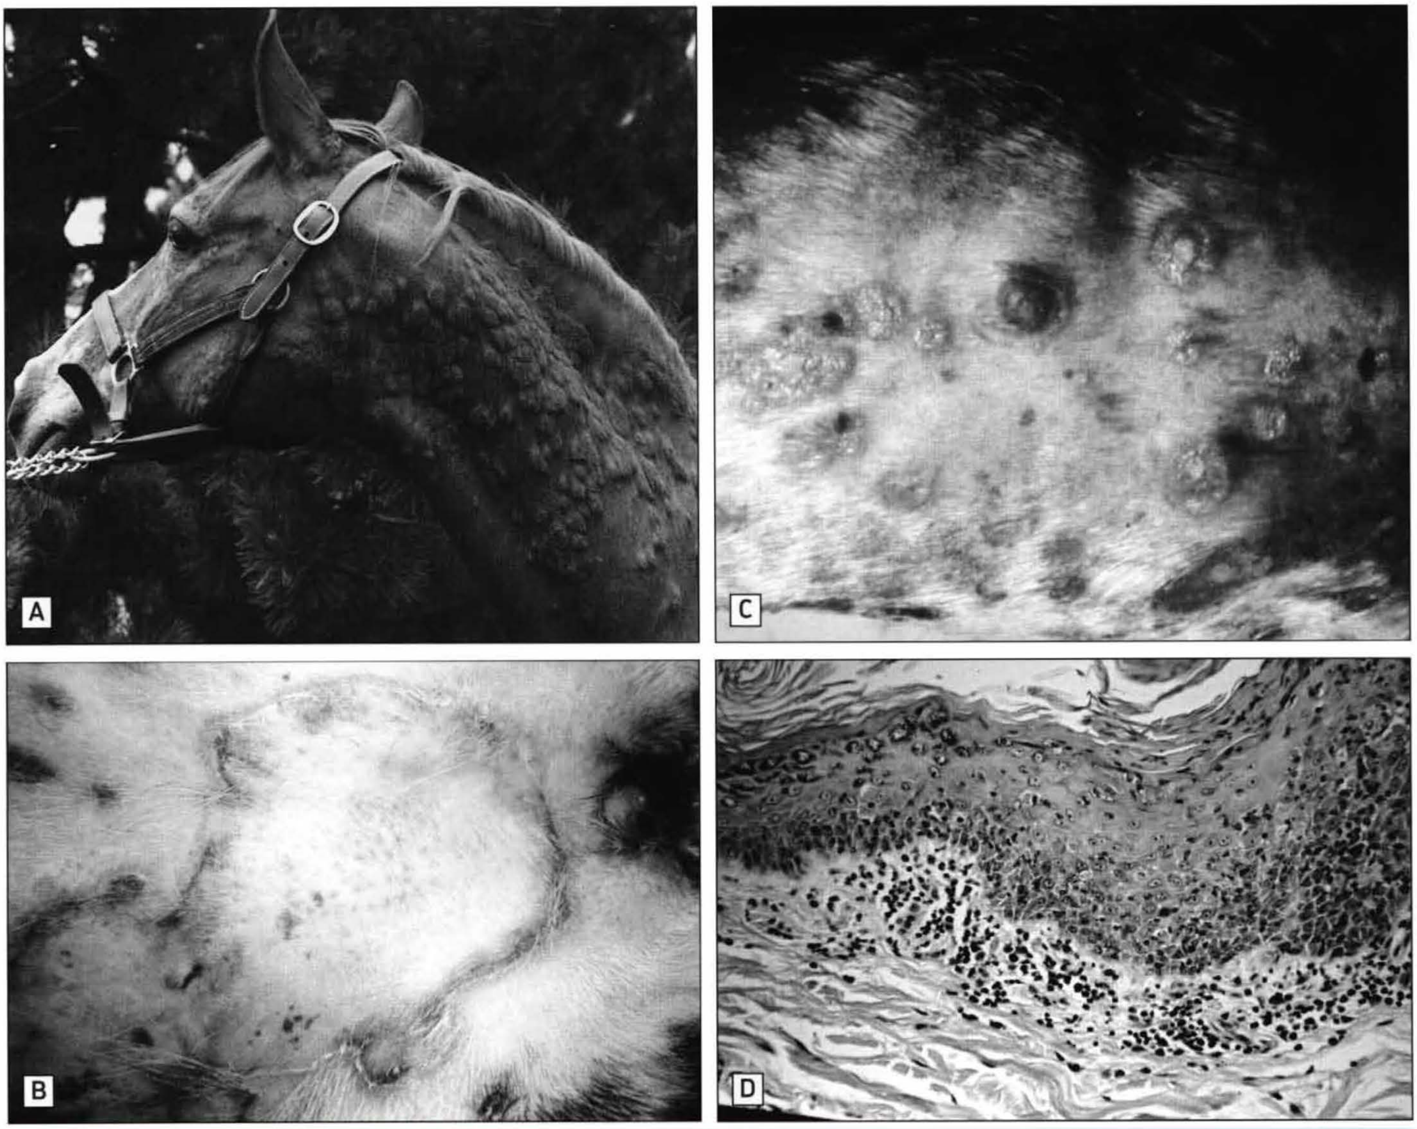

Figure 5.74 Erythema multiforme (EM). **A.** In a horse, **multiple irregular plaques** that are not transient as they are in urticaria (see Fig. 5.64). **B.** Erythematous and erosive **serpiginous to arciform lesions** in EM in a dog. (Courtesy of University of Florida Clinical Dermatology Service.) **C. Classical target lesions** with central clearing in EM in a dog. (Courtesy of University of Florida Clinical Dermatology Service.) **D.** Characteristic **interface dermatitis** with necrotic keratinocytes, often with lymphocytic satellitosis, scattered throughout the epidermis in EM in a dog.

the ventral trunk, proximal limbs and occasionally the nose and footpads. Pruritus is usually not a feature and there are no systemic signs, other than those attributable to the underlying cause. In **EM major** (Stevens–Johnson syndrome), *widespread mucosal lesions, extensive necrotizing and vesiculobullous skin lesions and signs of systemic illness such as pain, lethargy, pyrexia, and anorexia are present.* Histologically, the lesions of EM show the *characteristic interface dermatitis* (Fig. 5.74D). Necrotic keratinocytes, often with lymphocytic satellitosis, are scattered throughout the epidermis and the adnexal epithelia (see Fig. 5.11). A sparse lymphohistiocytic infiltrate occurs at the dermoepidermal junction and around superficial blood vessels. Vasculitis is not a feature. As the lesion ages, the infiltrate may become more dense, subepidermal bullae may develop and the epidermal necrosis may become confluent. Secondary exudation follows necrosis. *Clinical differentials* include TEN, burns, SLE, urticaria, vasculitis, other immune-mediated dermatoses, mycosis fungoides, superficial necrolytic dermatitis, and necrotic arachnidism. The *histologic pattern* is shared by GVH disease, acute lupus erythematosus, and less severe forms of toxic epidermal necrolysis. Occasionally, lesions may histologically resemble mycosis fungoides (MF). Important distinguishing features are atypical lymphocytes (MF) and apoptosis accompanied by lymphocytic satellitosis in all levels of the epidermis (EM). A less common finding in erythema multiforme is severe dermal edema with vertical orientation of dermal collagen and subepidermal vesiculation. *EM may be self-limiting, resolve with elimination of underlying triggering event, or as in some idiopathic cases, become chronic or recurrent.* Chronic EM is more commonly seen in older dogs and is characterized by the additional changes of a proliferative epidermis with marked parakeratosis and extensive lymphocytic exocytosis.

Toxic epidermal necrolysis

Toxic epidermal necrolysis (TEN) is characterized by disseminated erythema, widespread bullous necrosis of epidermis and mucous membranes,

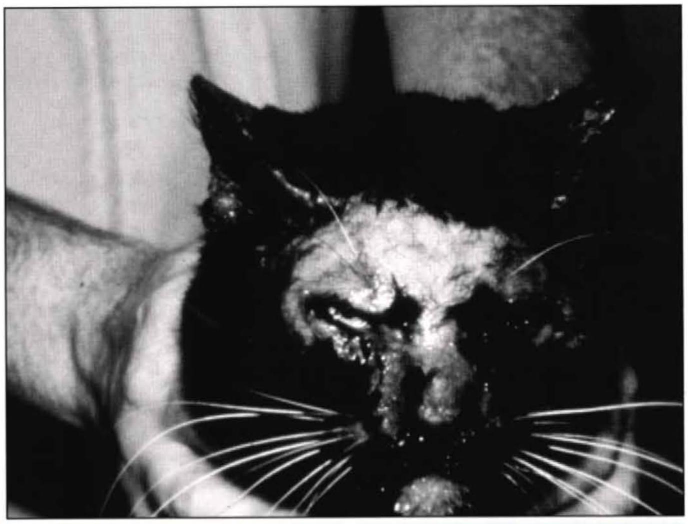

Figure 5.75 Complete loss of the epidermis of the skin of the face in **toxic epidermal necrolysis.** (Courtesy of University of Florida Clinical Dermatology Service.)

and severe toxicity. It is most often associated with drug intake or concurrent infections, but many cases are idiopathic. TEN and EM major (Stevens–Johnson syndrome) are very similar in clinical presentation, and one may be the extension of the other. The lesions of erythema multiforme major show areas of full-thickness epidermal necrosis as in TEN, but differences in the clinical course, response to therapy, and fatality rate suggest that they are separate entities.

The pathogenesis of TEN is not known. Cell-mediated immune mechanisms have been postulated as the basis for necrosis. Lymphopenia and alterations in the T-helper and T-suppressor lymphocyte ratios occur in human patients. Drugs associated with TEN, however, do not induce lymphocyte transformation in vitro. Furthermore, the widespread confluent epidermal necrosis, in the virtual absence of infiltrating inflammatory cells, argues against an effector role for cytotoxic lymphocytes. As in EM, lesional deposition of antibody and complement may represent epiphenomena.

Toxic epidermal necrolysis is a serious, acute-onset and life-threatening disease in dogs and cats. It has been associated with concurrent infectious disease or neoplasia, and *is a form of drug eruption*. Drugs implicated include penicillins, cephalosporins, levamisole, and 5-fluorocytosine. Affected animals are painful, anorectic, febrile, depressed and lethargic. Mortality is high. Lesions are usually generalized and involve mucous membranes, mucocutaneous junctions, and haired skin (Fig. 5.75). There is ulceration, often with an epidermal collarette, crusting, scaling and secondary pyoderma. The skin is extremely painful and fragile and may slough with routine handling. A *positive Nikolsky sign* is often present and large sheets of epidermis may detach. Vesiculation may occur but is often transient. Lesions may also involve the respiratory and digestive tracts. *Grossly*, toxic epidermal necrolysis may be difficult to distinguish from EM major, superficial burns, pemphigus vulgaris, bullous pemphigoid, systemic lupus erythematosus, thallium poisoning, mycosis fungoides, necrotic arachnidism and candidiasis.

Histologically, *TEN is characterized by full thickness coagulative necrosis of the epidermis, which may extend into the external root sheath of the hair follicle*. Separation of the necrotic epidermis occurs at the dermoepidermal junction and leads to subepidermal vesiculation. Dermal inflammation is minimal until the epidermis becomes detached. The reaction, when present, is perivascular or rarely lichenoid and chiefly lymphohistiocytic. Lesions with less than full-thickness epidermal necrosis and more intense dermal inflammation may be indistinguishable from cases of erythema multiforme with confluent zones of keratinocyte necrosis.

Vasculitis

Cutaneous vasculitis, a condition in which dermal vessels are the principal target of injury, can be associated with a primary immunopathogenic event, or may be secondary to drug therapy, infectious agents, systemic connective tissue disease, underlying malignancy, toxins, or, often may be idiopathic. Classic examples include infection with an endotheliotropic organism (*Rickettsia rickettsii*), immune-complex vasculitis (systemic lupus erythematosus) and septicemia (*Erysipelothrix rhusiopathiae*). Although cutaneous vasculitis has many causes, many cases fall into the category of type III hypersensitivity reactions. Cutaneous vasculitis may be a secondary event associated with cutaneous diseases such as staphylococcal infections. Drug-induced vasculitis is thought to be the result of haptenization of host proteins, direct drug toxicity against vessel walls, autoantibodies against endothelial cells, or possibly cell-mediated cytotoxic reactions against vessels.

Cutaneous vasculitis is seen most often in the *dog and horse* and is considered to be rare in cats, pigs and cattle. Approximately 50% of cases of vasculitis in dogs and horses are idiopathic. *Gross lesions suggestive of vasculitis include erythematous plaques or macules, palpable*

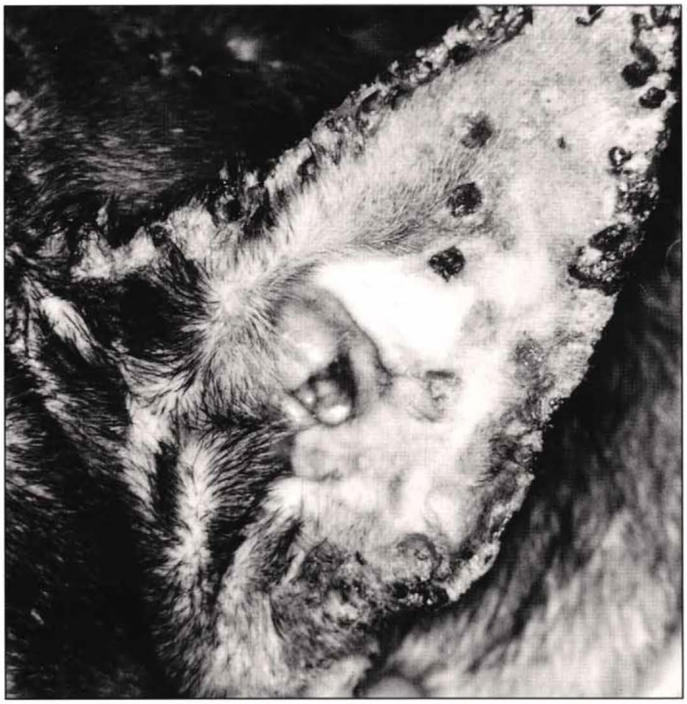

Figure 5.76 Typical punched-out ulcers on the margins of the ears, due to **vasculitis** in a dog.

purpura, hemorrhagic bullae, edema, necrosis, and well-demarcated ulcers (Fig. 5.76). Ischemic necrosis may occur leading to eschar formation and sloughing of the skin or distal extremities. Paws, pinnae, lips, tail, and oral mucosa are most commonly affected. Ischemic atrophy of folliculosebaceous units may lead to areas of alopecia and scaling in long standing lesions of more subtle vasculitis.

Small arterioles, capillaries and post-capillary venules are most often affected in cutaneous vasculitis. Histologic lesions in the classic case feature evidence of damage to the vessel wall such as *necrotic cell debris and fibrinoid necrosis within the vessel wall, mural infiltrates of either neutrophils or lymphocytes, and intramural or perivascular edema, hemorrhage or fibrin exudation* (see Fig. 5.15). Subtle cases of vasculitis may be characterized by edema, rare necrotic cells in the vicinity of vessels and a mild interstitial mononuclear cell infiltrate. Microscopic evidence of vasculitis in the dog is often subtle and may lead to underdiagnosis of the condition. Some pathologists prefer to refer to very cell-poor cases of vasculitis as a *vasculopathy* rather than true vasculitis when degenerative lesions of vessel wall and evidence of ischemia are detected in the absence of inflammation of vessel walls. Edema, hemorrhage, and evidence of ischemia and homogenization of dermal collagen are helpful changes. *A preponderance of leukocytes in vessels walls rather than in the dermis suggests that vessels are the primary target of inflammation and not just serving to deliver leukocytes.* Vessels will stand out in the section due to the attraction of leukocytes to vessel walls.

Some generalizations regarding the pathogenesis of the vasculitis can be made from types of leukocytes present within vessel walls; however, the types of leukocytes present does not necessarily point to a particular etiology and may simply reflect the stage of the disease process.

- *Neutrophilic vasculitis* is most suggestive of a type III immune-complex hypersensitivity reaction and is often referred to as *leukocytoclastic vasculitis* if neutrophil degeneration and nuclear karyorrhexis are evident. Examples include the vasculitis associated with staphylococcal dermatitis in dogs, immune-mediated vasculitis as in SLE, some drug eruptions, and septicemia.
- *Lymphocytic vasculitis* may suggest a cell-mediated immune basis, such as rabies vaccine-induced cutaneous vasculitis and some drug eruptions.
- *Eosinophilic vascular infiltrates* are most suggestive of a type I hypersensitivity reaction. Eosinophils may be the predominant cells in some cases of equine vasculitis and in association with the markedly eosinophilic dermatitis seen in some arthropod bite lesions, mast cell tumors, or in lesions of the eosinophilic granuloma complex in the cat.

Involvement of deep dermal blood vessels in all cases may suggest systemic disease.

In **dogs**, cutaneous vasculitis has been associated with drugs, systemic or localized infections (Rocky Mountain spotted fever, staphylococcal pyoderma), malignancies and connective tissue diseases. Familial or inherited forms of vasculitis have also been recognized.

- A syndrome of cutaneous ulceration in conjunction with limb edema and/or acute renal failure, referred to as *cutaneous and renal glomerular vasculopathy (CRGV) of Greyhounds* or in layman's terms "Alabama rot" has been reported sporadically in young greyhounds throughout the United States. Multifocal cutaneous ulcers, renal afferent arteriolar and dermal arterial thrombosis, azotemia, microangiopathic hemolytic anemia and thrombocytopenia with normal coagulation times characterize CRGV. Cutaneous lesions may occur in the absence of renal or other systemic disease. The syndrome has many features in common with the hemolytic-uremic syndrome in people caused by a Shiga-like toxin induced endothelial cell necrosis. *Studies have failed to identify infectious agents, toxins, or evidence of an immune-mediated reaction in CRGV.* Exposure to Shiga-like toxin-producing *E. coli* has not been completely ruled out. Affected dogs may be genetically predisposed to develop CRGV as outbreaks have occurred in related groups of dogs. Hemorrhage, fibrinoid arteritis, thrombosis with infarction and ulceration characterize the skin lesions which are most often found on the limbs. Renal glomerular necrosis and tubular necrosis are present in the kidneys.
- A genodermatosis affecting *German Shepherd Dog puppies* characterized by swelling, depigmentation and frequent ulceration of footpads, ear and tail tips and nasal planum depigmentation has been reported in Canada. A neutrophilic to mononuclear nodular dermatitis, dermal collagenolysis, and subtle vasculitis are present histologically. Nasal lesions correspond to an hydropic interface dermatitis. The cause is unknown but presumed to be immunologically mediated as lesions are temporally related to vaccination dates. Dogs recover by 5–6 months of age. The condition may also be related to an underlying collagen disorder, as musculoskeletal abnormalities are also present.
- Familial vasculitis has been reported in a litter of *Scottish Terriers*. Lesions were limited to the nasal epithelium and mucosa and were characterized by leukocytoclastic vasculitis and pyogranulomatous inflammation leading to ulceration and destruction of the nasal planum.
- Cutaneous vasculitis leading to alopecia and ulcerative lesions of the extremities and bony prominences with histologic lesions

virtually indistinguishable from dermatomyositis of Collies and Shetland Sheepdogs (see Congenital and hereditary diseases of skin) has been reported in *Jack Russell Terriers*.

- Lymphocytic to mixed mononuclear vasculitis, often associated with cutaneous infarction, has been noted in dogs with the systemic lymphoproliferative disorder, *lymphomatoid granulomatosis*.

In **horses**, cutaneous vasculitis has been seen with or following numerous infections, such as *Streptococcus, Influenza A virus, Equine arteritis virus, Equine infectious anemia virus, Ehrlichia, Rhodococcus equi,* and *Corynebacterium pseudotuberculosis*.

- *Equine purpura hemorrhagica* is an acute, usually streptococcal infection (strangles)-associated, leukocytoclastic vasculitis characterized clinically by urticaria and extensive edema of the distal limbs, ventrum and head. These swellings may progress to exudation and sloughing.
- *Pastern leukocytoclastic vasculitis* is a syndrome unique to the horse that affects the unpigmented, sun-exposed skin of distal extremities, hence ultraviolet radiation is thought to play a role in the pathogenesis. Adult horses are most often affected. There is no evidence of liver disease or exposure to photosensitizing compounds. Interestingly, a single limb may be affected although other limbs lack pigment as well. Lesions are crusty, eroded or ulcerated, sharply demarcated and may be associated with extensive edema and pain. Histologically, a leukocytoclastic vasculitis of the superficial dermal vessels is present. Chronic cases develop papillary hyperplasia of the epidermis giving the lesion a verrucous appearance.

Cutaneous vasculitis in **pigs** is most commonly associated with *Erysipelothrix rhusiopathiae* infection. Systemic vasculitis affecting primarily the skin and kidneys has been reported recently in pigs and has been called the *dermatitis/nephropathy syndrome*. Skin lesions consisted of irregularly enlarging hemorrhagic macules and papules on the ears, limbs, abdomen, thorax and perineum. *Leukocytoclastic vasculitis* was present in the dermis, panniculus, synovium, and renal pelvis. Pigs had concurrent pneumonia and immunological studies suggested *Porcine reproductive and respiratory syndrome virus* might be associated with the condition. Direct immunofluorescence testing or immunohistochemistry may demonstrate immunoglobulin and/or complement in vessel walls and occasionally at the basement membrane zone in suspected cases of vasculitis. Positive tests are most likely in lesions less than 24 hours old. False positives occur also. Adverse drug reactions, infection, familial vasculopathies, cryopathies, and systemic autoimmune diseases such as SLE should be ruled as possible causes. In many cases, a specific cause cannot be determined.

Rabies vaccine-induced vasculitis and alopecia in dogs

An ischemic dermatopathy leading to alopecic, hyperpigmented patches of atrophic skin (Fig. 5.77A) is a recognized form of injection-site reaction associated with the subcutaneous administration of rabies vaccines in dogs. All breeds are affected, but Poodles, Yorkshire and Silky Terriers are predisposed. Lesions most often develop at sites of previous vaccination, but occasionally multifocal lesions may occur. Lesions may appear months after the vaccine was administered. The *histologic appearance is highly characteristic*, although the vascular lesions are subtle. Venules, arterioles and small arteries develop a *very mild chronic lymphocytic vasculitis*, characterized by thickening of the vessel wall, a few intramural mononuclear inflammatory cells, scattered nuclear debris and variable perivascular mononuclear infiltrates (Fig. 5.77B). Occasionally a more florid leukocytoclastic vasculitis is seen. A cell-poor interface dermatitis with vacuolar change in the basal epithelial layer and pigmentary incontinence and mural folliculitis may be present in some cases. The dermis is atrophic and hyalinized, sometimes mucinous and hair follicles are in telogen and pale staining ("faded") (Fig. 5.77C). A diffuse increase in mononuclear cells throughout the dermis is accompanied by lymphocytic panniculitis. The additional lesions of erosions and ulcers of the oral mucosa and skin of the extremities and bony prominences and ischemic myopathy in subjacent musculature have been reported in cases with multicentric involvement. Immunofluorescence staining has identified rabies antigen in the vessels and epithelium of the hair follicles. A low-grade immune-mediated vasculitis with resultant tissue anoxia leading to the atrophic changes in the overlying skin has been suggested as the pathogenesis. Lesions may remain for months to years. Differential diagnoses include dermatomyositis, traction alopecia, idiopathic vasculopathy, and lupus profundus.

Canine uveodermatologic syndrome (Vogt–Koyanagi–Harada (VKH) syndrome)

This syndrome, seen only in dogs and humans, is characterized by the concurrent *acute onset of bilateral uveitis and depigmentation of the nose, lips, eyelids and occasionally the footpads and anus.* Although the cause of the disorder is unknown, a cell-mediated hypersensitivity to melanin has been hypothesized. It is discussed further under Disorders of pigmentation.

Plasma cell pododermatitis

This is a *rare disorder of cats* of all breeds, ages and sexes. A recent study found 50% of cases were positive for feline immunodeficiency virus. Although the pathogenesis is unknown, the tissue plasmacytosis, hypergammaglobulinemia, and beneficial response to immunomodulating drugs *suggest an immune-mediated basis*. In addition, occasional cats have other abnormalities, such as renal amyloidosis, plasmacytic stomatitis, positive anti-nuclear antibody tests, Coombs-positive anemia, polyclonal gammopathy, or glomerulonephritis with positive direct immunofluorescence testing (immunoglobulin deposited at the basement membrane zone). Clinically, plasma cell pododermatitis begins as soft, nonpainful swelling of multiple footpads on multiple paws. The central metacarpal or metatarsal pads are usually most severely affected. Affected pads feel soft due to collapse of the underlying fatpad. Footpad surfaces are crosshatched with white scaly striae but may become ulcerated or develop fleshy granulomatous proliferations which may hemorrhage. Lameness develops with progression of the lesions. Some cases spontaneously resolve or may recur seasonally.

Histologically, early lesions are characterized by *superficial and deep perivascular dermatitis with plasma cells predominating*. Later, there is a diffuse plasmacytic dermatitis. Russell bodies can be numerous. Leukocytoclastic vasculitis is rarely seen. Ulcerated or proliferative lesions show various degrees of superimposed suppurative-to-pyogranulomatous inflammation. The gross and histologic features are diagnostic.

Cutaneous amyloidosis

The physical structure of amyloid gives it special properties, such as apple green birefringence when Congo red-stained sections are polarized. The amyloid fibrils (AL amyloid) are derived from monoclonal immunoglobulin light chains. Cutaneous amyloidosis occurs rarely in *horses and dogs*. The cutaneous lesions are not usually associated with known triggering factors in horses; but in dogs, cutaneous amyloidosis has been associated with monoclonal gammopathy, dermatomyositis, and is seen occasionally in the stroma of plasmacytomas of skin and oral cavity (see Cutaneous plasmacytoma). In **dogs** with monoclonal gammopathy, purpuric lesions are seen, and cutaneous hemorrhage is easily induced by minor external trauma. The superficial dermis contains an amorphous, homogeneous, eosinophilic substance, and the walls of blood vessels in the involved area are thickened by deposition of the same substance.

In **horses**, the lesions are multiple, asymptomatic papules, nodules, and plaques that are most commonly seen on the head, neck, shoulders and pectoral region. There is no established breed, age, or sex predisposition. The lesions are firm, well-circumscribed and 0.5–10 cm in diameter. The overlying skin and haircoat are normal. The initial lesions may be urticarial in type. The cutaneous lesions may be accompanied by similar nodules in the respiratory mucosa and regional lymph nodes but are seldom associated with systemic amyloidosis. Lesions may regress, become recurrent or progressively enlarge. Histologic findings include *nodular-to-diffuse granulomatous dermatitis and panniculitis. Large extracellular deposits of amyloid appear as variably sized areas of homogeneous, amorphous, hyaline, eosinophilic material, which may contain clefts or fractures*. Multinucleated histiocytic giant cells are usually numerous. *Clinical differentials* include infectious and non-infectious granulomas, cutaneous neoplasms, and eosinophilic granulomas.

Alopecia areata

Alopecia areata (AA) is a non-scarring, asymptomatic, inflammatory alopecia occurring in humans, nonhuman primates, dogs, cats, horses and cattle. Alopecia areata may be focal, multifocal or generalized (alopecia universalis). Lesions occur most commonly on the face, neck and trunk. Leukotrichia may be seen in some animals initially. Areas of alopecia are usually hyperpigmented and areas of alopecia may exhibit sparse numbers of short, dystrophic hairs (Fig. 5.78A). Lesions may be bilaterally symmetrical. There is no apparent age, breed, or sex predilection. In horses, the mane and tail are often affected. Currently, there are two rodent models available to study the condition, the C3H/HeJ mouse and the Dundee experimental bald rat.

Early, clinically active lesions are characterized histologically by an accumulation of lymphocytes ("swarm of bees") in and around the inferior segment of anagen hair follicles – the classic example of *peribulbar lymphocytic folliculitis* (Fig. 5.78B). Unfortunately, the classic lesion is not always evident and more subtle bulbar inflammation is the rule. Bulbar keratinocytes are frequently vacuolated, apoptotic or karyorrhectic. Pigmentary incontinence and melanophagia in the peribulbar region are also typical findings. Telogen follicles are unaffected and dystrophic hair follicles may be present. Demonstration of the lymphocytic peribulbitis may be difficult and require examination of multiple sections from different levels of the paraffin-embedded biopsy specimen. Biopsies from the periphery of early, expanding lesions are most rewarding. *Histologic findings in chronic, clinically static lesions are nondiagnostic*, revealing a predominance of telogen hair follicles and follicular atrophy, that may be misdiagnosed as an endocrine skin disorder. Immunologic studies in dogs and horses have indicated that the intrabulbar lymphocytes are primarily cytotoxic CD8+ lymphocytes. CD1+ dendritic antigen-presenting cells and both CD8+ and CD4+ lymphocytes are found in the peribulbar infiltrate. In addition, various autoantibodies targeting trichohyaline, hair keratins, and other components of the hair follicle have been demonstrated in various species, indicating a role for humoral immunity. In dogs and horses, *AA frequently spontaneously reverses itself*, however sometimes the hair regrowth is white. *Clinical differentials* include telogen effluvium and many other causes of lymphocytic mural folliculitis such as EM, SLE, GVH, ischemia, and demodicosis, to name a few. *The distinguishing feature of AA is the fact that the hair bulb and inferior segment of anagen hairs are the primary*

VIRAL DISEASES OF SKIN

Cutaneous lesions occur in the course of a number of viral diseases in domestic animals. Viruses may induce skin lesions upon *local infection*, but the intact integument is resistant to viral penetration; injection via an arthropod bite or introduction through a cutaneous wound is a prerequisite for infection. Examples of local viral infection include papillomas induced by the Papovaviridae, bovine mammillitis induced by a herpesvirus, and the so-called milker's nodule in humans caused by a parapoxvirus. More often, viruses localize in the skin during the viremic phase of a *systemic infection.* Examples include some poxvirus infections, malignant catarrhal fever and the vesicular diseases, such as vesicular stomatitis, and foot and mouth disease. Pantropic viruses, such as *Canine distemper virus* and *Classical swine fever virus*, may cause cutaneous lesions; but *most viruses causing cutaneous lesions are epitheliotropic.* Some epitheliotropic viruses, in particular the Poxviridae, have a predilection for the epithelium of the skin. Others, including the viruses associated with the mucosal diseases, cause primary lesions in the alimentary tract with lesser involvement of the skin.

A "rash," comprising erythematous macules due to long-lasting dilation of dermal blood vessels, is often associated with systemic viral disease in humans. Such lesions are uncommon in animals, but may be hidden by the haircoat. Exceptions are the *cutaneous erythema* occurring in classical swine fever and African swine fever, and hemorrhagic diathesis of skin occurring with disseminated *Porcine adenovirus* infection. In addition, a condition known as *dermatitis/nephropathy syndrome of pigs*, seen clinically as erythematous macules, papules, and plaques, due to cutaneous and systemic necrotizing vasculitis, may be associated with *Porcine circovirus 2* (PCV2) infection, with possible roles for *Porcine reproductive and respiratory syndrome virus* (PRRSV) and *Pasteurella multocida*.

Cutaneous viral diseases are *more common in food-producing animals than in pets*. Some of these diseases, notably sheeppox, cause significant mortality. Others have an economic impact because of their deleterious effect on production. Herpes mammillitis and pseudocowpox, for example, reduce milk yield in dairy cattle; contagious pustular dermatitis affects the growth rate of lambs by interfering with their ability to suckle. A few of the large animal viral dermatoses are extremely mild, for example molluscum contagiosum in the horse. Systemic viral diseases with cutaneous manifestations are rare in dogs and cats. *Canine distemper virus* is associated with nasodigital hyperkeratosis, so-called "hard pad" disease, and pustular dermatitis. In cats, rare occurrences of cutaneous disease occur with *Feline calicivirus* infection. Cutaneous lesions caused by *Felid herpesvirus 1* can occur in the absence of respiratory disease, a presumed recrudescence of a latent herpesvirus infection.

Traditionally, viral diseases have been *diagnosed* by light and electron microscopy, serology, and viral culture. However, the development of monoclonal antibodies to specific viruses for use with immunofluorescence and immunoperoxidase techniques is increasingly being used for specific and rapid diagnosis.

Poxviral infections

The Poxviridae is a large family of complex DNA viruses. *Highly epitheliotropic, they cause cutaneous and systemic disease in birds, wild and domestic mammals and humans. Some members of the Poxviridae, including Sheeppox virus, Ectromelia virus, Monkeypox virus, and the now eradicated Variola virus (human smallpox), cause severe systemic disease.* Others cause mild, localized disease, for example pseudocowpox that chiefly affects the teats of milking cows. A few poxviruses are associated with hyperplastic or neoplastic conditions, such as molluscum contagiosum in horses and Shope fibroma of rabbits.

The Poxviridae share group-specific nucleoprotein antigens. Animal poxviruses are in the subfamily Chordopoxvirinae. The genera (*species names italicized*) include:

- *Orthopoxvirus – Camelpox virus, Cowpox virus, Ectromelia virus* (mousepox virus), *Monkeypox virus, Vaccinia virus* (buffalopox virus, rabbitpox virus). Unassigned member of the genus: Uasin Gishu disease virus.
- *Parapoxvirus – Bovine papular stomatitis virus, Orf virus* (contagious pustular dermatitis virus, contagious ecthyma virus), *Parapox virus of red deer, Pseudocowpox virus* (milker's nodule virus). Unassigned members in the genus: Auzduk disease virus (Camel contagious ecthyma virus), Chamois contagious ecthyma virus, Sealpox virus, and a virus that causes papillomatous dermatitis and pododermatitis in cattle.
- *Avipoxvirus – Fowlpox virus, Pigeonpox virus*, and many other avian poxviruses.
- *Capripoxvirus – Goatpox virus, Lumpy skin disease virus, Sheeppox virus.*
- *Leporipoxvirus – Myxoma virus; Rabbit fibroma virus* (Shope fibroma virus).
- *Suipoxvirus – Swinepox virus.*
- *Molluscipoxvirus – Molluscum contagiosum virus.*
- *Yatapoxvirus – Tanapox virus,* Yaba monkey tumor virus.

Many of the poxviruses are host-specific; but the orthopoxviruses, such as *Cowpox virus* and *Vaccinia virus*, affect a wide range of species. Some poxviruses, for example *Pseudocowpox virus*, are zoonotic. *Infection is usually achieved by cutaneous or respiratory routes.* Poxviruses, whether acquired by the subcutaneous or respiratory routes, usually gain access to the systemic circulation via the lymphatic system, although multiplication at the site of injection in the skin may lead to direct entry into the blood and primary viremia. Secondary viremia disseminates the virus back to the skin and to other target organs.

Poxviruses induce lesions by a variety of mechanisms. Degenerative changes in the epithelium are caused by virus replication and induce *vesicular lesions* typical of many poxvirus infections. Degenerative lesions in the dermal or submucosal tissues sometimes result from ischemia secondary to vascular damage caused by viral multiplication in endothelial cells. Poxvirus infections also *induce proliferative lesions*. Poxviruses, such as *Orf virus*, replicating in the epidermis typically induce hyperplasia along with degenerative changes. Host cell DNA synthesis is stimulated before the onset of cytoplasmic virus-related DNA replication. Proliferative changes may be explained by a gene, present in several poxviruses including *Molluscum contagiosum virus*, whose product has significant homology with epidermal growth factor. Poxviruses also encode for functions that may counteract host defenses. These include genes related to those encoding the SERPINs (a superfamily of related proteins important in regulating serine protease enzymes that mediate kinin, complement, fibrinolytic and coagulation pathways) and genes encoding anti-interferon activities.

Pox lesions have a typical developmental sequence. They commence as erythematous macules, become papular, and then vesicular. The vesicular stage is well developed in some pox infections, such as sheeppox, and is transient or non-existent in others, such as contagious pustular dermatitis. Vesicles develop into *umbilicated pustules* *with a depressed center and a raised, often erythematous border.* This lesion is the so-called *"pock."* The pustules rupture and a crust forms on the surface. This crust may become very thick, as in lesions of contagious pustular dermatitis. Lesions heal and often leave a residual scar. The mucosal lesions are briefly vesicular and develop into ulcers rather than pustules.

Histologically, pox lesions begin as epidermal cytoplasmic swelling and vacuolation, usually first affecting the cells of the outer stratum spinosum. There is evidence, from experimental studies with the virus of contagious pustular dermatitis, that post-injury proliferating keratinocytes are the target for viral replication. Rupture of the damaged keratinocytes produces multiloculated vesicles, so-called *reticular degeneration*. The early dermal lesions include edema, vascular dilation, a perivascular mononuclear cell infiltrate and a variable neutrophilic infiltrate. Neutrophils migrate into the epidermis and aggregate in vesicles to form microabscesses. Large intraepidermal pustules may form and sometimes extend into the superficial dermis. There is usually marked epithelial hyperplasia and sometimes pseudocarcinomatous hyperplasia of the adjacent epithelium. This contributes to the raised border of the umbilicated pustule. Rupture of the pustule produces an inflammatory crust, often colonized on its surface by bacteria.

Poxvirus lesions often contain *characteristic intracytoplasmic inclusion bodies*. These are single or multiple and of varying size and duration. The more prominent inclusions are designated *type A*. They are eosinophilic, reflecting their high protein content, and weakly Feulgen-positive. *Smaller, basophilic Feulgen-positive type B* bodies also occur and represent the site of virus replication.

Diagnosis of poxvirus infections is usually based on *typical clinical appearance* and may be supported by *characteristic histologic lesions*. Parapoxviruses are ultrastructurally distinct from the other poxviruses that are morphologically similar to each other when viewed by electron microscopy.

Parapoxviral diseases

Contagious pustular dermatitis

Contagious pustular dermatitis is a poxviral disease of *sheep and goats*, with incidental infections occurring in humans, camels, cows, and many wild ruminants, and very rarely dogs. The disease is caused by *Orf virus*, a *Parapoxvirus* closely related to *Pseudocowpox virus* and *Bovine papular stomatitis virus*. Synonyms for contagious pustular dermatitis include contagious ecthyma, orf, infectious labial dermatitis, soremouth, and scabby mouth.

The disease is geographically widespread and occurs wherever sheep or goats are raised. The virus can repeatedly infect sheep and goats; and while live-virus vaccines control the disease and decrease the severity of the disease, they also ensure its continuance by perpetuating infection in the environment. The economic significance of contagious pustular dermatitis results chiefly from loss of condition, since *affected animals neither suckle nor graze*. Morbidity in a susceptible population may reach 90%, but mortality rarely exceeds 1% unless secondary infection intervenes, or unless the animals are immunosuppressed or stressed in which case mortality can be high. Mortality often results from the invasion of primary lesions by the larvae of the screwworm fly (*Cochliomyia hominivorax*) or by bacteria such as *Fusobacterium necrophorum* and occasionally *Dermatophilus congolensis*. Cellulitis may complicate pedal lesions, mastitis may complicate mammary lesions, and necrotizing stomatitis and aspiration pneumonia may complicate oral lesions.

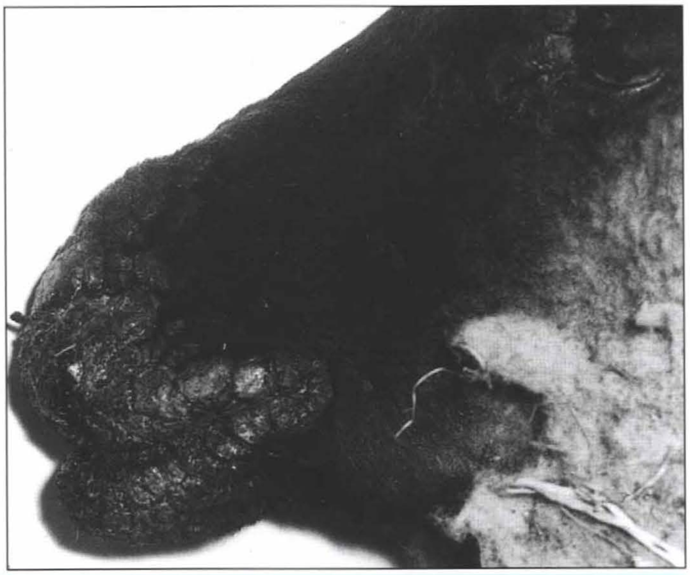

Figure 5.79 Contagious pustular dermatitis (orf) in a sheep. Scabby lesions at the margins of the lips.

Contagious pustular dermatitis affects sheep and goats of all breeds. *It is predominantly a disease of lambs and kids*. Infection is established through cutaneous abrasions, particularly those associated with dry and prickly pasture or forage. Clinically affected lambs may transmit the virus to the udder of the ewe. The virus is hardy and probably persists in a dry environment indefinitely in crust material shed from affected animals. Chronically infected, reinfected or, possibly, latently infected carrier animals may allow the virus to persist in a flock for several years.

Gross lesions usually commence at the commissures of the lips and spread around the lip margins to the muzzle (Fig. 5.79). Primary lesions sometimes occur on the face about the eyes. In severe cases, lesions may develop on the gingiva, dental pad, palate and tongue (Fig. 5.80A). Lesions mainly confined to the tongue must be differentiated from those of foot and mouth disease. The buccal lesions are raised, red or gray foci with a surrounding zone of hyperemia. Very rarely, lesions extend to the esophagus, rumen and omasum in the lower alimentary canal, causing ulcerative gastroenteritis, and in lungs and heart. Lesions on the limbs are less common than on the lips and tend to involve the coronet, interdigital cleft, and bulb of the heels. They may extend, in severe cases, to the knee or hock on the caudal aspect of the leg. Lesions of the mammary gland affect the teats and adjacent skin of the udder. Lesions may develop in other areas of sparsely wooled skin such as the inner thigh, axilla, and the edge of wounds in recently earmarked lambs, or tail-dock sites. Proliferative lesions affecting predominantly the head, neck and body have been described in Nubian goats.

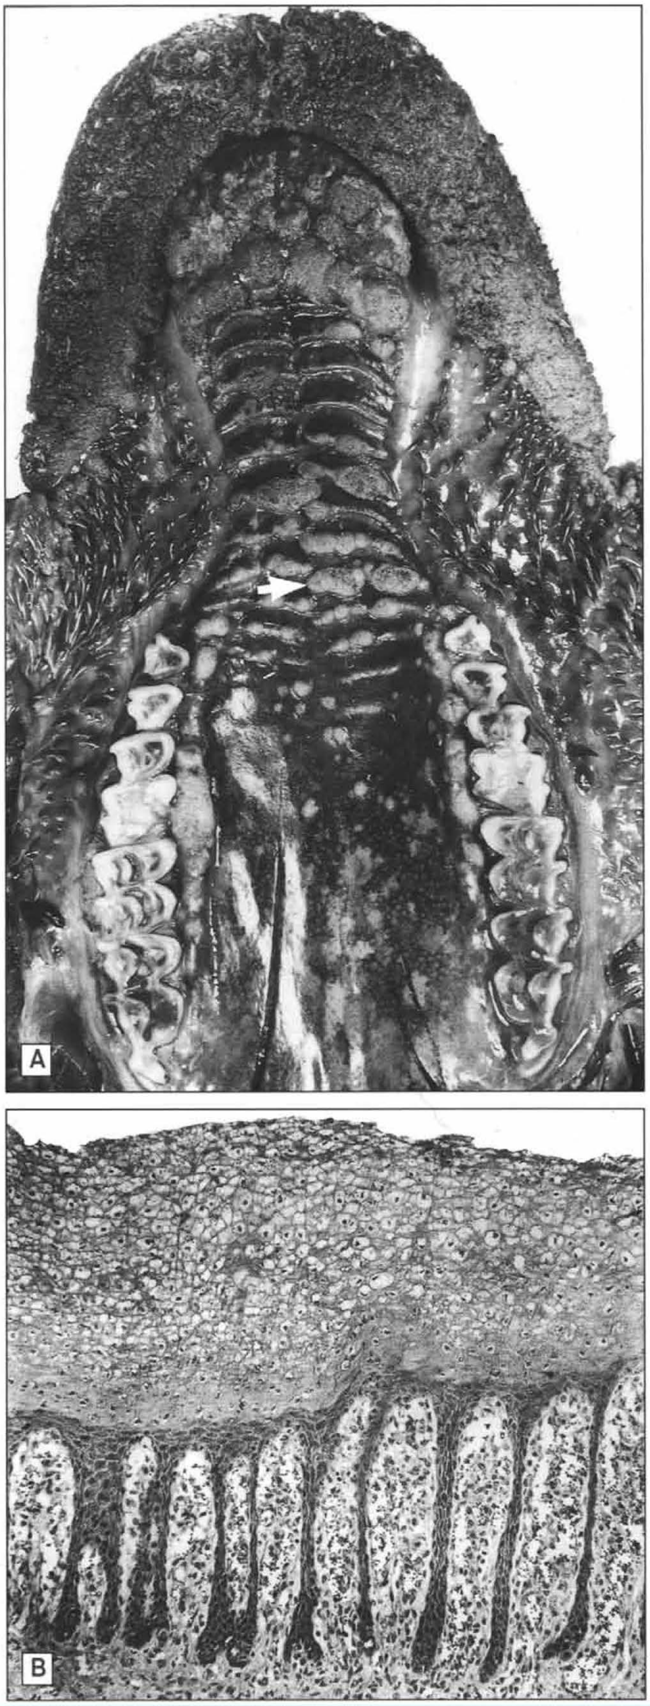

Figure 5.80 Contagious pustular dermatitis in a sheep. **A.** Crusty, proliferative lesions on the lips, dental pad, and palate (arrow). **B.** Note marked epithelial proliferation and increased vascularity and intracellular edema of keratinocytes.

The lesions develop through the typical pox phases but are much more proliferative. The vesicular stage is transient and pustules are flat rather than umbilicated. The most significant feature of the gross lesion is the layer of thick brown-gray crust that may be elevated 2–4 mm above the skin surface. Depending on the degree of secondary infection, regression is usually complete by 4 weeks. Papillomatous growths, resulting from continued epidermal proliferation, sometimes occur.

The microscopic lesions of contagious pustular dermatitis are characterized by vacuolation and swelling of keratinocytes in the stratum spinosum, reticular degeneration, marked epidermal proliferation, intraepidermal microabscesses, and accumulation of scale-crust. In experimentally abraded sheep skin, the active site of viral replication was found to be the newly proliferative keratinocyte population, growing up under the superficial necrotic layer. By ~30 hours postinfection, keratinocyte swelling and vacuolation commences in the outer stratum spinosum. It is accompanied by cytoplasmic basophilia, which corresponds ultrastructurally to an increased number of polyribosomes presumably active in viral protein synthesis. Basophilic intracytoplasmic inclusion bodies are reported as early as 31 hr post-infection. By 72 hours postinfection, the keratinocytes show nuclear pyknosis and marked hydropic change, leading to reticular degeneration. The term ballooning degeneration is often used, but the keratinocytes do not have the homogeneous eosinophilic cytoplasm typical of this condition. At this time intracytoplasmic eosinophilic inclusion bodies appear. The inclusion bodies persist for 3–4 days, as long as the hydropic cells are found. The proliferative reaction in the epidermis is underway by 55 hours postinfection with mitotic figures numerous in the stratum basale. By 3 days postinfection, the epithelium is 3–4 times normal thickness and rete ridges are markedly elongated (Fig. 5.80B). Pseudocarcinomatous hyperplasia is common.

Dermal lesions include superficial edema, marked capillary dilation, and an early influx of neutrophils, followed by a marked accumulation of MHC class II dendritic cells, with CD4+ T cells, CD8+ T cells, and B cells. A thick layer of scale-crust is built up, composed of ortho- and parakeratotic hyperkeratosis, proteinaceous fluid, degenerating neutrophils, cellular debris and bacterial colonies. The subsequent microscopic appearance of the lesions depends on the degree of secondary bacterial infection.

Contagious pustular dermatitis occurs in camels and a variety of wild and captive ungulates. Dogs may acquire infection by eating infected lamb carcasses. Lesions resemble those in sheep. It is a *zoonotic disease* and is a recognized occupational hazard amongst goat and sheep handlers.

Ulcerative dermatosis of sheep

Ulcerative dermatosis is a disease of the epidermis of sheep that has been reported in the literature as being caused by an *unclassified poxvirus*, which is similar to *Orf virus*, but the viruses do not cross-protect. The disease has been reported in South Africa where it is known as "pisgoed" or "pisgras," in the United Kingdom as a contagious venereal infection, and in the USA where it is known as "lip and leg ulceration," "anovulvitis," "infectious balanoposthitis" and "ulcerative vulvitis." The various names indicate the *essential features of the disease, which are ulcerative papules on the lips, face, legs, feet, vulva, prepuce and, occasionally, the glans penis.* The genital lesions are transmissible by coitus.

Presumably, infection results from viral contact with damaged skin. *The pathologic process is primarily ulcerative*, with ulcers of up to 4–5 cm in diameter and 3–5 mm deep. Pus covers the granulation tissue at the base of the ulcer and underlies a scab that is thin, brown and bloody, and unlike the thick parakeratotic crusts that develop in contagious pustular dermatitis. The underlying dermis is diffusely swollen, especially in distensible parts such as the vulva and prepuce. The lesions on the hairy parts of the face tend to be fairly well circumscribed, but those of the feet tend to spread, especially on the interdigital skin. The vulval lesions usually begin on the tip and spread around the margins of the lips. An ulcerative ring tends to form around the preputial orifice, but the preputial mucosa is spared. Lesions on the glans penis remain moist. The urethral process may become necrotic. The labial and pedal lesions must be distinguished from those of contagious pustular dermatitis and foot-and-mouth disease, and the preputial lesions must be distinguished from noncontagious forms of balanoposthitis. *Detailed descriptions of the histopathology of ulcerative dermatitis are lacking*; the lesions are supposedly distinguishable from those of contagious pustular dermatitis by the *lack of epithelial hyperplasia.*

Pseudocowpox

Pseudocowpox is caused by *Pseudocowpox virus*, a *Parapoxvirus*. The virus is closely related to *Bovine papular stomatitis virus* and *Orf virus. It is a common endemic infection in cattle throughout most of the world.* It affects chiefly milking herds and occasionally beef herds. Morbidity in a herd approaches 100% but only 10–15% of cows are affected at any one time. The economic significance lies in the effect on milk production, either as a result of sore teats or because of secondary bacterial mastitis. Lesions, which affect the teats (Fig. 5.81), udder, and perineum, commence as erythematous macules and papules, but do not form the umbilicated pustules seen in cowpox and vaccinia infections. Instead, a characteristic ring or horseshoe-shaped crust forms that may become umbilicated as it expands, but infrequently ulcerates. *The histologic appearance of lesions is typical of other poxviral infections*. The lesions usually heal within 6 weeks. Occasionally, lesions develop in the mouth and on the muzzle of suckling calves, and the infection can be spread by cross-suckling as well as poor hygiene in milking sheds. Transmission to people induces "milker's nodule."

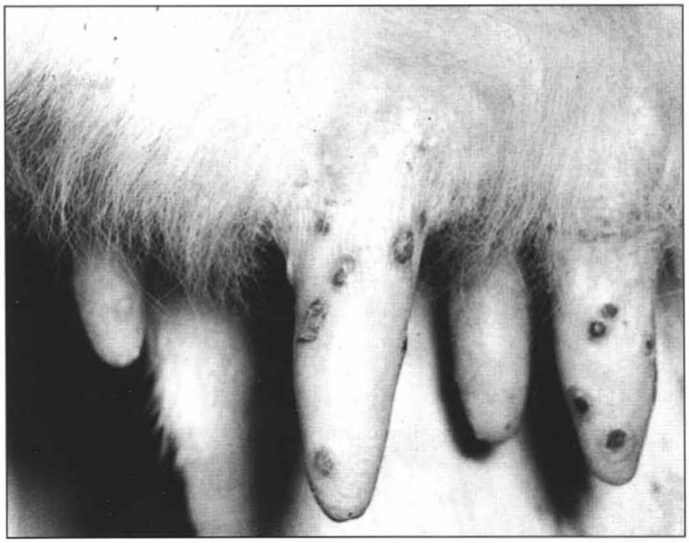

Figure 5.81 Pseudocowpox on the teats of a cow.

Bovine papular stomatitis

Bovine papular stomatitis virus is distributed worldwide, and although it causes disease more commonly in *cattle <2 years old* it can occur at any age and in any breed. Lesions occur on the *muzzle, nostrils, lips, and mouth* (see Vol. 2, Alimentary system), and cows with suckling calves can develop *teat and udder lesions*. The development and appearance of the lesions are similar to pseudocowpox, with resolution of lesions in days to weeks. A chronic form has been described in which exudative necrotic dermatitis involved the trunk as well as the mouth, and in which the animals died in 4–6 weeks. *Transmission to humans induces lesions identical to "milker's nodule"* caused by *Pseudocowpox virus* infection. The histologic appearance of lesions is typical of other poxviral infections.

Parapox of red deer

A new addition to the genus *Parapox* is the *Parapox virus of red deer*, first noted in 1986 in farmed red deer in New Zealand. Morbidity is high, but mortality is low unless secondary infections are present. The virus causes crusty lesions on the lips, muzzle, face, ears, and neck, and on the antler velvet in stags. Removal of the crusts leaves a red raw ulcer. Histologic lesions are characterized by *epithelial hyperplasia with ballooning degeneration, dyskeratosis, and eosinophilic cytoplasmic viral inclusions.*

Orthopoxviral diseases

Cowpox

Cowpox virus and cowpox-like viruses belong to the genus *Orthopoxvirus*. They are closely related to, but antigenically different from, *Vaccinia virus*. Cowpox affects a range of species including *wild and domestic Felidae, cattle, dogs*, rodents, humans, and several zoo and circus animals including elephants and rhinoceros. Cowpox occurs in the *UK and Europe*. Outbreaks reported from other geographical locations can be ascribed to *Vaccinia virus* infection; the lesions induced by the two orthopoxviruses are clinically indistinguishable. In cattle, *Cowpox virus* infection is manifested by poxvirus lesions that develop on the *teats and udder*, and occasionally at other sites such as the muzzle of suckling calves. *Cowpox virus* is not endemic in cattle and *infections in cattle are uncommon*. Re-evaluation of the epidemiology of *Cowpox virus* relegates cattle to a minor role, and it has become increasingly clear from serologic surveys that *small wild rodents, such as voles and mice, are the virus reservoir*, and it is from this reservoir that other mammals can become infected accidentally. Domestic cats, and rarely dogs, in UK and Europe, can be infected by hunting wild rodents, and cats occasionally have been shown to be able to transmit the infection to humans. The evidence suggests, however, that the virus is of low infectivity for humans. Since the first report in 1978, *Cowpox virus* infection has been documented with increasing frequency within its geographical range of the UK and Europe. Epidemiological studies show a higher prevalence in free-ranging country-dwelling cats and a seasonal incidence in the autumn, a time when the small mammal population is at its highest. These features further support the serologic evidence of a wild rodent reservoir of virus.

Domestic cats develop *cutaneous* and, occasionally, *respiratory lesions*. The primary lesions in cats have a predilection for the *face and forepaws*. Approximately 50% of cats show a single primary cutaneous lesion, usually on the head, neck, forelimbs, or paws. The initial lesion is ulcerative and has been described as "bite-like." Lesions heal by granulation, but may occasionally develop into abscesses or cellulitis. The secondary cutaneous lesions develop 4–16 days after the onset of the primary lesion. Generalization from primary inoculation sites in the skin has also been demonstrated in experimentally infected cats. Mucocutaneous junctions, oral mucosa and the tongue may also be involved. *Secondary lesions* are multiple (usually more than ten lesions). They commence as firm 2–3 mm nodules, enlarging over 2–3 days to form 0.5–2 cm, circular, ulcerated papules or plaques. Lesions are rarely vesicular except on the oral mucosa and inner aspect of the pinna. The ulcers heal with thick gray crusts over 2–3 weeks. Cellulitis may develop but generally secondary bacterial infection is not a significant complication. Corticosteroid or progesterone therapy may be responsible for converting a local infection into a generalized one or exacerbating the secondary lesions in some animals. Although fatal *Cowpox virus* infection has been seen in cats with concurrent *Feline immunodeficiency virus* (FIV) infection, there is no convincing evidence to show a direct relationship. Approximately 30% of *Cowpox virus*-infected cats concurrently infected with FIV have uneventful recoveries.

The disease is rarely fatal. Approximately 20% of cats show some signs of malaise in the acute stage of secondary lesion development, presumably associated with a viremic phase, and a few exhibit clinical signs of upper respiratory tract disease. Lower respiratory tract lesions, which are rare in domestic cats, include pleural effusion and localized areas of cream-colored consolidation in the ventral lung lobes. They are thought to develop from systemic spread rather than from primary respiratory infection.

The *microscopic lesions* in naturally infected cats are *focal, sharply demarcated ulcers covered by fibrinonecrotic exudate*. The ulcers may extend to the deep dermis, subcutis or even muscle. An intense dermal inflammatory cell infiltrate of neutrophils and mononuclear cells may be associated with the base of the ulcers. *Eosinophilic, homogeneous, intracytoplasmic inclusion bodies*, 3–7 μm in diameter, occur in keratinocytes in the hyperplastic epithelium at the margin of the ulcers and in the epithelium of the external root sheath and sebaceous gland. Epidermal lesions typical of poxvirus infections develop in cats experimentally infected intravenously or by skin scarification. These lesions include focal hyperplasia, with reticular degeneration and multilocular vesiculation. Epidermal cells bordering the vesicles contain eosinophilic intracytoplasmic inclusion bodies. Viral inclusions also occur in macrophages, fibroblasts and endothelial cells. The extensive necrosis is probably ischemic in origin following viral damage to endothelial cells. The pulmonary lesion is a necrotizing alveolitis in which eosinophilic inclusion bodies are present in the degenerating cells.

Electron microscopic examination of scabs reveals typical orthopox virions. *Cowpox virus* infection may be confirmed by immunohistochemical staining of lesions, PCR, or virus isolation. Serological tests may be helpful in establishing retrospective diagnoses, as virus neutralizing antibodies are persistent for several years.

There have been outbreaks of severe orthopox infections in several species of **nondomestic Felidae** in English and Russian zoos. Lions, cheetahs, pumas, jaguars, and ocelots have been affected. Rats were implicated as the source of infection in the Russian outbreaks. Two forms of the disease are recognized. The cutaneous form is rarely fatal. The lesions are ulcerative and crusted as described for domestic cats. The respiratory form is uniformly fatal and consist of severe fibrinous and necrotizing bronchopneumonia and pleuritis. A virus closely resembling *Cowpox virus* is responsible.

Vaccinia

Vaccinia virus, the type species for the *Orthopoxvirus* genus, *does not cause natural infection in domestic animals. The origin of the virus is controversial.* One theory is that it represents the laboratory survival of horsepoxvirus, which is now extinct in nature, and that horse-derived material was the source of vaccine material used by Edward Jenner in 1817 to protect against variola or smallpox. Another theory is that *Vaccinia virus* was derived from *Cowpox virus* by repeated passage on the skin of cows, sheep, and other animals, and that "horsepox" was due to the infection of horses with *Cowpox virus*. Incidental infections in cattle, horses and pigs were transferred from vaccinated people. The lesions in cattle are indistinguishable from those of cowpox and in swine are indistinguishable from those of swinepox. When vaccinia is inoculated onto scarified skin of horses, papular lesions resembling a naturally occurring poxvirus infection described in horses in the USA result. Furthermore, inoculation of the skin of the flexor surface of the pastern produces lesions resembling the classical "grease heel" form of horsepox. *Vaccinia virus infections of animals are rare* now that smallpox has been eradicated and routine vaccination has been discontinued.

Buffalopox

Buffalopox virus, an *Orthopoxvirus* closely related to *Vaccinia virus,* is the cause of buffalopox, an economically important disease of domestic buffaloes. It is thought that Buffalopox virus is a subspecies of *Vaccinia virus* resident in the water buffalo population. In India it is considered to be an emerging enzootic virus and can occur in epidemic form, with significant economic impact. It has been reported in Pakistan, Indonesia, Egypt, Italy, and Russia. Zebu cattle are apparently refractory to infection. The lesions predominantly affect the teats, udder, medial aspects of the thighs, lips and muzzle but may be generalized, especially in calves. *Buffalopox virus can be zoonotic*, causing lesions primarily on the hands. Human-to-human transmission has been postulated following the occurrence of disease in children who had had no contact with infected animals. Experimentally, the virus can be transmitted to cattle, rabbits, guinea pigs, and mice.

Camelpox

Camelpox virus, a distinct species of *Orthopoxvirus*, causes severe disease in *dromedary camels*. It is characterized by *high morbidity and a relatively high mortality rate* in young animals. A major effect is a fall in milk production and loss of condition. The disease is widespread in northern and eastern Africa and mid-eastern Asia but has not been reported in Australia. Lesions affect both *skin and mucous membranes* and follow the usual pattern of pox lesions. Lesions tend to be most concentrated around the mucocutaneous junctions of the face but may be found on the neck and forelegs. Rarely, the infection can involve the respiratory system or become systemic. Generalized skin lesions occur more typically in calves. Fatalities are usually associated with *secondary bacterial infection leading to septicemia*, a phenomenon more prevalent in the rainy season. Clinically, *the lesions can be identical to parapox* (camel contagious ecthyma) and laboratory tests such as ELISA, PCR, and immunohistochemistry, as well as electron microscopy, can be used to differentiate the infections.

"Horsepox" and Uasin Gishu disease

Horsepox was a common disease of horses in the 18th and 19th centuries; however, *it became naturally extinct at the end of the 19th century*. It is thought that Jenner, in his "cowpox" vaccination experiments to protect humans from smallpox, was actually using horse-derived material as a source of the vaccine, and that *Vaccinia virus* may be the long-lost agent of horsepox. Experimental infection of horses with *Vaccinia virus* reproduces the "grease heel" lesions of Jenner's horsepox and the more generalized form known as *equine papular dermatitis*. Orthopoxviruses have been isolated from equine papular dermatitis; however, the virus has not been fully characterized. *Orthopoxvirus* has also been isolated from Uasin Gishu disease in Kenya, and Uasin Gishu disease virus is closely related to *Vaccinia virus* and *Cowpox virus*.

Poxviral lesions in the horse take *several clinical forms*. Jenner originally described an exudative dermatitis of the flexor aspects of the hind pasterns. The condition is colloquially named "*grease heel*" because thick, yellow grease-like exudate mats the hair. Unfortunately, poxvirus infection is only one manifestation of this clinical entity, sparking considerable controversy as to the true nature of equine pox.

A second form has a predilection for the *muzzle and buccal cavity*. The lesions, which develop in the typical sequence of a pock, affect the inner surface of the lips and cheeks, the gums, and the ventral surface of the tongue. Following the development of the buccal eruptions, crops of pocks may appear in the rostral nares, on the face and on other parts of the body. It is a benign infection, sometimes seriously complicated by bacterial contamination.

Another manifestation takes the form of generalized papular eruptions. In the USA and Australia, the disease is known as

equine papular dermatitis. This is a highly contagious disorder, spreading by direct contact and through infected harness, bedding and grooming tools. The lesions are firm papules, up to 0.5 cm diameter, which tend to develop on the lateral neck and shoulder and thorax but become generalized. The papules become crusted and the crusts slough to leave circular alopecic patches. Resolution may take 6 weeks.

Uasin Gishu disease from Kenya is also characterized by generalized skin lesions but the disease differs clinically from equine papular dermatitis. Lesions begin similarly as small papules but develop into crusted papillomatous proliferations, up to 2 cm diameter. Lesions eventually resolve but the disease may continue for 2 years. The histologic lesions of Uasin Gishu are identical to molluscum contagiosum.

Equine molluscum contagiosum

Equine molluscum contagiosum is another proliferative poxvirus infection in the horse, and *the causal virus is now thought to be identical to, or closely related to, human Molluscum contagiosum virus.* In horses this is a mildly contagious, self-limiting cutaneous infection. In situ hybridization experiments indicate there is very close homology between the equine and human *Molluscum contagiosum virus*. Attempts to grow both the human and equine *Molluscum contagiosum virus* in culture have failed, and this can help differentiate the virus from the orthopoxvirus of Uasin Gishu, which produces histologically and clinically similar lesions, but which can be grown in culture. Cutaneous lesions resembling the human and equine condition clinically, microscopically and ultrastructurally occur in macropods (kangaroos and quokkas) and chimpanzees. The small, self-limiting lesions are easily overlooked and usually are found incidentally at autopsy or surgery. The equine lesions may be localized to the *penis, prepuce, axillary and inguinal areas, and muzzle.* Concurrent systemic disease, such as granulomatous enteritis, may predispose to more widespread distribution. Commencing as multiple, circular, smooth-surfaced, gray-white 1–2 mm papules, the lesions become umbilicated and develop a central pore from which a tiny caseous plug is extruded.

The microscopic lesions of molluscum contagiosum are highly characteristic. *Well-demarcated foci of epidermal hyperplasia and hypertrophy form pear-shaped lobules in the superficial dermis.* The individual keratinocytes are markedly swollen and contain *large intracytoplasmic inclusions known as "molluscum bodies"* (Fig. 5.82). These occur initially as eosinophilic, floccular aggregates in the cells of the inner stratum spinosum. As the keratinocytes move towards the surface, the inclusions grow in size and density, compressing the nucleus against the cytoplasmic membrane until it is a thin crescent. The inclusion becomes increasingly basophilic so that cells of the stratum corneum contain deep-purple molluscum bodies. These exfoliate through a pore that forms in the stratum corneum and enlarges into a central crater. There is usually no dermal reaction. Molluscum bodies are easily identified in cytological preparations. The inclusions contain myriads of poxvirus particles at various developmental stages, but to date no attempts have been made to culture these viruses, presumably because the diagnosis has been post-mortem.

Capripoxviral diseases

Sheeppox, goatpox and lumpy skin disease of cattle are caused by viruses of the genus *Capripoxvirus* and cause significant economic losses in countries where they are endemic. The exact relationship between these viruses has been controversial. *It is believed that they represent strains of a single virus.* The evidence includes antigenic and biochemical similarity, a high degree of nucleotide sequence homology, lack of absolute host specificity in most strains, evidence of recombination in the field, and demonstration of cross-infection and cross-protection. The viruses are indistinguishable by conventional serology; nevertheless the geographic distributions of the

3 are different indicating the viruses are distinct, and most strains of *Capripoxvirus* show definite host preferences. PCR methods of diagnosis of capripoxvirus have been developed so that classical virology methods based on live virus need not be used in areas of the world where the virus is exotic.

Sheeppox

Sheeppox is the most serious of the pox diseases of domestic animals. It exists in Africa, Asia, and the Middle East where, despite attempts at vaccination, it is responsible for cycles of epidemic disease followed by periods of endemic maintenance with low morbidity. The disease is exotic to the Americas, Australia, and New Zealand. Eradication measures eliminated the disease from Britain in the mid-19th century but have only recently been successful in Eastern European countries. *Sheeppox causes extensive economic loss* through high mortality, reduced meat, milk or wool yields, commercial inhibitions from quarantine requirements, and the cost of disease prevention programs.

Transmission of infection is by direct contact with diseased sheep or indirect contact via contaminated environment. Insect transmission has been demonstrated experimentally. *Sheeppox virus* is resistant to desiccation and remains viable for up to 2 months on wool or 6 months in dried crust. There are breed differences in disease susceptibility. Fine-wooled Merino sheep are particularly sensitive whereas breeds native to endemic areas, such as Algerian sheep, are comparatively resistant. Sheeppox occurs in all ages of sheep with high morbidity, and mortality as high as 50%; but the disease is most severe in lambs, with mortality reaching 80–100%. A high level of background immunity, such as occurs in endemic areas of Kenya, is associated with low mortality, even in the young.

Sheeppox is a *systemic disease*. Infection is usually by the respiratory route but may occur through skin abrasions. The incubation period is 4–7 days and is followed by a leukocyte-associated viremia. The virus localizes in many organs including the skin where the virus concentration is highest 10–14 days postinfection. The initial clinical signs are fever, lacrimation, drooling, serous nasal discharge, and hyperesthesia. Skin lesions, which develop 1–2 days later, have a predilection for the sparsely wooled areas and typically involve eyelids, cheeks, nostrils, vulva, udder, scrotum, prepuce, ventral surface of the tail, and medial thigh.

The macroscopic lesions follow the typical pattern for pox infections. *Sheeppox lesions have a prominent vesicular stage* (Fig. 5.83A, B). The vesicles are umbilicated and, being multilocular, yield only a small amount of fluid if punctured. Occasionally a large vesicle forms as a result of cleavage of necrotic epidermis from underlying dermis. The *pustule stage* is characterized by the formation of a thin crust. In severely affected animals, the lesions coalesce. There may be marked, gelatinous dermal edema. Highly susceptible animals often develop hemorrhagic papules early in the course of the disease and, later, ulcerative lesions in the gastrointestinal and respiratory tracts. Approximately one-third of animals develop multiple pulmonary lesions that comprise *foci of pulmonary consolidation*.

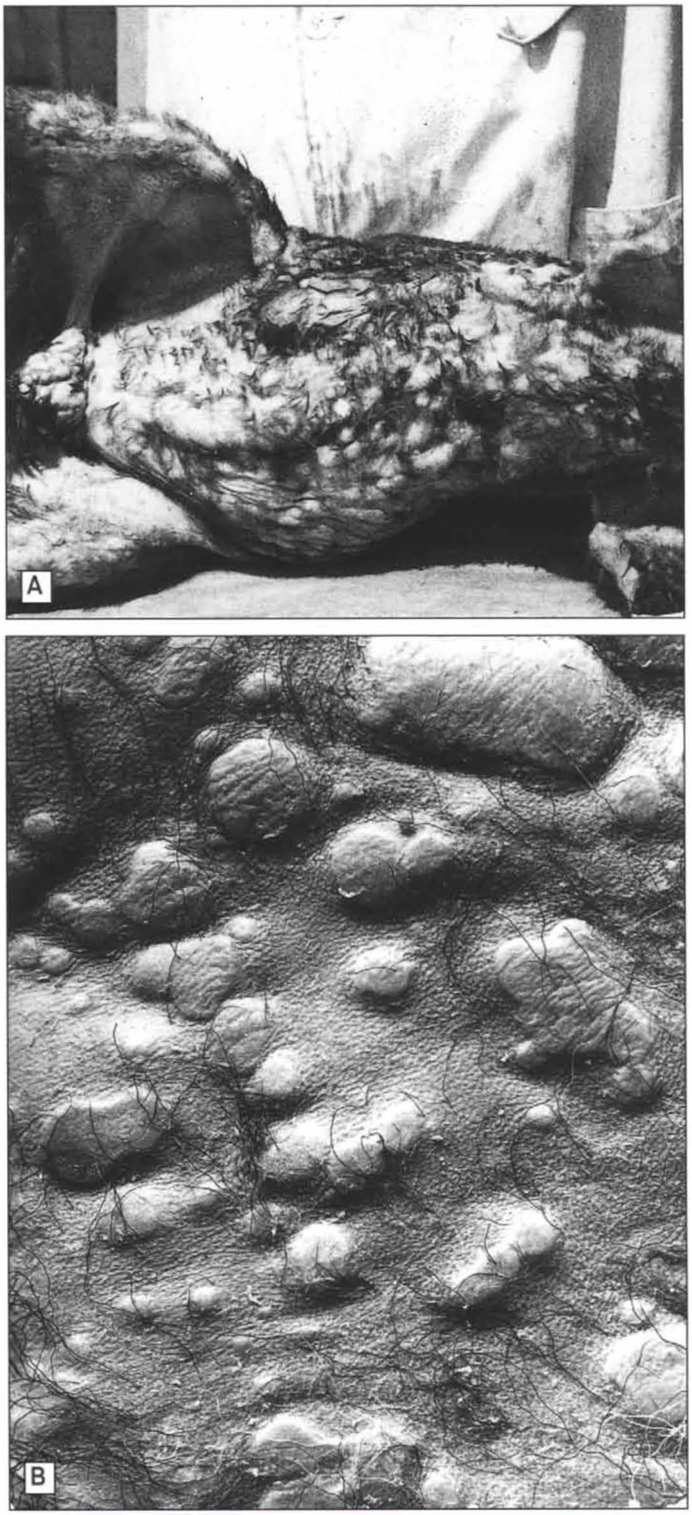

Figure 5.83 Sheeppox. (Courtesy of X Ivanov). **A.** Disseminated irregular swellings involving ventral abdomen and scrotum **B.** Close-up of papules.

The kidneys have multifocal, circular, fleshy nodules throughout the renal cortices.

Healing of the skin lesions is slow, taking up to 6 weeks and a scar may remain. In the milder form of the disease, seen in endemic areas, the full range of pox lesions does not develop. Instead, epidermal proliferation produces papules covered by scale-crust, which heal with desquamation in a few days. Such lesions often occur on the ventral surface of the tail.

Sheeppox lesions have the typical epithelial changes for the group, including marked vacuolar degeneration of stratum spinosum keratinocytes, microvesiculation, eosinophilic intracytoplasmic inclusion bodies, and epidermal hyperplasia. The lesions affect both surface epithelium and that of the hair follicles. There are, in addition, *marked dermal lesions* reflecting the systemic route of cutaneous involvement and possibly implicating immune-mediated lesions in addition to those caused by direct viral damage. The initial dermal lesions, corresponding to the macroscopic erythematous macule, are marked edema, hyperemia and neutrophilic exocytosis. During the papular stage, large numbers of mononuclear cells accumulate in the increasingly edematous dermis. These cells, first described by Borrel, are called "cellules claveleuses" or "*sheeppox cells*" and are characteristic of the disease. The nuclei of sheeppox cells are vacuolated and have marginated chromatin. The vacuolated cytoplasm contains single, occasionally multiple, *eosinophilic intracytoplasmic inclusion bodies.* Sheeppox cells are virus-infected monocytes, macrophages and fibroblasts, but not endothelial cells. Approximately 10 days post-infection and corresponding with the most prominent epithelial lesions and peak of skin infectivity, severe necrotizing vasculitis develops in arterioles and post-capillary venules. Virus particles have not been identified in endothelial cells, and the vasculitis may be due to immune-complex deposition. Ischemic necrosis of the dermis and overlying epidermis follows.

The pulmonary lesions are proliferative alveolitis and bronchiolitis with focal areas of caseous necrosis. Alveolar septal cells contain intracytoplasmic inclusion bodies. Additional histologic lesions, characterized by the accumulation of sheeppox cells, may involve heart, kidney, liver, adrenals, thyroid and pancreas.

The course and outcome of sheeppox depend not only on the usual host-virus relationship but also on the nature and location of secondary infections. The virus itself may cause death during the febrile, eruptive phase of the disease. Of great importance, however, are the secondary bacterial infections that rapidly develop in the necrotic tissue of the pocks. Death is often due to bacterial septicemia or pneumonia.

Goatpox

Goatpox, caused by *Goatpox virus*, occurs in North Africa and the Middle East. A benign form of goatpox occurs in California and Sweden. The clinical signs of goatpox vary in different geographic areas. The disease has *many parallels with sheeppox, but is generally milder* with a low mortality rate (5%), although generalized eruption with mortality rates approaching 100% may occur. The cutaneous lesions have a predilection for the same areas as for sheeppox. In nursing kids, lesions may appear on the buccal mucosa or rostral nares. In animals with higher levels of resistance, the lesions may be confined to the udder, teats, inner aspects of thighs or ventral surface of the tail.

Lumpy skin disease

Lumpy skin disease, caused by *Lumpy skin disease virus* of the *Capripoxvirus* genus, is a disease of cattle, buffalo, and occasionally other wild species of hoofstock, characterized by the *eruption of multiple, well-circumscribed skin nodules, accompanied by fever, ventral edema, and generalized lymphadenopathy.* Lumpy-skin disease is found throughout the African continent and Madagascar, with sporadic reports from the Middle East and Israel.

Cattle of all ages, sex and breeds are affected, although the disease is more severe in Channel Island breeds. Both *Bos indicus* and *Bos taurus* cattle are susceptible, however the disease can be less clinically severe in Zebu breeds. The disease occurs in epidemics – a notable one in 1944 affected 8 million cattle. Infection is transmitted mechanically by a variety of biting insects. Epidemics tend to follow periods of prolonged rainfall, which favor population increases in vector species. A forest maintenance cycle, probably involving Cape buffalo, is thought to be the reservoir of infection in the inter-epidemic periods. No reservoir host apart from cattle has been identified.

The morbidity is extremely variable and inapparent infection is not uncommon. *Mortality is usually low*; around 1% but may be >50%. Economic losses are due to debilitation, loss of milk and meat production, damage to hides, and reproductive wastage due to fever-associated abortions and temporary sterility in bulls.

The natural incubation period of lumpy-skin disease is 2–4 weeks, but this may be halved in experimental infection. In severely affected animals, the development of large numbers of cutaneous lesions over most of the body is preceded by fever, marked weight loss, profuse drooling, oculonasal discharge, ventral edema and generalized lymphadenopathy. In the mild disease, there may be few isolated nodules and no prodromal fever. *The cutaneous lesions are firm, circumscribed, flat-topped nodules 0.5–5.0 cm in diameter* (Fig. 5.84). They may coalesce. The nodules have a creamy-gray color on cut section and involve the full width of the cutis, extending into the subcutis and occasionally adjacent muscles. Nodules affecting the scrotum, perineum, udder, vulva, glans penis, eyelids and conjunctiva are usually flatter, and in non-pigmented tissue are surrounded by a zone of intense hyperemia. *The fate of the nodules varies. Typically, they undergo central necrosis and sequestration, but some may resolve rapidly and completely, and others may fail to separate but, instead, become indurated and persist as hard intradermal lumps for many months.* Sequestration is preceded by central necrosis in the nodule and occurs rapidly. Separation of the epidermis around the margin of the nodule exposes a rim of dermal granulation tissue. As the process of separation extends into the dermis, the nodule comes to contain a *core or sequestrum of*

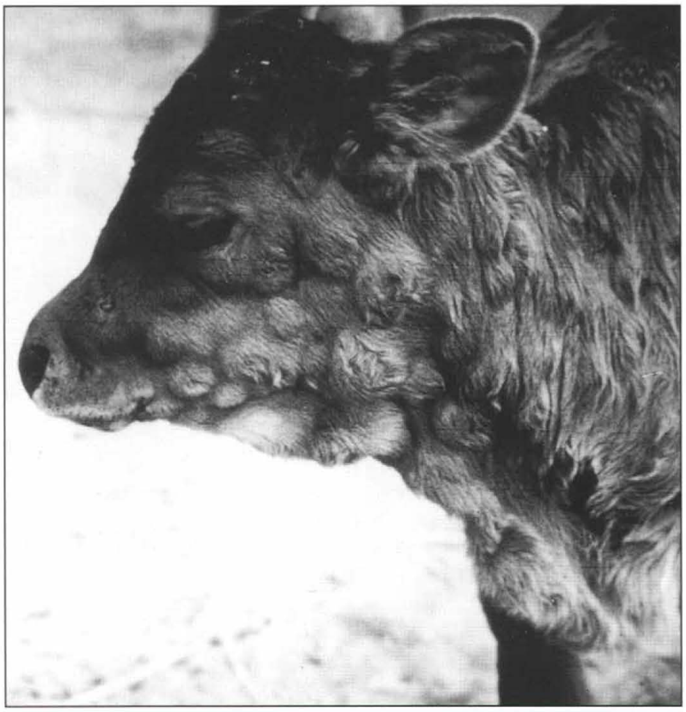

Figure 5.84 Circumscribed, nodular lesions of the skin in **lumpy skin disease** in a calf. (Courtesy of CC Brown.)

necrotic material ("sit-fast"), which is cone-shaped and flat-topped. When the sequestrum is removed, a deep ulcer remains which is slowly filled with granulation tissue. *Secondary bacterial infections* develop in the necrotic cores of the nodules and contribute very significantly to the seriousness of the disease. Large craterous ulcers develop which lead to lymphangitis and lymphadenitis. Local extension of lesions causes blindness, tenosynovitis, arthritis or mastitis.

The mucous membranes of the upper respiratory and upper alimentary tracts often develop multiple, discrete ulcerative lesions, irrespective of the number of cutaneous nodules. Those in the respiratory tract may cause swelling sufficient to result in severe dyspnea and asphyxia. Aspiration may lead to pneumonia or, if the animal recovers, scarring may cause stenosis of the cranial portion of the trachea. Nodules occasionally occur in parenchymal organs including kidneys, lungs and testes.

Although the virus is introduced percutaneously, *the infection is systemic*. A leukocyte-associated viremia disseminates the virus to various tissues, including the skin where greatest virus concentration occurs 9–12 days postinfection. The virus infects a wide range of cells, including keratinocytes, mucous and serous glandular epithelium, fibrocytes, skeletal muscle, macrophages, pericytes, and endothelial cells. *Damage to endothelial cells causes vasculitis that is central to the pathogenesis of the lumpy-skin disease lesions.*

Acute lesions consist of vasculitis, lymphangitis, thrombosis, marked dermal edema that sometimes induces dermoepidermal separation, and infarction. The epidermis shows the typical vacuolar changes associated with poxvirus infection. *Intracytoplasmic, eosinophilic, homogeneous, and occasionally granular, inclusion bodies* occur in endothelial cells, pericytes, keratinocytes, macrophages and fibroblasts. Virions in various stages of development are present in these inclusion-containing cells and in peripheral nerves. Neutrophils, macrophages and occasionally eosinophils migrate into the dermis in the acute lesions to be replaced as the lesion ages by a predominantly mononuclear cell population. The infarcted tissue is sequestered and surrounded by granulation tissue. Inclusion bodies are absent from the resolving lesions but may be present in adjacent skin or sebaceous glands. Lymph nodes are edematous and hyperplastic.

The chief differential diagnosis is **pseudo-lumpy skin disease** *caused by a herpesvirus identical to the bovine herpes mammillitis virus but originally known as the Allerton virus.* Pseudo-lumpy skin disease is a milder condition clinically and the nodules are superficial, resembling only the early stage of lumpy-skin disease. Confirmation of the latter is best achieved by demonstration of poxvirus particles in fresh or formalin fixed tissue.

Suipoxviral disease

Swinepox

The host-specific *Swinepox virus*, the sole member of genus *Suipoxvirus*, is the chief cause of pox lesions in swine. In the past, *Vaccinia virus* was also responsible. The disease occurs worldwide and is endemic in areas of intensive swine production. The disease has received relatively little attention as it is *usually mild and mortality is negligible. It chiefly affects young, growing piglets* but occurs in neonates promoting speculation that transplacental infection may be possible. Normally, *swinepox virus* is transmitted by contact. The virus is resistant and persists in dried crust from infected animals. The sucking louse *Haematopinus suis* often acts as a mechanical vector and also assists infection by causing skin trauma. *The gross lesions typically affect the ventral and lateral abdomen, lateral thorax, and medial foreleg and thigh* (Fig. 5.85A). Occasionally, lesions on the dorsum predominate. In severe infection, lesions may be generalized and rarely involve the oral cavity, pharynx, esophagus, stomach, trachea and bronchi. The morphology of the gross lesions follows the typical pattern of pox infection. The erythematous papules usually transform into umbilicated pustules without a significant vesicular stage. The inflammatory crust eventually sheds to leave a white macule. *Grossly, swinepox must be differentiated from the vesicular diseases, classical swine fever, pityriasis rosea, dermatosis vegetans, and sunburn.*

The histologic lesions also follow the pattern for pox infections (Fig. 5.85B). The eosinophilic, intracytoplasmic inclusion bodies are quite transient and are not found in older lesions. Vacuoles develop in the nuclei of infected stratum spinosum keratinocytes early in the course of swinepox infection.

Vaccinia virus causes lesions in swine that are clinically difficult to differentiate from *Swinepox virus* infection. However with the eradication of smallpox and the cessation of smallpox vaccination, swinepox is now the primary poxviral disease of swine. Vaccinia viral infections have a shorter incubation period and smaller, more

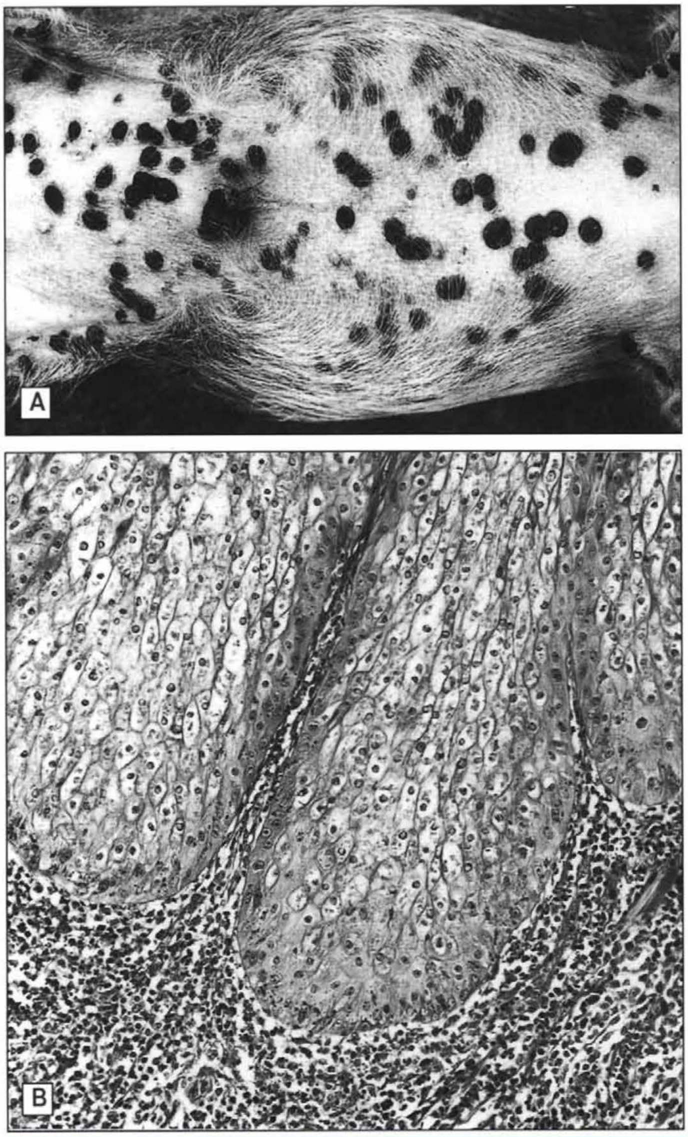

Figure 5.85 Swinepox. A. Gross lesions on ventral body. **B.** Marked acanthosis and intracellular edema and diffuse dermatitis.

transient lesions. Histologically the lesions are very similar except that nuclear vacuoles are not observed. The diseases are definitively differentiated only by virological examination.

Herpesviral infections

The Herpesviridae is a large family of *enveloped DNA viruses* responsible for important animal diseases, of which relatively few are primary skin diseases. *Bovine herpesvirus 2* causes primary cutaneous infections and is widespread in many parts of the world. It is responsible for 2 distinct clinical forms of skin disease; *bovine mammillitis of cattle*, which is the major cutaneous infection, and *pseudo-lumpy skin disease*. Skin lesions occur in systemic herpesvirus infections such as *malignant catarrhal fever*, and *infectious bovine rhinotracheitis* in cattle, and *pseudorabies* in pigs. Skin lesions associated with *Felid herpesvirus 1* infection are also recognized, usually in the absence of respiratory lesions. Vesicles, pustules, ulcers and depigmentation are seen on the genital organs and occasionally the lips and nostrils of horses with *Equid herpesvirus 3* infection (equine coital exanthema), and in *Bovine herpesvirus 1* infectious vulvovaginitis and balanoposthitis.

Bovine herpesvirus 2 diseases

Pseudo-lumpy skin disease

Bovine herpesvirus 2 (BoHV2) is a member of the Alphaherpesvirinae subfamily and is antigenically related to human Herpes simplex virus 1. First isolated in Africa in 1957 from lesions resembling lumpy-skin disease, it was named the *Allerton virus*. The associated disease was subsequently named "pseudo-lumpy skin disease" to differentiate it from the more serious disease caused by *Lumpy skin disease virus*. Pseudo-lumpy skin disease is widespread in southern Africa with sporadic reports from Australia, the UK, and the USA. It is characterized by a generalized eruption of superficial cutaneous nodules that develop a central depression but that heal without scar formation and do not produce the deep necrotic sequestra of true lumpy skin disease.

Bovine herpes mammillitis

Bovine herpes mammillitis, or ulcerative mammillitis, is a localized form of BoHV2 infection seen sporadically in the USA, Canada, Great Britain, Europe, Africa, and Australia. Serological surveys indicate that *infection is much more common than disease*. In Africa and Asia, several species of wild animals have antibody titers to the virus, although clinical disease is not seen.

Herpes mammillitis is *chiefly a disease of lactating dairy cows* but occurs in heifers about to calve and in beef animals. The incidence is usually sporadic with occasional local epidemics in fully susceptible herds. In previously exposed herds, the disease affects only the recently introduced nonimmune, first-calf heifers. There is no mortality. The economic significance of teat lesions lies in the effect on milk production or secondary bacterial mastitis, which complicate ~20% of cases.

Intact teat skin is refractory to virus penetration, indicating that *some form of teat trauma precedes infection*. Transmission of the virus is presumed to involve mechanical vectors, particularly the milking machine, but biting flies, such as *Stomoxys calcitrans*, have also been implicated. In the latter instance, it is difficult to explain the localization of lesions to the teat and mammary gland. Local tissue temperature has, however, been shown to be critical in the pathogenesis, and environmental conditions have been associated with the incidence of outbreaks. Experimental cutaneous inoculation of BoHV2 results in higher virus titers and larger and more persistent lesions when the site is kept cold. The increased prevalence of disease in the autumn months may also relate to the temperature sensitivity of the virus. The source of infection within a herd is not known, but latency, a characteristic of the Herpesviridae, is likely important. Latency has been demonstrated in experimental BoHV2 infections.

The macroscopic lesions affect the teats, less frequently the udder and occasionally the perineum of lactating cows. Transmission of infection to nursing calves may result in ulcerative lesions of the muzzle, chin, lips, and occasionally the oral cavity. Teat lesions develop after a 3–7-day incubation period. *The teat becomes very swollen and painful and develops 1–2 cm diameter plaques*. Vesicles are rare. The epidermis in the center of the plaque becomes necrotic and sloughs to expose an erythematous, irregularly shaped ulcer. Exuded serum mixed with blood forms a thin brown crust, which is easily displaced by the teat cups. The lesions heal beneath the crust and there is no residual scar. Lesions on the udder are often diffuse, giving rise to the term "gangrene of the udder." Regional lymph nodes are swollen in the early stages.

The microscopic lesions are characterized by the formation of epithelial syncytia containing prominent intranuclear eosinophilic inclusion bodies. The inclusion bodies are typical Cowdry type A. The nuclear chromatin is marginated and the eosinophilic inclusions are surrounded by a clear halo. The inclusions are numerous from the time of the first macroscopic lesion until the fifth day. Thereafter, they are very difficult to find. Syncytial cell formation commences early in groups of cells in the stratum basale and inner stratum spinosum. The process extends to involve the full thickness of the epidermis, the outer root sheath of the hair follicle infundibulum, and the sebaceous gland. By day 5 after macroscopic lesions develop, the epidermis is necrotic, although the outlines of syncytial cells are apparent. The inclusion bodies lose their sharp outline and fill the entire nucleus. Some are free in the necrotic epidermis, released from fragmenting nuclei. The necrotic epidermis and adnexa are infiltrated with large numbers of neutrophils. Loss of the necrotic epithelium leaves an ulcer, which is covered by hemorrhagic and fibrinous exudate and a band of degenerating neutrophils. Deeper, there is dermal edema and a predominantly mononuclear cell infiltrate. In the healed lesion, the epithelium is re-established; there is superficial dermal fibrosis, and a perivascular infiltrate of predominantly mononuclear cells.

The diagnosis of herpes mammillitis is confirmed by isolation of the virus. A rapid provisional diagnosis may be made by examining clinical material by electron microscopy. Biopsy is diagnostic if lesions are collected before the fifth day. Cytology smears prepared from an early lesion are diagnostic if syncytial cells containing eosinophilic intranuclear inclusion bodies are found. Serological tests allow a retrospective diagnosis provided paired samples are collected and a rising titer identified.

Experimental intravenous inoculation of **sheep** with BoHV2 results in lesions resembling those of similarly inoculated cattle. Naturally occurring outbreaks of dermatitis of the pasterns caused by BoHV2 have been described in captive Dahl sheep. Goats will only develop skin lesions following intravenous inoculation.

Bovine herpesvirus 4 diseases

A strain of *Bovine herpesvirus 4* (BoHV-4) can cause udder lesions on dairy cows (**mammary pustular dermatitis**); the teats are not involved. The macroscopic lesions are *vesicles, pustules, ulcers and crusts*, originally 2–4 mm in diameter, becoming larger with coalescence. The microscopic lesion is *intraepidermal pustular dermatitis*. The etiologic association between BoHV-4 and the cutaneous disease is controversial however, as the virus is an ubiquitous herpesvirus of cattle that can produce no disease when experimentally inoculated into susceptible cattle and can be isolated from cell cultures prepared from clinically normal cattle. While not a primary mastitis pathogen, BoHV-4 may prolong cases of bacterial mastitis. BoHV-4 infection is considered a risk factor for abortion in cows, and is reported as a cause of endometritis in postparturient dairy cows.

Felid herpesvirus 1

Felid herpesvirus 1 (FeHV-1, Feline viral rhinotracheitis virus), a well recognized pathogen of the upper respiratory tract, is commonly associated with oral ulceration. It can also be associated with *focal ulcerative lesions primarily on the haired skin of the face or on the nasal planum*, with rare reports of lesions on the feet and trunk. The lesions generally occur in the absence of clinical respiratory signs. In common with other herpesviruses, FeHV-1 can establish latency in the trigeminal ganglion. As affected cats often have a history of previous respiratory disease or recent stress, recrudescence of a latent herpesvirus infection is likely. *The macroscopic lesions consist of crusts, ulcers, and vesicles, frequently on the face or nasal planum, which can be persistent or recurrent* (Fig. 5.86A). Microscopically, the lesions are

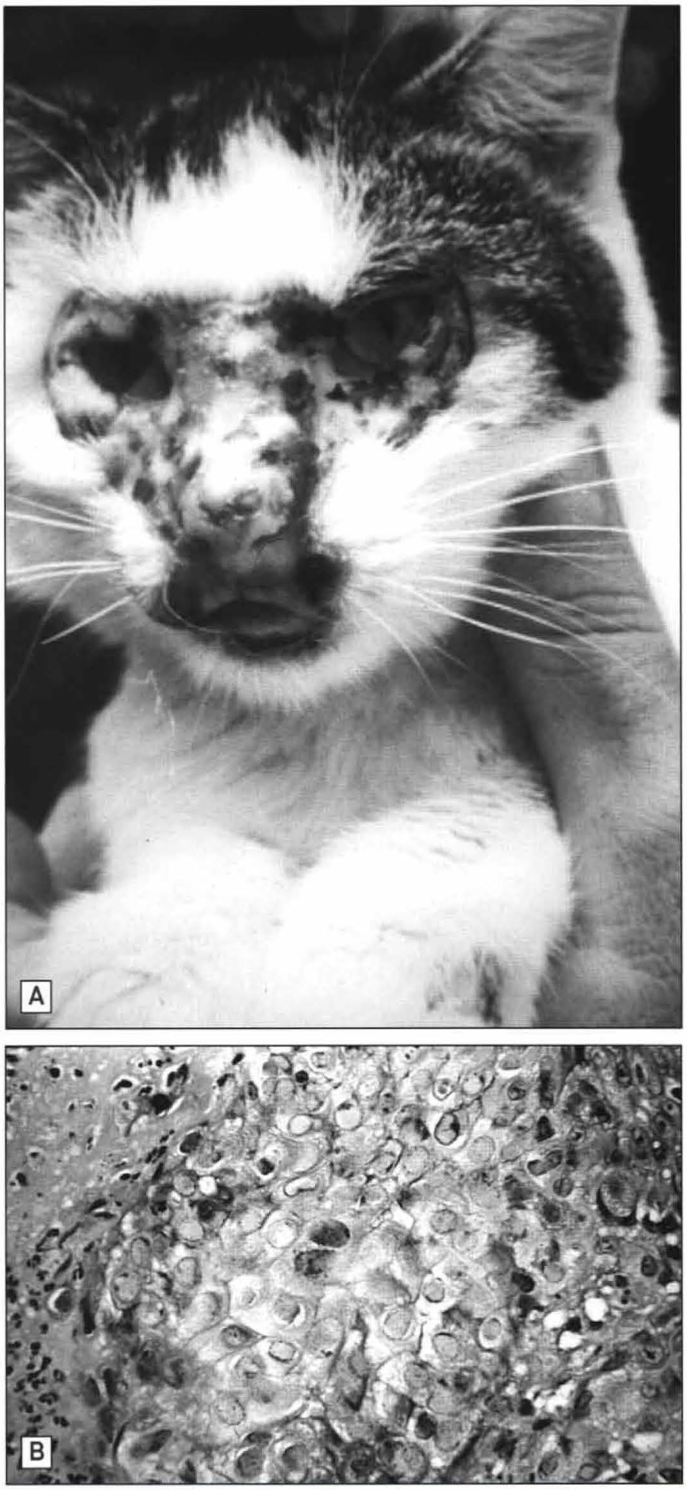

Figure 5.86 Feline herpesvirus dermatitis. A. Marked ulceration and crusting lesions of the face. (Courtesy of University of Florida Clinical Dermatology Service.) **B.** Note marked intracellular edema and **intranuclear inclusions** within keratinocytes.

ulcerative and necrotizing, and the mixed dermal inflammation frequently includes numerous eosinophils. Adnexae can be destroyed and free keratin in the dermis is associated with eosinophils and foci of collagen degeneration. *Large amphophilic or glassy intranuclear inclusions* are present in the surface and adnexal epithelium (Fig. 5.86B). They are variable in number and sometimes hard to find in small rafts of epithelial cells surrounded by necrotic debris. The similarity of the inflammatory component in this condition with that of the feline hypersensitivity conditions, such as mosquito bite hypersensitivity or feline eosinophilic ulcer, warrants close scrutiny of eosinophilic necrotizing cutaneous lesions for intranuclear inclusions or examination by molecular techniques.

Retroviral infections

Several skin disorders have been associated with retroviral infections caused by ***Feline leukemia virus*** (FeLV) and ***Feline immunodeficiency virus*** (FIV) in **cats**. Since both viruses are immunosuppressive, *most dermatological conditions are considered secondary*. However, primary viral infection of keratinocytes has been reported. Scaling, crusting and alopecic lesions affecting primarily the head and face with occasional involvement of trunk and extremities is seen uncommonly in FeLV-infected cats. Histologically, syncytial keratinocytes are seen in the epidermis and superficial follicular epithelium, accompanied by dyskeratosis, pustules, and ulcers. Immunohistochemical staining demonstrates FeLV antigen in epithelial cells and giant cells. In addition, cutaneous keratin horns seen in FeLV-infected cats have been represented as a primary effect of viral infection of keratinocytes. Recurrent pyoderma and paronychia have been attributed to the immunosuppressive effects of FeLV. Bacterial skin disease affecting the face and cellulitis associated with ear tags are described in the acute stage of experimental FIV infection in specific-pathogen-free kittens. Dermatological diseases associated with naturally occurring chronic FIV infection include generalized demodectic mange, notoedric mange, cowpoxvirus infections, pustular pyoderma, atypical mycobacteriosis, miliary dermatitis and abscesses. Cats that are FIV-positive are more frequently diagnosed as having subcutaneous abscesses and cellulitis than are noninfected cats. Since the virus is shed in high titer in the saliva, and bite wounds are thought to be an important mode of transmission, this finding may simply reflect a greater tendency for cats that fight to become FIV-positive. Many of the associations made between retroviral infection and specific diseases are anecdotal.

Parvoviral infections

More typically associated with reproductive problems, ***Porcine parvovirus*** (PPV) has been implicated in outbreaks of vesicular and ulcerative dermatitis and glossitis in 1–4-week-old piglets in the midwestern USA. Various clinical signs, including diarrhea and sneezing, accompanied the skin lesions. *Small slit-like erosions, ruptured vesicles, and extensive ulceration were seen on the tongue, lips, snout, coronary band and interdigital spaces.* Severe lesions sometimes led to separation and sloughing of the hoof wall. Intact vesicles were seen rarely. Sporadic cases have been reported in which the lesions were exudative rather than ulcerative. They were grossly indistinguishable from those of exudative epidermitis. PPV has been cultured from skin and internal organs of affected piglets and PPV antigen has been detected in hair follicles of lesional skin. Skin lesions were reproduced with tissue culture-origin PPV, but were not as severe as those induced with crude suspensions prepared from the skin lesions. In the sporadic cases, *Staphylococcus* spp. and *Swinepox virus* were also recovered. It is likely that the severe clinical disease results from dual bacterial and viral infection.

Papillomaviral infections

Papillomaviruses are associated with a variety of proliferative skin lesions, typically benign epithelial neoplasms, although they have also been shown to be associated with proliferative cutaneous plaques and papules. Although these lesions are almost always benign and often self-limiting, there is evidence that in some cases, both in humans and animals, the virus can be a factor in the development of malignant tumors. Papillomaviruses tend to be species-specific viruses that affect stratified squamous epithelium in all domestic, and numerous wildlife, species. Papillomavirus-associated lesions are discussed under Tumors of the epidermis.

BACTERIAL DISEASES OF SKIN

Normal skin of healthy individuals is highly resistant to invasion by bacteria due to natural defense mechanisms, consisting of physical, chemical, and microbial components. The stratum corneum is composed of tightly packed keratinized cells and intercellular substance derived from lamellar granules that form an impermeable physical barrier. Furthermore, this layer continually desquamates and any adherent bacteria are lost as the outer cells are shed. The sebum-sweat emulsion, which spreads along the skin surface, contains a variety of antibacterial substances including fatty acids, inorganic salts, and proteins such as complement components, transferrin, and immunoglobulins. Finally, the normal skin microflora prevents pathogenic bacteria from multiplying and becoming established on the skin. These normal resident bacteria are a mixture of organisms that live in symbiosis and maintain static, consistent populations restricted to the superficial layers of the stratum corneum and hair follicle infundibula. They inhibit colonization of invading organisms by competition for limited nutrients and production of antibacterial substances. The protective effect of bacterial interference is well documented. For example, the development of exudative epidermitis has been prevented by exposing piglets to avirulent strains of *Staphylococcus hyicus*.

The normal skin flora is established shortly after birth and it is difficult subsequently to introduce other bacteria. The normal resident flora of skin has been investigated most extensively in dogs. Coagulase-negative staphylococci, *Micrococcus* spp, some aerobic gram-negative species, and *Clostridium* spp. are most numerous and are probably residents of canine skin. The presence of coagulase-positive staphylococci in the normal canine microflora is controversial. *Staphylococcus intermedius*, the most common canine skin pathogen, is commonly isolated from the anus and nares and less frequently from the skin and hair of dogs. The mucous membrane sites may act as carrier sites for seeding of the skin, where *S. intermedius* may be a transient organism taking advantage of temporary changes in local microenvironment that permit its short-term proliferation. In all species, skin surface humidity and temperature are important factors in determining the composition and density of skin microflora, with hot humid conditions being associated with increased numbers of skin bacteria. Regional variation in numbers and types of bacteria occurs, and moist intertriginous areas and oily skin have the highest numbers of bacteria.

Cutaneous bacterial infections are typically pyogenic and are thus commonly called **pyodermas**. They can be categorized as *primary and secondary* or *superficial and deep*. Primary pyodermas are those in which no underlying cause can be found. However, *it is now thought that the vast majority of pyodermas are secondary to underlying cutaneous, endocrine, or immunologic abnormalities*. Localized disruption of normal host defenses may be produced by maceration, biting ectoparasites, scratching, abrasions and other skin wounds, or introduction of foreign bodies such as plant thorns or awns; such disruption promotes development of clinical infection. Allergic, seborrheic, and follicular disorders are the most common predisposing causes of bacterial skin infection in dogs. Hypothyroidism and spontaneous and iatrogenic hyperadrenocorticism are common metabolic conditions associated with pyoderma. Primary immunologic abnormalities are uncommon predisposing factors.

Bacterial skin disease is seen much more frequently in dogs than in any other mammalian species, and pyoderma is one of the most common skin diseases in dogs. This apparent increased susceptibility of dogs to pyoderma has been attributed to the relatively thin, compact stratum corneum, the small amount of intercellular lipids in the stratum corneum, lack of a protective lipid seal at the entrance of canine hair follicles, and the relatively high pH of canine skin. *S. intermedius* is the predominant bacterial isolate from canine pyodermas. The factors that promote proliferation of *S. intermedius* on the skin and development of pyoderma are poorly understood. Pathogenicity of staphylococci in humans correlates with various proteins and toxins thought to act as virulence factors. Similarly, a role has been suggested for *S. intermedius* exotoxins (superantigens) in the pathogenesis of canine pyoderma.

Coagulase-positive staphylococci are also the most common bacteria isolated from pyoderma in horses (*S. aureus*, *S. intermedius*), in goats (*S. intermedius*, *S. aureus*), and in cattle and sheep (*S. aureus*). *Staphylococcus hyicus* causes exudative epidermitis in piglets and has been associated with superficial pyoderma in several other species.

Many other bacteria cause skin infections. *Dermatophilus congolensis* is responsible for superficial pyoderma in many species. Many gram-negative bacteria are opportunistic pathogens that can invade already diseased or compromised skin. Organisms that are typically associated with infections of other organ systems occasionally cause skin disease. *Listeria monocytogenes* has been found to be the cause of pyoderma in a small number of humans and a dog. Although bacterial infections are typically associated with neutrophilic inflammation, certain bacteria such as mycobacteria, *Actinomyces,* and *Nocardia* typically produce *granulomatous dermatitis or panniculitis.*

Superficial bacterial pyoderma

Superficial pyodermas involve the epidermis and/or superficial portion of hair follicles. They occur more commonly than deep pyodermas. Superficial pyodermas usually are of short duration, heal without scarring, and are not usually associated with systemic illness. *Gross lesions are extremely variable* and include papules, pustules, crusts, circular scaling areas of alopecia (**epidermal collarettes**) (Fig. 5.87), hyperpigmented or erythematous macules, a moth-eaten appearance to the hair coat, diffuse erythroderma, and hyperpigmented lichenified plaques. *Microscopic lesions* consist of subcorneal or loosely organized, spongiotic superficial epidermal pustules, superficial folliculitis, and crusts. Neutrophils are the predominant inflammatory cell. Bacteria are not always visible histologically and culture may be necessary to confirm the etiology.

Impetigo

Impetigo is a superficial pustular dermatitis that does not involve hair follicles. It is most common in dogs but also occurs in kittens, piglets, cows, sheep, and goats. Impetigo is usually caused by *coagulase-positive staphylococci in association with predisposing causes.* Moist and dirty environments, cutaneous abrasions, parasitism, stress, and poor nutrition are common predisposing factors in most species. Impetigo in adult dogs is frequently seen in conjunction with diabetes mellitus, hypothyroidism, and natural or iatrogenic hyperglucocorticism. Lesions develop in young kittens as a result of excessive wetting of the skin by the queen as she transports the kittens.

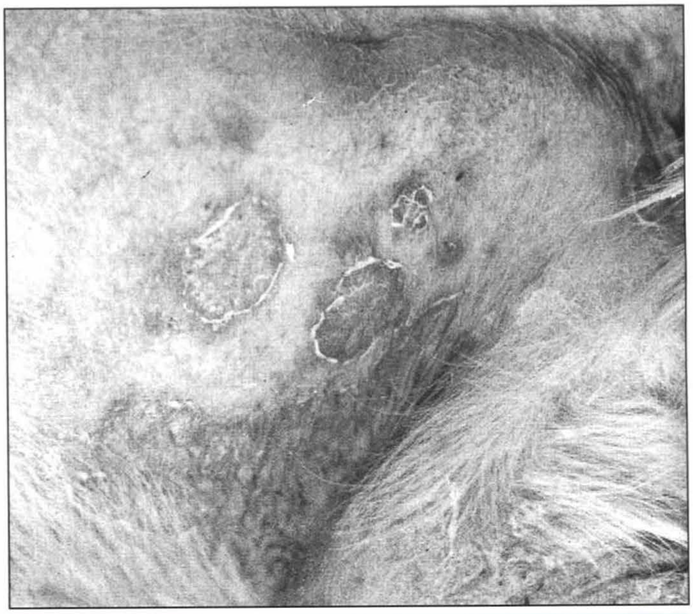

Figure 5.87 Superficial pyoderma. Annular erythematous lesions with epidermal collarette.

The lesions begin as small erythematous papules that develop into superficial pustules (Fig. 5.88A). They are fragile and rupture easily, leaving a honey-colored crust adherent to a shallow erosion. A *bullous form of impetigo*, consisting of large flaccid pustules, is more common in adult dogs. In *puppies*, the lesions are most common on the glabrous skin of the inguinal and axillary areas. In *kittens*, the lesions are usually confined to sites which are most commonly in contact with the queen's mouth; these include the back of the neck, head, and shoulder areas. Lesions in *cows and does* are usually on the udder, especially at the base of the teats and the intermammary sulcus. Occasionally, the infection extends to involve the teats, ventral abdomen, medial thighs, perineum, and ventral surface of the tail. The lesions are infectious and may be spread by the milker to other cows or does and to the hands of milkers. One outbreak of contagious impetigo in a herd of dairy cattle was associated with crowding and intensive showering of the cows to decrease heat stress during the heat of summer.

The microscopic lesion of impetigo is a subcorneal pustule composed of neutrophils primarily (Fig. 5.88B). The pustules usually extend above the skin surface and are located between hair follicles. Bullous impetigo consists of larger pustules that span several hair follicles. Acantholysis may be mild. Gram-positive cocci are present within intact pustules. The epidermis is mildly to moderately acanthotic and variable intercellular edema is common beneath pustules. The superficial dermis is edematous and superficial perivascular to interstitial inflammation is composed of neutrophils primarily. *The principal differential diagnosis is pemphigus foliaceus.* However, in contrast to pemphigus, acantholysis is absent or minimal in impetigo and bacteria are present in intact pustules of impetigo.

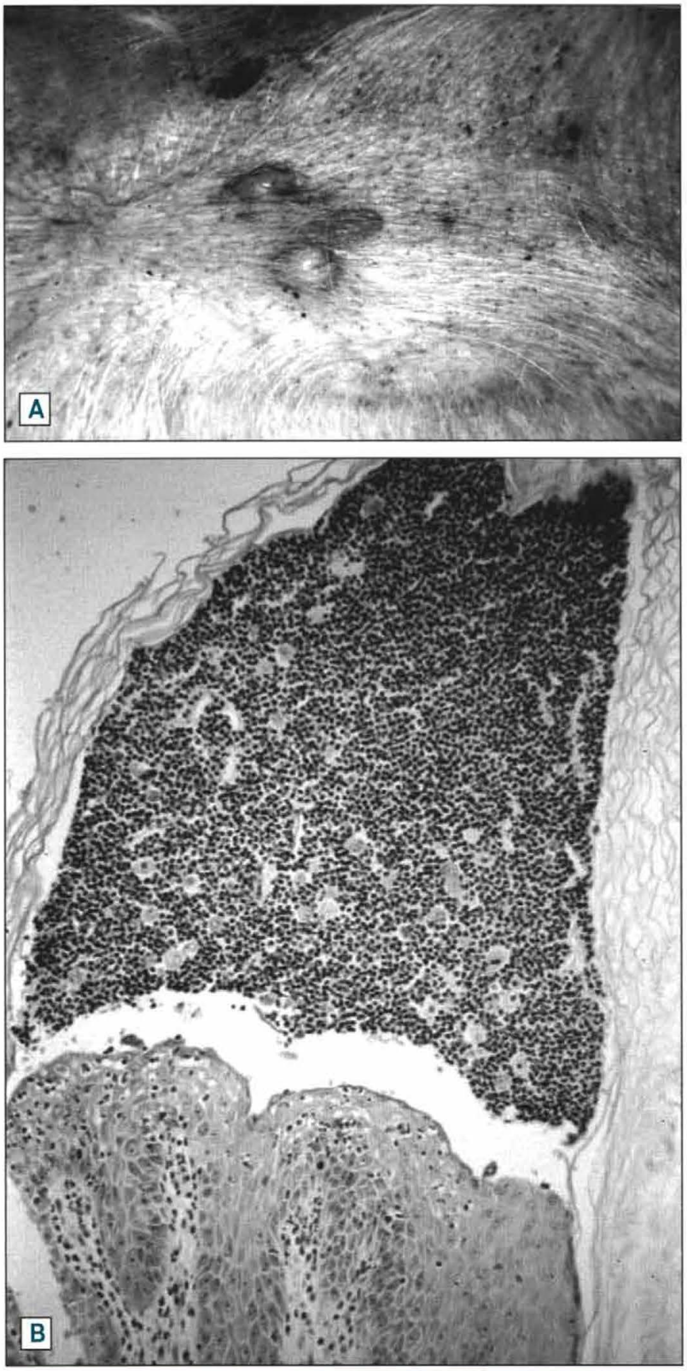

Figure 5.88 Superficial pyoderma (impetigo) in a puppy. **A.** Note pustules. (Courtesy of University of Florida Clinical Dermatology Service.) **B. Subcorneal pustule** in superficial pyoderma (impetigo).

Exudative epidermitis of pigs

Exudative epidermitis is an acute, exudative, superficial pyoderma of young pigs caused by Staphylococcus hyicus. The disease has also been called **greasy-pig disease**, impetigo contagiosa suis, and seborrhea oleosa. The infection occurs worldwide wherever intensive pig production is carried out. It is most common in *piglets 5–35 days of age*, but mild cases occur in older pigs also. The morbidity ranges from 10–90% and mortality from 5–90%. Mortality is higher in young pigs with lower resistance. Usually, when a litter is affected, all piglets develop the disease. *The infection may cause significant economic loss*; and in some countries, such as Denmark, the incidence appears to be increasing. Autogenous vaccines prepared from toxigenic strains of bacteria are used to prevent infection.

The *pathogenesis* of exudative epidermitis is incompletely understood. Both virulent and nonvirulent strains of *S. hyicus* are part of the normal skin flora of healthy pigs. The highest rates of carriage of the organism are found in the youngest piglets, suggesting that the organisms are acquired at birth. However, the presence of virulent organisms is not sufficient to produce disease. It is thought that infection develops as a result of *trauma* that breaches the skin barrier. Other factors that may predispose piglets to developing clinical disease include *agalactia of the sow, concurrent infections, and nutritional deficiencies. S. hyicus* strains are virulent by virtue of their ability to produce an *exotoxin* which, when injected in purified form or in cell-free extracts, is capable of producing exfoliative skin lesions in pigs which are typical of exudative epidermitis. Initial characterization of the exotoxin indicated that it has a molecular weight of approximately 27 kDa, is heat labile, appears to target epidermal cells of the stratum granulosum, and thereby produces intra-epidermal cleavage between the stratum corneum and stratum granulosum. More recent studies have identified at least three, and possibly four, antigenically distinct exfoliative toxins and shown them to be *metalloproteases*.

Exudative epidermitis has been compared to staphylococcal scalded skin syndrome of humans, which is also caused by several serologically distinct types of exfoliative toxins (epidermolysins). However, the presence of cocci in the lesions of piglets makes exudative epidermitis *more comparable to human bullous impetigo*, a superficial vesiculopustular infection that is also caused by staphylococcal exfoliative toxins and which contains gram-positive cocci within intact pustules. In contrast, staphylococci are present at a distant, usually extra-cutaneous, site in staphylococcal scalded skin syndrome rather than in the skin lesions. The toxins in both of these human conditions cause separation at the interface between the stratum spinosum and stratum granulosum by an unknown mechanism. However, it appears that the toxin acts primarily on intercellular substance, and binding to filaggrin may be involved in the pathogenesis. The disease affects children primarily, because the exfoliative toxin is excreted more slowly by the immature kidneys of young children. In addition, most adults are protected by anti-toxin antibody which young children do not have. Less rapid toxin excretion and lack of protective antibodies may also explain the greater incidence and severity of exudative epidermitis in the youngest piglets.

The disease can be divided into peracute, acute, and subacute forms.

- In the *peracute form*, most common in piglets only a few days old, there is abrupt onset of lesions around the eyes, snout, chin, and on the ears with extension to the medial aspect of the legs. Lesions then rapidly spread to the thorax, abdomen, entire legs, and hooves. Lesions begin as peeling of small areas of the stratum corneum leaving red, glistening, moist areas. These areas are quickly covered by *greasy, dark brown exudate*. Lesions become generalized in 24 to 48 hours and the entire body is erythematous and covered with brown, greasy, malodorous exudate (Fig. 5.89). Erosions of the coronary bands and heels commonly develop. Conjunctivitis also occurs frequently and typically causes matting together of the eyelids and results in an inability to see.

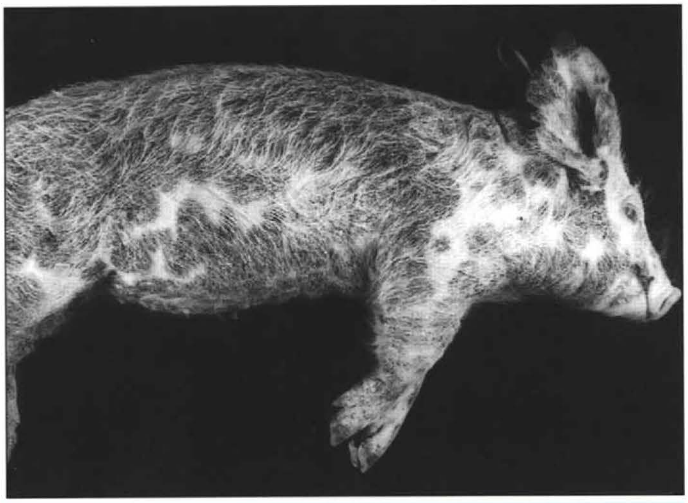

Figure 5.89 Exudative epidermitis ("greasy-pig disease").

Death occurs within 3–5 days as a result of dehydration, electrolyte imbalance, negative energy balance, and septicemia.

- In the *acute form*, the course is more protracted. The skin becomes thick and wrinkled and the exudate covering the entire body becomes dry, hard, and cracked, producing a generalized furrowed appearance. The underlying skin visible in the furrows is red.
- The *subacute form* occurs in older piglets and skin lesions are milder and usually confined to the head and ears. The subacute disease may appear as a dandruff-like scaling or as red-brown macules. Older piglets with less severe forms of disease frequently survive, however recovery is slow and the piglets are severely stunted. Additional lesions that may also occur in affected piglets are subcutaneous abscesses, necrosis of the ears and tail, and polyarthritis.

The earliest *microscopic lesion* is a subcorneal vesicular to pustular dermatitis. Extension of infection to hair follicles results in a superficial purulent folliculitis. In fully developed lesions, the skin is covered with a thick crust composed of ortho- and parakeratotic keratin, lakes of serum, accumulations of neutrophils, necrotic debris, and microcolonies of gram-positive cocci. The epidermis is variably acanthotic and rete ridges are elongated. Cells in the outer stratum spinosum exhibit variable intracellular edema. Neutrophilic exocytosis, intercellular edema, and spongiotic pustules may be seen in the epidermis and infundibular portion of hair follicles. The dermis is edematous, dermal vessels are congested, and there is a perivascular to interstitial neutrophilic infiltrate. Dermal inflammation is more intense and diffuse in areas of ulceration. In subacute cases, exudation is less severe and there is more marked epidermal hyperplasia, hyperkeratosis, and parakeratosis. Inflammation in the dermis becomes primarily mononuclear.

Microscopic lesions may also be seen in *other tissues*. Lymph nodes draining severely affected areas of skin contain foci of hemorrhage, purulent inflammation, and occasional microcolonies of bacterial cocci. Renal lesions are common and bacteremia is not required for them to be present. The lesions are distinctive, with early vacuolation of the epithelium of collecting ducts and renal pelvis progressing to epithelial degeneration and exfoliation. Intratubular casts of desquamated epithelium may be sufficiently severe to be evident macroscopically, leading to linear striations of the renal pelvis, and accumulation of cellular sediment in the pelvis and ureters. The process may be sufficiently severe to occlude the ureters. In cases in which bacteremia is present, purulent pyelonephritis is common. Animals with greasy pig disease may also have lesions in the oral cavity and conjunctiva, and the causative organism has been associated with abortion in sows.

The *differential diagnoses* for exudative epidermitis include zinc deficiency/ parakeratosis, sarcoptic mange, streptococcal pyoderma, and viral infections. In young pigs, the lesions are sufficiently distinctive that the disease is not confused with other conditions.

Staphylococcus hyicus has also been proposed as the cause of the so-called *flank-biting and necrotic ear syndromes of pigs*. Both conditions are characterized by large erosive to ulcerative crusty skin lesions in early weaned pigs. *S. hyicus* has been associated with skin lesions in *other species*. The organism is not uncommon in cattle and is frequently secondary to parasitic skin disease. The organism was isolated from skin lesions of a young pygmy goat with chronic generalized seborrheic dermatitis and alopecia. The microscopic lesion was a purulent exudative epidermitis similar to that in pigs. *S. hyicus* has been cultured from a number of horses with exudative crusty alopecic skin lesions on the distal limbs that resembled "grease heel" clinically.

Dermatophilosis

Dermatophilosis (cutaneous streptothricosis, mycotic dermatitis, cutaneous actinomycosis, lumpy wool, strawberry foot rot, rain scald, rain rot, Kirchi, Gasin-Gishu, Senkobo disease, Drodo-Boka, Savi, Ambarr-Madow) is an *acute, subacute, or chronic superficial exudative dermatitis caused by the actinomycete Dermatophilus congolensis*. The disease occurs worldwide and has a wide host range but it is *most* *common in the hot humid tropics and subtropics and in areas with heavy prolonged rains.* In hot monsoon climates, cattle are the primary animals affected and the disease is endemic in some portions of Africa. In more temperate climates, sheep and goats are involved primarily. The disease is occasional in horses and it is rare in dogs, cats, pigs, and humans. Cases of dermatophilosis have also been reported in camels, mules, donkeys, zebras, giraffes, Thompson's gazelles, woodchucks, striped skunks, raccoons, hedgehogs, gerbils, foxes, ground squirrels, seals, owl monkeys, captive polar bears, chamois, tortoises, and Australian bearded lizards. There is no apparent sex or age predilection; and congenital infections have been reported in calves and lambs.

In cattle and sheep, dermatophilosis causes important economic losses by virtue of decreased meat and milk production, damaged hides, wool loss, and devaluation, infertility, and early culling. Severe udder and teat lesions may interfere with suckling by calves and result in decreased growth rate. Affected animals are predisposed to secondary infections and cutaneous myiasis. Severely affected animals of any species may become emaciated and die.

Dermatophilus congolensis is a gram-positive pleomorphic bacterium whose natural habitat is unknown. The organism is probably not free-living since attempts to culture it from soil have been unsuccessful. Clinically normal carrier animals and crusts from infected animals probably serve as sources of infection. *D. congolensis* has a distinctive life cycle in which *coccoid bodies germinate to produce branching filaments* (Fig. 5.90A). These filaments undergo transverse and longitudinal septation to *form parallel rows of coccoid bodies.* The cocci are resistant to unfavorable conditions and are reproductively dormant until the appropriate wet conditions occur and they are activated to become motile zoospores.

Dermatophilosis cannot be reproduced experimentally to resemble natural disease, even with large doses of the organism. *Multiple factors* appear to be involved in pathogenesis of the natural disease. Two factors that appear to be most important are trauma to the skin and prolonged wetting. Zoospores are unable to overcome the protective barriers of the hair, surface lipid film, and stratum corneum, and their entry is facilitated by breaks in the skin surface. Trauma from ectoparasites, shearing, dipping, barb wire injuries, sharp stones, and scratches from sharp vegetation can act as portals of entry for the organisms. Besides producing skin trauma, external parasites such as flies, mites, lice, ticks, and mosquitoes also act as mechanical vectors. *In addition to skin trauma, prolonged moisture is needed for the activation, proliferation, and spread of the zoospores.* Wetting may also act to breach skin barriers by dissolving the surface lipid film and softening the stratum corneum. Outbreaks of dermatophilosis are frequently associated with periods of unusually heavy rainfall, housing in pastures or paddocks with standing water or mud, or after intensive high-pressure washing of animals.

Other factors involved in development of disease are less well understood. Genetic factors may be involved, since some breeds of cattle appear to be more resistant to disease than are others. Skin color appears to have an effect because some light-skinned breeds or light-skinned areas may be more susceptible to infection. A definite association between infestation with the tick *Amblyomma variegatum* and occurrence of dermatophilosis in cattle has been found. In herds with effective tick prevention, there is a much lower incidence or diminished severity of the disease. Since the lesions of dermatophilosis do not correspond to sites of tick attachment, a systemic effect on the animal's immune system has been suspected. Experimental support for tick-induced immunosuppression has been found in studies comparing in vitro lymphocyte stimulation responses wherein tick-infested cattle had lower mitogen-induced lymphoblast transformation responses than tick-free cattle, and addition of their serum to lymphocytes from tick-free cattle had an inhibitory effect on the response. In addition, concurrent diseases or stresses may contribute to the development of dermatophilosis by compromising the host's immune system. Intestinal parasitism, nutritional deficiencies, stress of pregnancy or migration, viral infections, and other infectious diseases may increase susceptibility to the condition.

Once the normal skin surface has been disrupted and activated zoospores gain access to the epidermis, infection can develop. The zoospores are apparently attracted to the low carbon dioxide concentration of the normal epidermis and there they germinate to *form mycelia that invade the viable epidermis and outer root sheaths of hair follicles.* Only rarely do the bacteria proliferate in the dermis or deeper tissues. The means by which *D. congolensis* invades the epidermis is unknown but recent investigations have found a variety of enzymes released into the culture fluid of the bacteria suggesting that *the ability of the organism to produce exoenzymes may be the pathogenetic mechanism.* As the filaments invade the epidermis, keratinocytes at sites of penetration begin to cornify and numerous neutrophils accumulate beneath and migrate into the epidermis, which subsequently separates from the underlying dermis. The neutrophils inhibit further invasion by the organism, and the epidermis reforms from cells in adjacent external hair follicle sheaths. This new epidermis is again invaded by organisms arising from the hair follicles to initiate another cycle of epidermal penetration, neutrophilic exocytosis, and epidermal detachment. *These repeated sequences of bacterial invasion, inflammation, and epidermal regeneration produce the thick laminar and parakeratotic crusts characteristic of dermatophilosis.*

Why some animals develop mild localized disease that resolves rapidly and spontaneously while others develop chronic widespread and debilitating disease is unknown. Skin commensal bacteria, primarily *Bacillus spp.*, have been shown to produce substances inhibitory to growth of *D. congolensis* in culture. It has been suggested that if a similar effect is present in vitro, bacteria normally present on skin produce substances that are bacteriostatic or bactericidal and thus prevent *D. congolensis* from proliferating. Differences in microflora of different individuals or breeds of animals could explain differences in response to infection. Furthermore, during the rainy season these bacterial inhibitors could be leached out or diluted to ineffective concentrations, permitting proliferation of *D. congolensis*. Differences in individual immune function or responses have been sought to explain why some animals recover quickly while others develop chronic infections. Chronically infected sheep have been found to have decreased numbers of dendritic cells in the dermis, to produce lower antibody titers in response to a novel antigen injected subcutaneously, and to have differences in an allele of a molecule which forms a portion of the T-cell receptor complex when compared to sheep which recovered spontaneously. The conclusions drawn from these studies were that poorer antigen presentation, differences in T-cell function, and a less vigorous antibody response to bacterial cell surface antigens may have allowed more widespread establishment of lesions and decreased ability to resolve lesions by chronically infected sheep. However, in other studies no correlation between serum antibody level and resistance

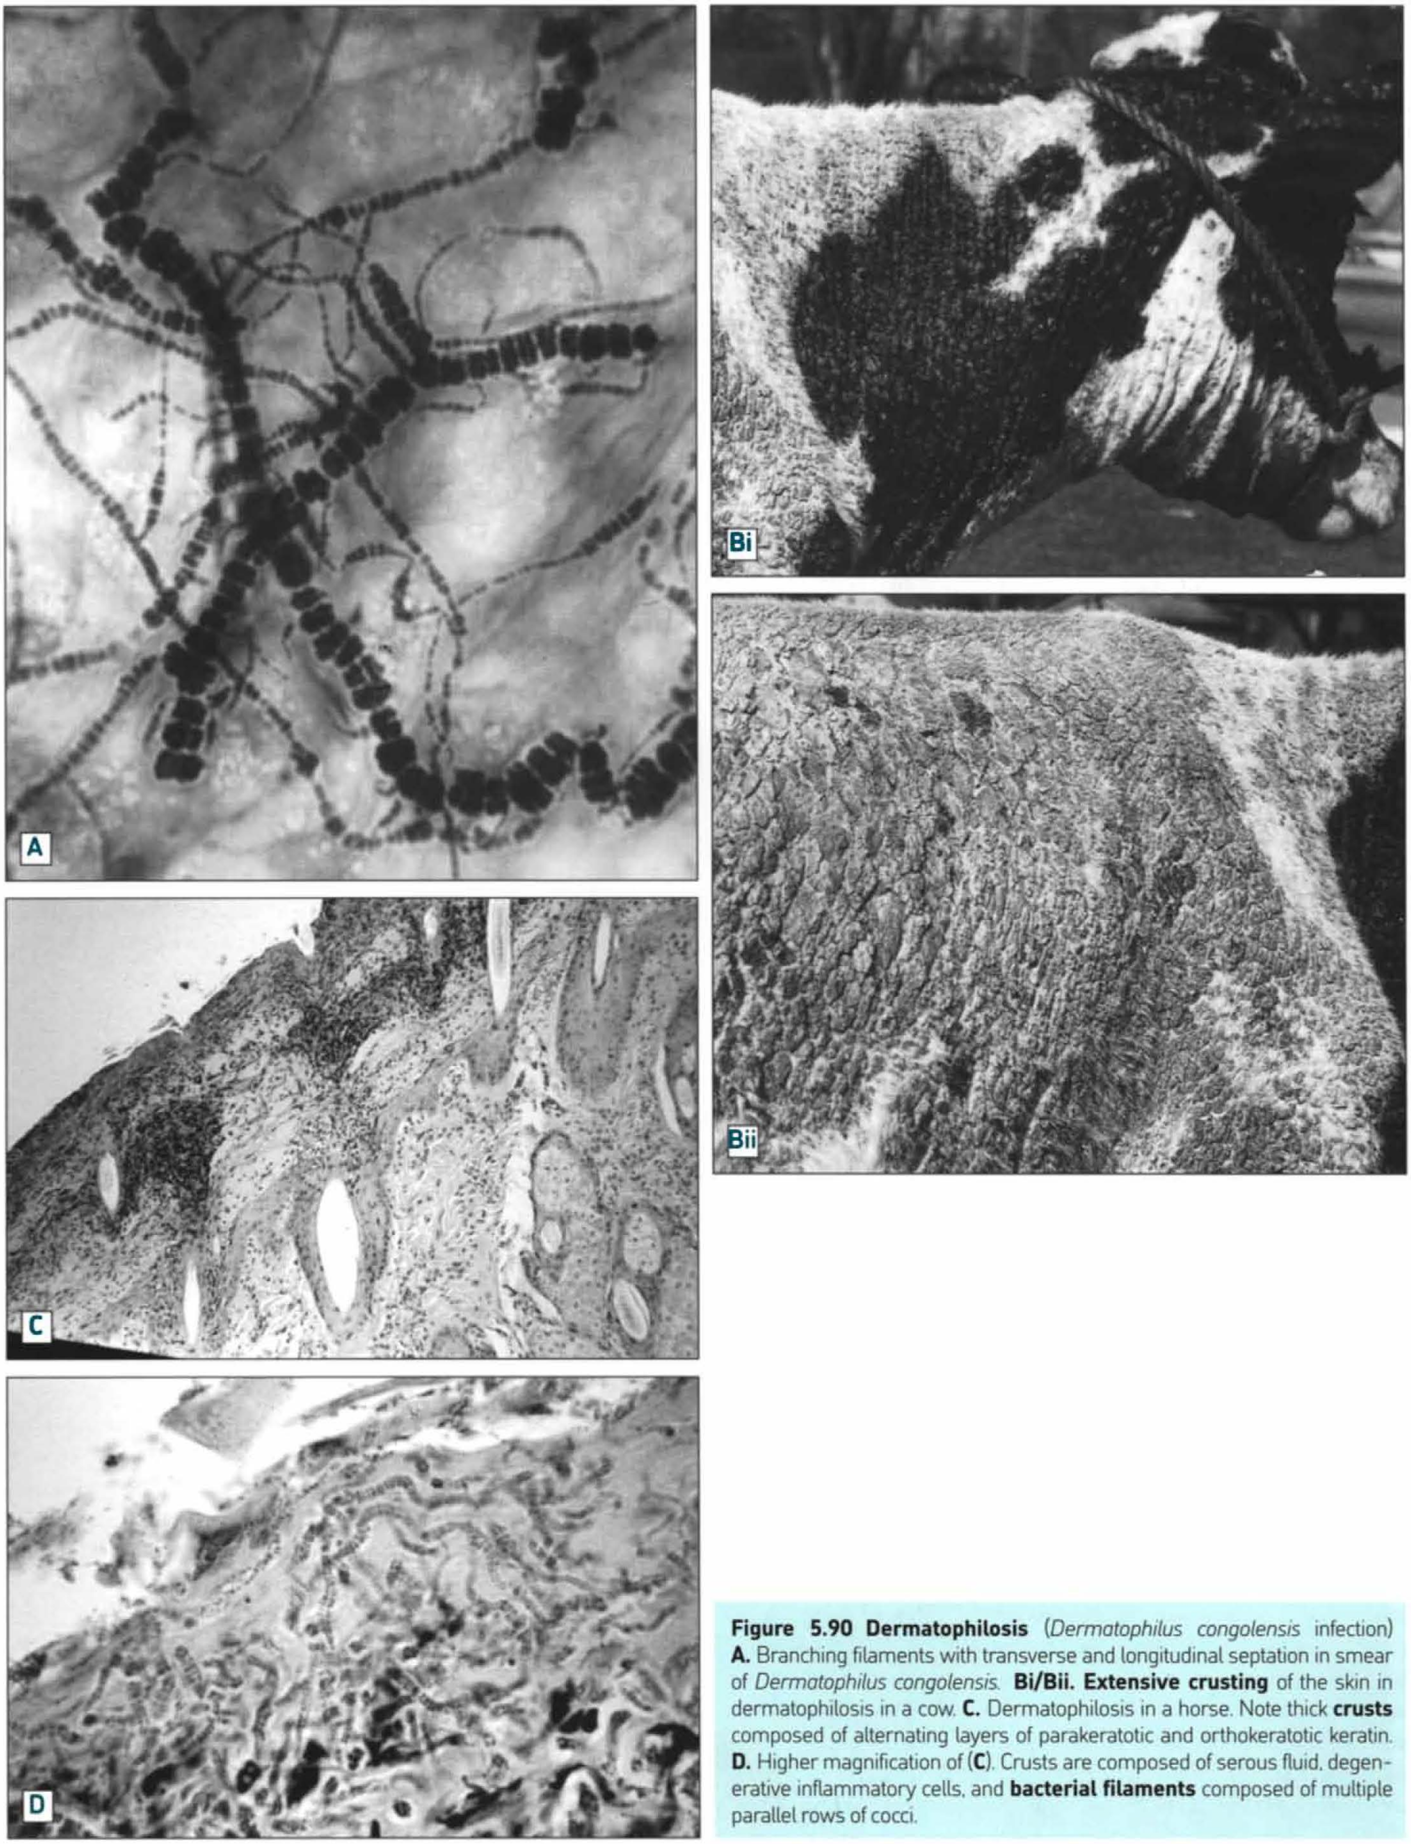

Figure 5.90 Dermatophilosis (*Dermatophilus congolensis* infection) **A.** Branching filaments with transverse and longitudinal septation in smear of *Dermatophilus congolensis*. **Bi/Bii. Extensive crusting** of the skin in dermatophilosis in a cow. **C.** Dermatophilosis in a horse. Note thick **crusts** composed of alternating layers of parakeratotic and orthokeratotic keratin. **D.** Higher magnification of (**C**). Crusts are composed of serous fluid, degenerative inflammatory cells, and **bacterial filaments** composed of multiple parallel rows of cocci.

to infection was found. Specific antibodies of various classes have also been detected on the skin surface but their role is unknown. Studies of vaccines against *D. congolensis* in sheep have shown that vaccines based on one strain of *D. congolensis* gave some protection against homologous challenge but were ineffective against challenge with a different strain of the bacterium. The involvement of antibody in resolution of disease is supported by histologic observations in which a chronological correlation was shown between lesion resolution and the presence of increased numbers of dermal plasma cells, many of which contained IgA, suggesting a role for this immunoglobulin in humoral immunity at the skin surface.

The *earliest lesions* of dermatophilosis consist of patches of slight erythema that are visible only in unpigmented areas. Very small papules and pustules develop next and are more evident by palpation than by visual inspection. As the lesions become covered by exudate and hairs become entrapped within the developing crust, they form small tufts that resemble paintbrushes. *As these small lesions coalesce, they form the typical large oval to circular domed yellow-brown adherent scabs which when removed leave a moist hyperemic base that may bleed.* The lesions are painful and nonpruritic. In chronic cases, lesions progress to form thick layers of dry spongy material involving extensive areas of long hair or hard wart-like crusts that protrude above the hair surface, usually in areas with a short haircoat (Fig. 5.90B). *Differential diagnoses include dermatophytosis, staphylococcal dermatitis, mite infestation, various viral infections, zinc-responsive dermatosis, and pemphigus foliaceus.*

The distribution of lesions in **cattle** is variable. Lesions confined to the face and ears are most often seen in young suckling calves. In other forms of the disease, lesions occur on the brisket, axillae, and inguinal areas or on the udder and teats of cows and scrotum and prepuce of bulls. Cattle standing in deep water or mud develop lesions on the legs. Lesions located in the perineum and tail are assumed to result from trauma caused by mounting by other animals. In many cases, lesions are diffusely distributed over the head, topline of the neck and body to the tail, and dorsal sides. *Animals with greater than 50% of body involvement often show weight loss, dehydration, and death.* Rare instances of subcutaneous abscesses, lymphadenitis, and oral lesions have been reported.

In **sheep**, infection of the wooled areas is frequently missed in early stages and some animals recover spontaneously during the acute stage of infection. If the disease continues to progress, the wool of the neck, back, and flank becomes matted with exudate to form dense pyramidal masses (lumpy wool, mycotic dermatitis) which may last for months to years in some individuals. *Strawberry foot rot* is an infection that begins at the coronet regions and may progress to involve the skin to the carpi and/or tarsi. In some cases, crusts may be confined to the ears, nose, and face, a clinical form common in lambs. Concurrent infection with contagious ecthyma has been reported.

Dermatophilosis in **goats** frequently consists of 2–3-mm crusty lesions on the pinnae and tail of kids and large pyramidal crusts on the dorsal midline, sides, caudal thighs, and scrotum of adults. Lesions involving the distal limbs resemble strawberry foot rot of sheep. Concurrent infection with contagious ecthyma may occur and secondary infections with staphylococci, streptococci, or corynebacteria may develop.

In **horses**, lesions of dermatophilosis are frequently located on the dorsal aspect of the body and look as if large drops of liquid have scalded the skin (*rain scald*). Horses kept in wet, marshy, or muddy enclosures, and undergoing trauma to the legs develop lesions of the distal extremities primarily (grease heel, scratches, mud fever). Lesions on the legs may be associated with swelling, pain, and lameness. In some instances, only the head is affected. Unpigmented skin may be more susceptible to infection and lesions on these areas are typically very erythematous. Outbreaks in show horses have been associated with frequent high-pressure washing.

Dermatophilosis cases reported in **cats** are notable in that they have all been subcutaneous or extracutaneous infections. The lesions consisted of draining nodules involving or in the area of the popliteal lymph nodes or the subcutaneous tissue of a paw and masses on the tongue and serosal surface of the urinary bladder. In at least one of the cats with subcutaneous infection, superficial wounds suggestive of a recent cat fight were seen, prompting speculation that the infection was traumatically introduced.

The earliest *histologic lesions* of dermatophilosis are superficial dermal congestion, edema, and neutrophil infiltration of the superficial dermis. Exocytosis of neutrophils becomes more pronounced as lesions progress and intraepidermal or subcorneal pustules may develop. Eventually, repeated cycles of bacterial invasion and inflammation result in *thick crusts composed of alternating layers of parakeratotic and orthokeratotic keratin, serous fluid, degenerate inflammatory cells, and bacterial filaments composed of multiple parallel rows of cocci* (Fig. 5.90C, D). The epidermis is acanthotic with orthokeratotic and parakeratotic hyperkeratosis. Purulent folliculitis with intralesional bacterial filaments is also usually present. Dermal inflammation is usually mild and superficial perivascular. In cases of dermatophilosis in cats and rare instances of subcutaneous and lymph node infection in cattle, the lesions consist of granulomas or pyogranulomas with scattered necrotic foci which contain typical *D. congolensis* filaments.

Deep bacterial pyoderma

Deep pyodermas are serious bacterial infections that involve the hair follicle, dermis, and/or subcutis. They are usually chronic or recurrent, heal with scarring, and are commonly associated with regional or generalized lymphadenopathy and systemic signs. The clinical appearance of deep pyoderma is tremendously diverse. Lesions commonly seen in deep pyodermas include dark red or violaceous raised nodules, poorly demarcated areas of tissue swelling, hemorrhagic bullae, fistulous tracts, abscesses, purulent or serosanguineous exudate that dries to form crusts, and necrotic or ulcerated skin covered by crusts. Pain may be severe. Microscopic changes associated with deep pyodermas include folliculitis, furunculosis, nodular to diffuse dermatitis or panniculitis, and variable fibrosis. Bacteria may not be seen microscopically even with special stains.

Staphylococcal folliculitis and furunculosis

Staphylococcus spp. are the most common cause of folliculitis in domestic animals. Other organisms less frequently or rarely associated with folliculitis include *Streptococcus* spp., *Corynebacterium* spp., *Pseudomonas* spp., *Bacillus* spp., and *Pasteurella multocida*. Inflammation of the deep portion of hair follicles frequently results in rupture of the follicular wall (furunculosis) and extension of infection to the surrounding dermis and panniculus. *Staphylococcal folliculitis and furunculosis are very common in the dog, common in horses, goats, and sheep, and uncommon in cats, cattle, and pigs.* Skin lesions associated with folliculitis and furunculosis are extremely variable. The earliest skin lesion is a follicular papule with one or several hairs protruding from the center. The papule develops into a pustule but these are very fragile, break easily, and are thus very transient. Consequently, crusted papules are seen more commonly than are pustules. In short-haired dogs, horses, and cattle, the earliest clinical sign is a dishevelment of the haircoat produced by small groups of hairs tufting together above the skin surface, an appearance that can be confused with urticaria. As the hairs fall out of infected follicles, multiple small foci of alopecia and scaling develop. The hair coat develops a moth-eaten appearance as the areas of alopecia become progressively larger. Lesions often enlarge and develop a central ulcer that discharges purulent or serosanguineous exudate that dries to form a crust. When furunculosis occurs, dark red to violaceous nodules, draining fistulae, ulcers, and extensive tissue swelling develop (Fig. 5.91). Hemorrhagic bullae may be prominent in some cases. Scarring, alterations in pigmentation of the hair and skin, and lichenification may result. Regional and generalized lymphadenopathy are common. Constitutional signs, such as fever and anorexia, may occur when infection is severe or extensive.

The *microscopic changes* of staphylococcal folliculitis and furunculosis are as varied as the gross lesions. The epidermis is variably acanthotic and may be ulcerated. Serocellular crusting is common. Staphylococcal folliculitis is characterized by *neutrophilic inflammation* but the relative number of neutrophils is extremely variable, depending on the duration of the infection and presence of furunculosis. Pustules composed of neutrophils and variable numbers of eosinophils may be seen within the infundibulum or ostium of hair follicles. Neutrophils accumulate within the lumen of hair follicles, distending the lumen and frequently causing rupture of the hair follicle wall (see Fig. 5.5B). Neutrophils, eosinophils, macrophages, and plasma cells form dense sheets in the dermis and may extend to the panniculus. Hemorrhagic bullae consist of large pustules with hemorrhage in the interfollicular dermis. Large dermal pustules may form cavitary lesions. Release of hair and keratin into the dermis or panniculus induces an *intense foreign body reaction* that may completely efface the follicle (see Fig. 5.6). Fragments of hair or keratin may be surrounded by discrete granulomas composed of multinucleated giant cells, epithelioid macrophages, and neutrophils

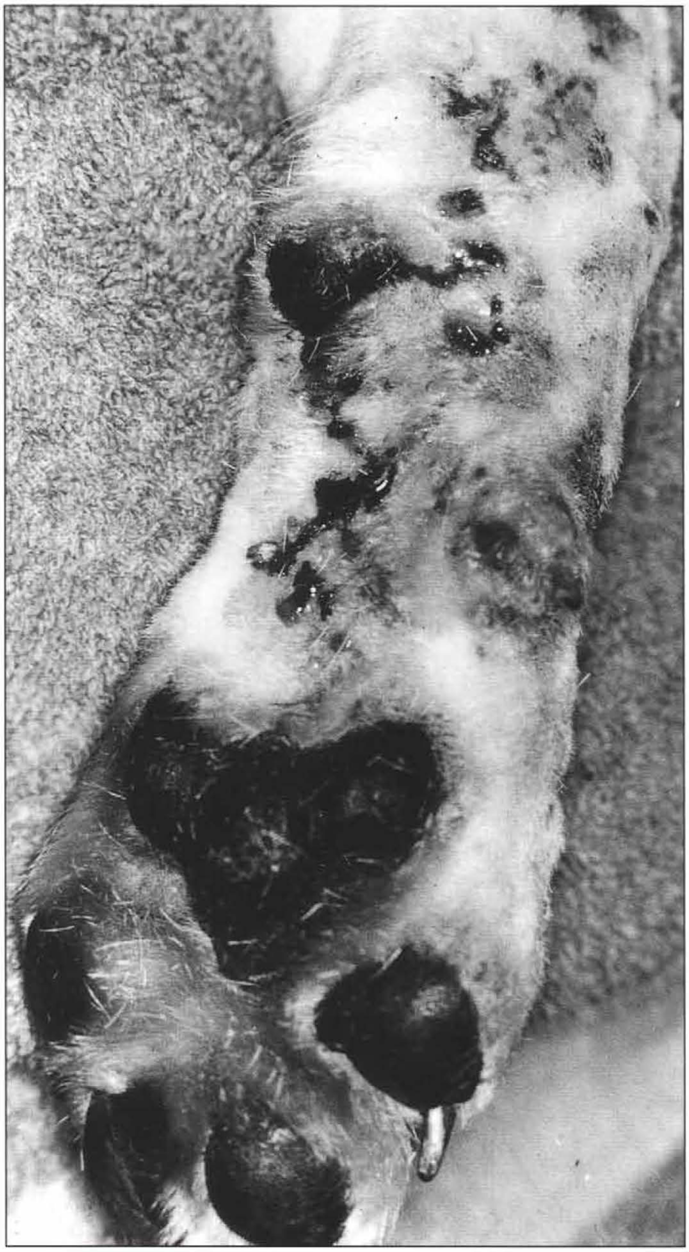

Figure 5.91 Deep pyoderma in a dog. Swollen paw with multiple draining tracts.

(*trichogranuloma*). Eosinophils may be numerous around the fragments of hair and keratin. Inflammation may become diffuse as adjacent furuncles coalesce and replace normal dermal structures completely. Hemorrhage and fibroplasia are variable. Bacteria may not be evident even with special stains such as tissue Gram stain or Giemsa stain.

Deep pyoderma is not as common as superficial pyoderma but is still a relatively common disease in **dogs**. *Staphylococcus intermedius* is usually the primary pathogen in bacterial folliculitis and furunculosis in dogs. However, gram-negative bacteria such as *Proteus*, *Pseudomonas*, and *E. coli* are not uncommon secondary invaders. Infection may be localized or widespread. *Localized forms* of staphylococcal deep pyoderma commonly involve the bridge of the nose, the chin ("canine acne"), feet (pedal folliculitis-furunculosis), and pressure points. A particularly refractory form of staphylococcal pyoderma has been recognized in German Shepherd Dogs. *German Shepherd pyoderma* is poorly understood; but because of the breed predilection, an inherited component has been suggested. The condition typically begins as pruritus involving the lumbosacral, caudal abdominal, and medial thigh regions. Lesions initially resemble pyotraumatic dermatitis and the lesion distribution is suggestive of flea allergy dermatitis. As the condition progresses, lesions assume an appearance typical of chronic pyoderma and frequently become more widespread. An underlying predisposing cause is frequently not apparent, and an immunologic abnormality is suspected. Neutrophil chemotaxis and killing capacity appear to be normal. Limited studies in a small number of affected German Shepherd Dogs have found a cell-mediated immunodeficiency by the lymphocyte transformation test and a marked increase in the CD8+ T lymphocytes in peripheral blood. Whether these changes are a cause or effect of the disease is unknown. Examination of T and B lymphocytes in histologic sections found a marked paucity of T lymphocytes in lesions of deep pyoderma of German Shepherd Dogs as compared to similar lesions from dogs of other breeds.

Staphylococcal pyoderma in **horses** most often involves the harness, saddle (saddle scab, saddle boils), neck, and dorsal lumbosacral regions. *Friction from tack* is considered an important initiating factor. It is most common in the summer, coincident with excessive sweating, higher environmental temperature and humidity, and increased numbers of biting insects. Lesions are usually painful rather than pruritic. *Staphylococcal pyoderma may be one of many causes of "grease heel,"* in which lesions involve the caudal aspect of the pastern and fetlock areas of one or more legs. In tail pyoderma, the dorsal surface of the tail is particularly affected and infection is usually secondary to skin abrasions caused by tail rubbing associated with insect bites, mange, biting lice, pinworms, or vice. Although much less common, *Corynebacterium pseudotuberculosis* can cause folliculitis and clinical lesions ("contagious acne") similar to those with staphylococcal folliculitis.

Staphylococcal pyoderma is common in **goats** and frequently begins on the udder and spreads to the ventral abdomen, medial thighs, perineal area, face, pinnae, and distal limbs. Severe infections, particularly those with secondary mastitis, may produce pyrexia, anorexia, depression, and septicemia. In **sheep**, staphylococcal pyoderma may occur as a benign pustular dermatitis on the lips and perineum in otherwise healthy 3- to 4-week-old lambs. Lesions usually regress spontaneously within 3 weeks. A more severe form of infection involves the face (facial eczema, eye scab), particularly of adult ewes just prior to lambing. Facial dermatitis appears to be contagious, and spread is thought to result from head abrasions sustained while feeding at troughs or by fighting.

Staphylococcal pyoderma occurs occasionally in cattle, pigs, and cats. Infection in **cattle** is seen most commonly in young bulls on the tail, perineum, scrotum, and face. Trauma and poor hygiene may be initiating factors. Staphylococcal pyoderma in **pigs** usually occurs on the hindquarters, abdomen, and chest of piglets less than 8 weeks of age and spontaneously regresses. Pyoderma is uncommon in **cats** and may be mistaken for other diseases. Lesions may consist of a crusted papular eruption on the face, head, or over the dorsum that clinically resembles miliary dermatitis associated with various hypersensitivity conditions. Scaling, crusting, or ulceration of footpads or nailbeds may be confused with pemphigus foliaceus or dermatophytosis.

Abscesses and cellulitis

Abscesses *are well-circumscribed accumulations of pus.* **Cellulitis** *is a severe, deep, suppurative infection that is poorly defined and tends to dissect through tissue planes. The lesions are usually painful and overlying skin is often friable, dark, devitalized, and may be sloughed.* The wounds frequently have a putrid smell and may be emphysematous if the organism is a gas-producer (*Clostridium* spp., *Bacteroides* spp.). Pyrexia and regional lymphadenopathy may be present. Abscesses and cellulitis are fairly common in large animals and are *one of the most common disorders in cats*, where they are a frequent sequel to fight wounds. Other predisposing causes include traumatic puncture wounds, foreign bodies, injections, and shearing and clipping wounds. Microscopically, abscesses consist of central accumulations of neutrophils and/or necrotic debris, frequently surrounded by a wall of granulation tissue or dense collagenous connective tissue, depending on duration. In contrast, cellulitis is poorly circumscribed and consists of extensive purulent to pyogranulomatous dermal and subcutaneous inflammation that may be accompanied by hemorrhage, necrosis, and thrombosis. Bacteria may or may not be visible histologically.

A wide variety of aerobic and anaerobic bacteria have been associated with abscesses and cellulitis. The most common organisms include staphylococci (dogs, Thoroughbred horses, cattle), *Clostridium* spp. (malignant edema, gas gangrene, and big head in horses, cattle, sheep, goats, pigs, and dogs), *Pasteurella multocida* (cats), and *Corynebacterium pseudotuberculosis* (abscesses in horses, goats, cattle, and sheep; ulcerative lymphangitis in horses, cattle, sheep, and goats; caseous lymphadenitis in sheep and goats). *Rhodococcus equi,* most commonly associated with pneumonia in young horses, has been isolated from cutaneous abscesses and cellulitis in young horses and rarely in cats. *Pasteurella granulomatis* has been associated with a disease in southern Brazil called *lechiguana* which is characterized by large subcutaneous fibrosing eosinophilic abscesses. Lesions are most commonly located in the scapular region and the condition is frequently fatal if untreated. Various *mycoplasmas* and mycoplasma-like organisms have been recovered from abscesses in cats and from decubital abscesses in calves.

Streptococcus canis has been isolated from dogs with an intensely painful **necrotizing fasciitis.** The infection begins as cellulitis, frequently 12–48 hours after minor trauma, that rapidly progresses to shock and necrotizing fasciitis. The condition is similar to streptococcal toxic shock syndrome of humans caused by *S. pyogenes.* The condition is characterized grossly by *extensive exudation along fascial planes and necrosis of subcutaneous fat and fascia,* resulting in extensive sloughing of necrotic skin. The microscopic lesions of necrotizing fasciitis include severe necrosis, suppuration, fibrinous exudation, and hemorrhage of the dermis and subcutaneous fat, fascia, and muscle. In some instances, the epidermis and superficial dermis are infarcted as a result of thrombosis of dermal and subcutaneous blood vessels. Colonies of bacterial cocci may be evident in the inflamed subcutaneous tissue.

Conditions that resemble **toxic shock syndrome** in humans have been described in dogs. *Streptococcus canis* has been documented as the cause in most dogs; however, other bacteria, especially *Staphylococcus intermedius,* that produce exotoxins – including toxic shock syndrome toxin-1 – could potentially play a role. The site of infection can be the skin, as seen with necrotizing fasciitis; however, the primary site of infection in some dogs has been the lung or urinary tract. In dogs with toxic shock-like syndrome, but without necrotizing fasciitis, clinical skin lesions include multicentric to generalized cutaneous erythema. Some dogs also have edema and vesicles or pustules that progress to ulcers. The ears, extremities, and ventrum are frequently affected, and dogs can be depressed and have fever, anemia, thrombocytopenia, and neutrophilia. Histologically, these dogs have superficial dermatitis with apoptotic keratinocytes bordered by neutrophils. The lesions can progress to full-thickness necrosis and ulceration of the epidermis. As in necrotizing fasciitis, lesions can be fatal without early therapy with appropriate antibiotics. The cause of the skin lesions in the dogs with toxic shock-like syndrome, but without necrotizing fasciitis, has not been determined. In humans, the skin lesion is thought to result from nonspecific stimulation of lymphocytes by exotoxins with superantigen activity and the release of cytokines, including TNF-α.

Cutaneous bacterial granulomas

A wide variety of bacteria are capable of producing granulomatous inflammation of the skin. The organisms are frequently of *low virulence* and are introduced by *traumatic implantation.* These infections are typically *slowly progressive* and produce *cutaneous or subcutaneous nodules.* Inflammation is nodular or diffuse, granulomatous or pyogranulomatous, and involves the dermis, panniculus, or both. *Diagnosis commonly requires special stains such as tissue Gram stain and routine or modified acid-fast stains.* Staining frozen sections of formalin-fixed tissue may be necessary to demonstrate the bacteria in some atypical mycobacterial infections. Organisms are so infrequent in some cases that confirmation of the bacterial etiology cannot be made histologically and depends instead on cultural isolation of the agent.

Actinomycosis and nocardiosis

Actinomycosis and nocardiosis are uncommon subacute-to-chronic opportunistic cutaneous, pulmonary, and disseminated infections that develop secondary to wound contamination, inhalation, or ingestion. The diseases are discussed together because of their clinical and histologic similarities. *Actinomyces* and *Nocardia* are the most common actinomycetes, so-called higher bacteria, which cause disease, but occasional reports of infections in animals by other actinomycetes include *Streptomyces* and *Actinomadura.* The infections occur sporadically and are worldwide in distribution. They are not considered of public health significance.

Actinomyces species are gram-positive, non-acid fast, filamentous anaerobic or microaerophilic rods that are *commensal inhabitants of the oral cavity, intestine, and upper respiratory tract.* Cutaneous infection is usually secondary to bites, penetrating wounds caused by foreign bodies such as quills or grass awns, and wounds contaminated by licking. Cutaneous actinomycosis occurs in dogs, cats, horses, and cattle. Infection in pigs usually involves the mammary gland. Several retrospective studies in dogs indicate that young, large breed, male dogs that are used or housed outdoors are most commonly affected. *Actinomyces viscosus* is cultured most commonly from animal infections; but the organism is fastidious and difficult to culture and frequently it is not speciated even when cultured.

Nocardia species are common *soil saprophytes* that are ubiquitous in the soil and water and on plants. They cause infection by wound contamination, inhalation, or ingestion. They are aerobic, gram-positive, filamentous organisms that may be acid fast. There appears to be considerable variation in the degree of pathogenicity among various strains of the organism. Experimental infections suggest that defense against nocardial infections involves both neutrophils, which may have an immediate role in inhibiting the growth of the organisms, and cell-mediated immunity, which is responsible for the ultimate clearance of infection. Cutaneous nocardiosis is reported most frequently in dogs, cats, horses, and cattle. The most common isolate is *Nocardia asteroides.* Cutaneous nocardiosis in cattle, called *bovine farcy*, is caused by an organism originally called *N. farcinica* but is now thought to be *N. asteroides*. Farcy occurs in Africa, Asia, and South America.

The *gross lesions* of actinomycosis and nocardiosis are usually indistinguishable. They consist of abscesses, cellulitis, ulcerated nodules, draining fistulous tracts, and dense fibrous masses. *When the triad of clinical signs consisting of tumefaction, draining sinuses, and tissue grains is present, the lesion can be termed an* **actinomycotic mycetoma**. Lesions progress slowly by local extension. They occur most commonly on the head, neck, and extremities. Pleural and retroperitoneal infections may extend to involve the subcutaneous tissues of the lateral thoracic wall and flank area, respectively. The exudate is variable and ranges from thin serosanguineous to thick purulohemorrhagic. It may be odorless or foul-smelling and contain white, yellow, tan, or gray "**sulfur granules**." Sulfur granules are more common in actinomycosis than in nocardiosis. Regional lymphadenopathy frequently accompanies skin lesions. In cats, lesions on the ventral abdomen resemble mycobacterial infections. Actinomycosis in cattle usually involves the mandible or maxilla causing proliferative osteitis ("*lumpy jaw*"); the infection may extend from the bone to the overlying skin to form firm nodules, abscesses, and draining sinus tracts with extensive fibrosis. The cutaneous lesions of bovine farcy are typically associated with lymphangitis and lymphadenitis and are clinically similar to those caused by tuberculosis.

Microscopically, actinomycosis and nocardiosis are characterized by *pyogranulomatous dermatitis and panniculitis*. The epidermis is variably acanthotic and may be ulcerated. The dermis and subcutis contain central accumulations of neutrophils surrounded by a wall of epithelioid macrophages and variable numbers of multinucleated giant cells. Necrosis may be prominent within the central abscess. The pyogranulomas are separated by granulation tissue or dense fibrous connective tissue containing lymphocytes and plasma cells. Fibrosis tends to be more common and severe in actinomycosis than in nocardiosis. Organized masses, measuring 30–3000 μm or more in diameter, of basophilic or amphophilic-staining organisms, may be seen in the centers of the abscesses (Fig. 5.92). They are commonly bordered by a clubbed corona of brightly eosinophilic *Splendore-Hoeppli material. These structures correspond to the sulfur granules seen grossly in the exudate.* Granule formation is a more common feature of actinomycosis; in nocardiosis, the bacteria tend to be distributed singly among the neutrophils or within the macrophages and are difficult or impossible to see in HE-stained sections. However, *Nocardia* species may form granules in cutaneous lesions that are morphologically indistinguishable from those of *Actinomyces*. In Gram-stained sections, the bacteria are evident as delicate, branched, and beaded filaments, from 10–30 μm or more long and 0.5–1.0 μm wide. Fragmentation of filaments produces coccobacillary forms. The filamentous nature of the bacteria is most apparent at the periphery of granules; while coccobacillary forms constitute the centers of granules. The beaded appearance is due to alternating gram-positive and gram-negative regions within the filament and is less prominent with *Actinomyces* than with *Nocardia* species. *Actinomyces* are acid-fast negative with most acid-fast stains. Some, but not all, filaments of *Nocardia* may stain strongly acid-fast with modified acid-fast stain. However, *Nocardia* species are not invariably acid-fast and, if negative, cannot be differentiated from *Actinomyces*. Thus culture must be done to identify the organism. *Nocardia* species may resemble opportunistic mycobacteria but they do not stain with routine acid-fast stain as do mycobacteria. A single random section may not contain granules and serial sections may be necessary to find organisms. However, small biopsies may not contain organisms at all. Since granules or individual organisms may be rare, a wide *wedge biopsy* including deep subcutaneous tissue is more likely to contain organisms than are punch biopsies.

Mycobacterial infections

The genus *Mycobacterium* is a large group of acid-fast organisms that includes both obligate pathogens and many saprophytic organisms that are occasionally opportunistic pathogens. They cause chronic infections of various organ systems, including the skin. The members of the *tuberculosis complex*, *M. tuberculosis*, and *M. bovis*, are obligate pathogens that cause tuberculosis in humans and a wide range of domestic animals worldwide. Pulmonary and gastrointestinal lesions are most common in tuberculosis, *but the skin can become involved in disseminated infections* and, rarely, infection may be confined to the skin. In contrast, *infections with saprophytic mycobacteria frequently involve the skin and they are usually acquired by wound contamination or traumatic implantation.* Cutaneous mycobacterial infections are reported most frequently in cats and less often in dogs. *Mycobacterial lesions are all characterized by granulomatous or pyogranulomatous dermatitis and/or panniculitis with variable necrosis.* These infections can be diagnosed by cytologic or histologic examination and organisms are best visualized with acid-fast or modified acid-fast stain. The organisms may be rare to numerous and the number of acid-fast bacilli seen within the lesion cannot be used to identify the specific organism involved.

Culture is necessary for definitive identification of the organism so that appropriate therapy and the zoonotic potential of the infection may be determined. *Many of the organisms are extremely fastidious and difficult to culture and isolation may require many weeks to months.* The need for culture is becoming increasingly obviated by molecular-based techniques which can identify the organisms in tissue section and can be completed within a few days.

Feline leprosy

Feline leprosy is a rare localized cutaneous infection caused by acid-fast bacilli that are not culturable by standard mycobacteriological methods. The infection has a widespread distribution, with cases reported in New Zealand, Australia, North America, and Europe. Cases are frequently associated with temperate maritime regions. Feline leprosy has no zoonotic potential.

Based on successful transmission to rats and mice and comparison of delayed type hypersensitivity skin reactions in cats, the causative agent of feline leprosy has been speculated to be *Mycobacterium lepraemurium.* This is the organism that causes rodent leprosy; it is a slow-growing organism that is isolated only with difficulty using enrichment techniques. The means of transmission is unknown, but *bites of cats or rodents, contact with rodents, and soil contamination of cutaneous wounds are thought to be involved.* Since the agent of human leprosy, or Hansen's disease, has been found in viable form in mosquitoes, bed bugs, ticks, and fleas, it has been suggested that transmission of feline leprosy may involve similar vectors. *Immunosuppression* has been suggested as contributing to development of infection, but such factors have not been identified in the vast majority of reported cases. Recently, the organism was identified by molecular analysis as *M. lepraemurium* in tissue specimens from four of eight cases of feline leprosy examined. However, two cases were found to be infected with a mycobacterium that had 16S ribosomal RNA gene sequence sharing closest nucleotide sequence identity with that of *M. malmoense.* These findings suggest that *feline leprosy may not be caused by a single agent.*

Feline leprosy occurs most commonly in young adult cats 1–3 years old; no breed or sex predilection is evident. Several studies have found an increased incidence of disease in the winter. Lesions may be located anywhere but are most frequent on the head and limbs. They consist of single or multiple, nonpainful cutaneous or subcutaneous nodules which are haired, alopecic, or ulcerated. They may be soft and fleshy or firm and measure up to 3–4 cm diameter. *The nodules are frequently mistaken for neoplasms.* Affected cats may also have regional lymphadenopathy but they are usually otherwise healthy. A second syndrome has been identified in cats >9 years old, with generalized skin involvement and a slowly progressive clinical course, caused by a novel mycobacterial species that is present in large to enormous numbers.

The *histologic changes* consist of granulomatous inflammation involving the dermis and frequently the subcutis. The epidermis is variably acanthotic or ulcerated. The predominant cells are *large, pale, foamy epithelioid macrophages* arranged in focal aggregates or diffuse sheets that replace normal architecture (Fig. 5.93). Lymphocytes, plasma cells, and neutrophils are in variable numbers. Multinucleated giant cells and small foci of caseous necrosis are present in some lesions. *Acid-fast organisms are demonstrable by routine acid-fast stains, such as Ziehl–Neelsen and Kinyoun's,* and are usually in moderate numbers within macrophages or in necrotic foci. However, acid-fast bacilli may be in massive numbers in some cases or only rare in others. Mineralization and encapsulation are not typical of feline leprosy. The *histologic features* of feline leprosy have been compared to human leprosy, in which the particular histologic reaction is associated with the host's resistance. Whether this is also true for feline leprosy has not been determined. Reactions consisting of epithelioid granulomas with central caseous necrosis surrounded by a zone of lymphocytes usually contain numerous organisms within the necrotic foci. These lesions are compared to the *tuberculoid response* of human Hansen's disease, which is considered a *high-resistance form.* A second type of reaction in cats consists of solid sheets of large foamy macrophages and many multinucleated giant cells, with acid-fast bacilli being numerous in both cell types. Perivascular lymphocytes and plasma cells vary from few to many. This latter type of reaction has been compared to the *lepromatous form* of human leprosy which is considered to be the *low-resistance form* associated with a deficit in cell-mediated immunity. Neutrophils are present in both types of lesions but are most numerous in the lepromatous form, often resulting in a pyogranulomatous reaction. Nerve involvement, the most important histologic feature of Hansen's disease, is only sporadically observed in feline leprosy. Regional lymph nodes are characterized by variable architectural disruption by infiltrates of macrophages. Acid-fast bacteria are rare within lymph nodes.

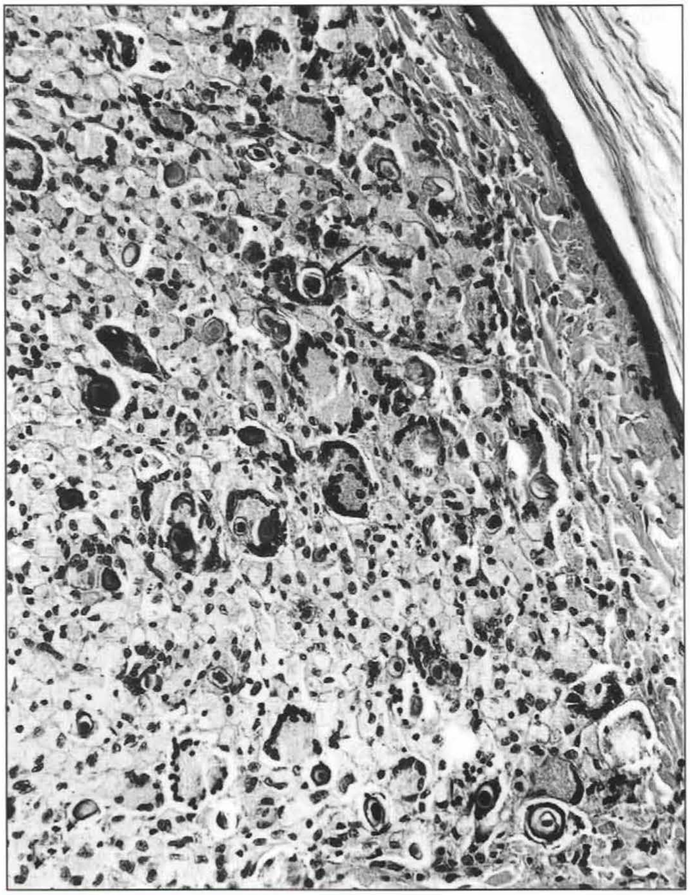

Figure 5.93 Macrophages, concretions (arrow), and multinucleate giant cells in **feline leprosy**.

Differential diagnoses include other mycobacterial infections, mycotic infections, and cutaneous xanthoma/xanthogranuloma. Xanthomas are sterile granulomatous lesions composed of foamy macrophages, which resemble the lepromatous form of feline leprosy. However, this form of feline leprosy is usually associated with numerous acid-fast bacteria and acid-fast staining will allow differentiation from xanthomas. Mycotic infections can usually be differentiated by demonstration of fungal elements with special stains and culture of a compatible fungal agent. Diagnosis of feline leprosy is complicated by the fact that it cannot be reliably differentiated from other mycobacterial infections histologically. Traditionally, feline leprosy has been diagnosed when acid-fast bacteria were identified in a granulomatous skin lesion from which mycobacteria could not be cultured. However, failure to culture mycobacteria does not confirm a diagnosis of feline leprosy since there are other mycobacterial species that are difficult to culture, organisms may not be cultured because of technical difficulties, or because organisms may be rare or unevenly distributed within the tissue and the sample may not be representative. As molecular-based diagnostic tests become more common, the diagnosis of feline leprosy as well as other mycobacterial infections will become more rapid and accurate than when based on histologic examination and culture.

Opportunistic, or atypical, mycobacteria

Opportunistic, or atypical, mycobacteria are widespread saprophytes commonly found in *water, soil, and decaying vegetation.* They include rapidly growing and slow-growing organisms. Human and animal infections caused by opportunistic mycobacteria are being reported with increasing frequency. Cutaneous lesions with rapidly growing opportunistic mycobacteria have been reported primarily in cats and less frequently in dogs. Isolates associated with skin infections include *Mycobacterium chelonae, M. fortuitum, M. phlei, M. smegmatis, M. thermoresistible,* and *M. xenopi.* Although cutaneous disease has also been caused by slow-growing atypical mycobacteria, these organisms are more commonly associated with disseminated disease that is indistinguishable from tuberculosis. *M. avium-intracellulare* complex (MAC) is the most common slow-growing opportunistic mycobacterium isolated from cutaneous disease in cats and dogs. *M. kansasii* has been cultured from skin lesions in cattle. Cutaneous infections are thought to be acquired from the environment following trauma such as bite or fight wounds, abrasions, and puncture wounds. Cutaneous disease occurs most commonly in adult cats that hunt or fight frequently and may be more common in obese individuals. After inoculation of organisms into a wound, the lesion develops slowly over a period of weeks to months. Experimental evidence indicates that introduction of acid-fast bacilli into oil or adipose tissue enhances their pathogenicity, possibly by providing nutrients for their growth or by protecting them from the host immune response. Animal-to-animal transmission is not thought to occur. Underlying predisposing diseases or immunologic compromise are often present in humans with these infections but are usually not identified in animals. Affected cats tested for feline leukemia virus and feline immunodeficiency virus infections have been negative.

The clinical course of opportunistic mycobacterial infection is typically prolonged. *Lesions include single or multiple cutaneous and subcutaneous nodules, plaques, purpuric macules, or diffuse swellings.* Multiple punctate ulcers or large fistulous tracts frequently develop and discharge serous, serosanguineous, or purulent exudate that is not usually malodorous. Lesions in cats caused by rapidly growing opportunistic organisms are characteristically located in the subcutaneous fat of the inguinal area. The tissue becomes progressively thickened, board-like, and firmly attached to the body wall. Lesions slowly enlarge and may involve the entire ventrum or extend up the lateral aspect of the trunk. Regional lymph nodes may become enlarged. Despite extensive cutaneous involvement, affected animals usually remain active and normal and exhibit no systemic signs. Skin lesions in cattle are frequently located on the distal limbs.

The *microscopic lesions* of atypical cutaneous mycobacteriosis are usually *multinodular-to-diffuse pyogranulomatous dermatitis and panniculitis.* Since inflammation is generally most intense in the subcutaneous fat, a *deep wedge biopsy* is preferable to a punch biopsy for diagnosis. Infections caused by rapidly growing mycobacteria typically contain circular clear vacuoles surrounded by a rim of neutrophils and a wider outer zone of epithelioid macrophages and variable numbers of neutrophils among more diffuse inflammation composed of macrophages, neutrophils, and lymphoid cells (Fig. 5.94A). Multinucleated giant cells are infrequent. *Organisms are characteristically rare and difficult to find but are usually located in small clumps within the clear vacuoles* (Fig. 5.94B). Small numbers of organisms may also be found within macrophages. The bacilli may stain more intensely with modified acid-fast stain than with routine acid-fast stain. In some instances, staining frozen sections of formalin-fixed tissue may result in enhanced acid-fast staining. The organisms are long rods to short filamentous bacilli. Intracellular bacteria tend to be shorter rods. The organisms stain unevenly positive with tissue Gram stains, resulting in a beaded appearance to the bacilli. *Because of the scarcity of organisms, any single section may lack organisms and the diagnosis will be missed.* The clear vacuoles characteristically seen among inflammatory cells in lesions with rapidly growing opportunistic mycobacteria are not typical of lesions caused by MAC organisms. Moreover, acid-fast bacilli are frequently numerous and are demonstrable by routine acid-fast stains in MAC infections. Lesions in cats caused by MAC organisms may be indistinguishable from feline leprosy. In rare instances, fibroplasia may be marked and the lesion may be confused for a spindle cell tumor. *The specific diagnosis of opportunistic mycobacterial infection requires identification by culture or molecular-based techniques.* Because of the scarcity of organisms in some lesions, diagnosis may require multiple attempts at biopsy and culture.

Miscellaneous mycobacterial infections

Although tuberculosis caused by *M. bovis* typically produces pulmonary or alimentary lesions, in some cases the skin may be the only apparent site of infection. In a survey of 57 cats with *M. bovis* infection in New Zealand, *nonhealing skin lesions* were the most common clinical sign and no evidence of internal disease was evident in the cats with skin disease. Lesions occurred in various body locations, including the legs, shoulder, flank, and inguinal area. The majority of cases occurred in regions in which *M. bovis* is endemic in the Australian brush-tailed possum and it was speculated that skin infections were more common than the classical forms of tuberculosis because they were acquired from *bite or scratch wounds from infected possums.* The histologic features consisted of poorly circumscribed pyogranulomatous inflammation extending along fascial

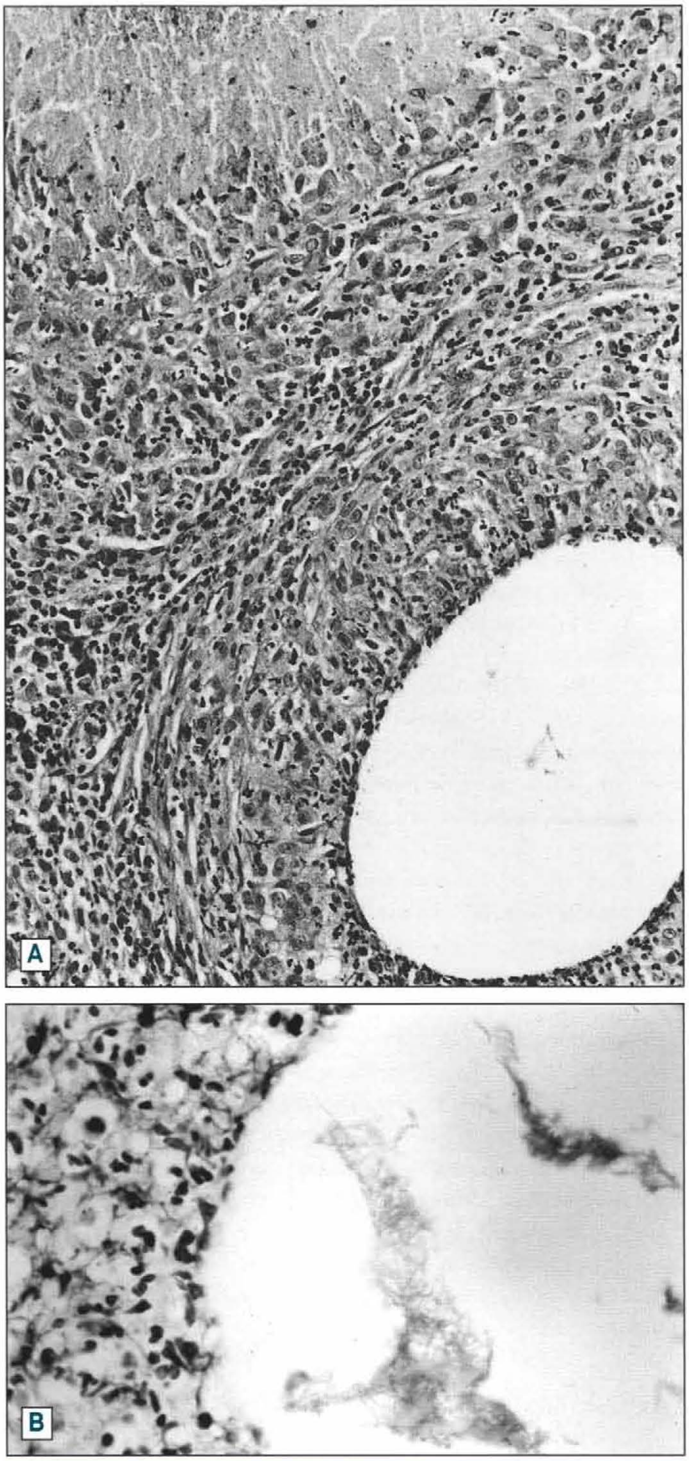

Figure 5.94 Atypical mycobacteriosis in a cat. **A.** Accumulations of mixed leukocytes with neutrophils, bordering a fat globule. **B.** High magnification of fat globule containing **filamentous organisms**.

planes. Coagulative necrosis was moderate to extensive. Acid-fast bacilli varied from rare to innumerable. Without cultural identification of the organisms, the histologic lesions could be confused for feline leprosy and other mycobacterial infections. No evidence of a zoonotic risk was found, since no pet owners became infected despite the presence of large numbers of organisms in some of the skin lesions.

Infection with an as yet unidentified mycobacterium with characteristics intermediate between *M. tuberculosis* and *M. bovis* has been described in cats in the United Kingdom and Channel Islands and termed **feline tuberculosis syndrome.** Adult cats with a history of hunting may be predisposed to the infection. All cats tested for feline leukemia virus and feline immunodeficiency virus were negative and no evidence of immunosuppression was found. *The primary clinical signs were cutaneous lesions*; while lesions more typical of classical tuberculosis, such as generalized lymphadenopathy and respiratory signs, were evident in only a few of the cats. *Skin lesions included swellings, firm raised nodules, and draining sinuses.* Some of the lesions arose in sites of previous bite wounds. Regional lymphadenopathy was frequently present. Microscopic lesions consisted of *discrete and coalescing pyogranulomatous dermatitis and panniculitis.* Granulomas composed of epithelioid macrophages and fewer neutrophils were surrounded by more diffuse infiltrates of macrophages, neutrophils, plasma cells, and lymphocytes in a proliferating granulation tissue stroma. Necrosis was variable and ranged from a few scattered foci located within some of the granulomas to extensive coalescing foci. Organisms were visible with routine acid-fast stain and were usually in low numbers but were numerous in a few cases. The zoonotic potential of this mycobacterial infection is unknown.

A condition referred to as **canine leproid granuloma syndrome** has been described in dogs in Australia, Africa, and North America. The disease is characterized by *cutaneous lesions in which acid-fast bacteria are visible histologically but cannot be cultured.* Short-coated breeds, particularly Boxers and their crosses as well as Doberman Pinschers and Bullmastiffs, appear to have a predilection for the infection. Lesions consist of *single or multiple, firm, painless nodules primarily on the head and especially on the dorsal surface of the pinnae.* The frequent location on the head led to speculation that transmission involves biting flies or insects. In some cases, lesions spontaneously resolved after weeks to months. In other cases, lesions persisted indefinitely and progressively enlarged or additional lesions developed and became ulcerated. Lymph node and internal organ involvement was not seen. The microscopic features of the condition were not described but acid-fast bacteria were reported to vary from numerous to infrequent, widely scattered, and very difficult to find in tissue sections. Preliminary molecular-based identification of the organisms suggests that the etiological agent(s) is *a new mycobacterial species grouped within the saprophytic mycobacteria.*

Botryomycosis

Botryomycosis (bacterial pseudomycosis, bacterial granuloma) is *a chronic infection caused by nonfilamentous bacteria that form colonies visible as tissue grains or granules within lesions*. Clinically and histologically, the condition resembles actinomycotic and eumycotic mycetomas. The disease occurs in humans and all domestic animals. Although reported rarely, the condition is probably not uncommon. Lesions are usually localized in the skin and subcutis but may extend deep to involve underlying bone and muscle. Disseminated infection with visceral involvement is rare. Coagulase-positive staphylococci are involved most commonly; but streptococci, *Pseudomonas, Actinobacillus, Pasteurella, Proteus, Escherichia*, and other organisms have also been isolated from lesions. Infection is thought to develop as a result of wound contamination or trauma such as bites, lacerations, or puncture wounds with foreign bodies.

Lesions typically consist of *firm, nonpruritic single or multiple nodules that ulcerate and develop draining fistulae*. They discharge purulent material which frequently contains *white to yellow sand-like grains*. The microscopic lesion is characterized by the presence of *basophilic granules within the center of neutrophilic abscesses or pyogranulomas in the dermis or subcutis.* These granules correspond to the grains seen grossly in the discharge. They are surrounded and separated by fibrous tissue which may be quite extensive. Plant debris or other foreign material may also be seen in the lesions and indicate the means of infection. The granules consist of compact bacterial colonies which are usually surrounded by amorphous, deeply eosinophilic, radially arranged Splendore-Hoeppli material. The name of the condition is, in part, derived from the appearance of the granules which was thought to be suggestive of a *bunch of grapes*. The bacteria are not well delineated in H&E-stained sections, thus *special stains are usually necessary to distinguish the organisms from actinomycotic bacteria and fungi*. Individual cocci or bacilli within the granules are seen most clearly in sections stained with tissue Gram or Giemsa stains. The GMS procedure also stains bacteria and allows differentiation from fungi.

Bacterial pododermatitis of ruminants

Footrot

Footrot is a highly contagious bacterial infection of the digits of *sheep, cattle, and goats*. It has also been reported in *pigs*. The multistrain, gram-negative, obligate anaerobe *Dichelobacter* (formerly *Bacteroides*) *nodosus* is the essential causal pathogen. *Footrot should not be confused with necrobacillosis of the ruminant foot*, which is a noncontagious, mixed bacterial infection in which *Fusobacterium necrophorum* is the principal pathogen. Footrot occurs worldwide in areas with temperate climate and moderate to high rainfall. The condition is particularly important in sheep because of the economic impact it has on both the wool and meat industries. *Footrot is a major disease in high rainfall areas*, such as Australia and New Zealand, and *can produce severe lameness* because of necrosis of the sensitive laminae and separation of the hoof. The reduced mobility and reluctance of affected animals to eat results in weight loss and decreased wool quality and growth rate, which correlate in a linear manner with the number of feet infected. In addition to the production losses, the cost of treatment and control contribute to significant economic losses.

The pathogenesis of footrot is complex and has been studied most extensively in sheep. The disease is initiated by *maceration of the interdigital skin* brought about commonly by extended exposure to lush, continually wet pasture. Disease is thus most common in rainy seasons. Minor wounds, abrasions from stones, sharp plants, or long coarse grasses, and damage caused by migrating *Strongyloides* larvae are additional factors that can predispose to development of clinical footrot. The damaged epidermis then becomes colonized by *Fusobacterium necrophorum*, aerobic diphtheroids, coliforms, and other common bacteria originating from the soil, skin, and feces. *Footrot develops if the dermatitis is subsequently complicated by infection with D. nodosus.* The bacterium is an obligate parasite of the ruminant hoof and carrier animals serve as the source for uninfected stock. Transmission of infection requires adequate moisture and a mean ambient temperature greater than 10°C. Direct contact between susceptible and infected sheep is not required for transmission of infection. Contact with contaminated substrate for less than 1 hour has been shown to be adequate for transmission; and outbreaks have been associated with contact with environment contaminated by affected animals as long as 4 days previously. *F. necrophorum* and *D. nodosus* act synergistically to produce clinical disease. *D. nodosus* produces a variety of *extracellular proteases* that are thought to digest the horn and allow bacterial invasion of the epidermal matrix of the horn. It also produces a *heat-stable soluble factor* that enhances the growth and invasiveness of *F. necrophorum*. *F. necrophorum* produces a *leukocidal exotoxin* that reduces phagocytosis.

The separation of horn is caused by lysis of the epidermal matrix as a result of the local inflammatory response rather than from direct bacterial attack. *Arcanobacterium pyogenes* and other aerobic bacteria are usually located superficially in the lesion where they remove oxygen, destroy hydrogen peroxide, and create the anaerobic environment necessary for the growth of the two anaerobic pathogens.

Footrot in sheep is a complex clinical disease syndrome. The spectrum of clinical disease is divided into three major forms: *virulent, intermediate, and benign*. Factors associated with severity and persistence of infection include virulence of the particular strain of *D. nodosus*, the environment, and host resistance. Considerable variation exists in the natural resistance to the disease and there is evidence to suggest a genetic basis for the variation in resistance. A possible association between alleles of the major histocompatibility complex (MHC) class II region and resistance to footrot has been found. Most Merino flocks are considered to have a high proportion of susceptible animals. Virulence of *D. nodosus* varies widely from strain to strain. Virulent strains of the bacterium produce more extracellular proteases, including elastase; and proteases from virulent strains tend to be more thermostable than those from benign strains. Two genomic regions of *D. nodosus* are preferentially associated with more virulent isolates of the bacterium. These regions have been named *vap*, for virulence-associated protein, and *vrl*, for virulence-related locus. Although useful as indicators of virulence, the function of these two regions has not been determined. The *virulent form of footrot in sheep* is the serious, persistent form of the disease characterized by severe necrotic damage to the hoof and extensive separation of hoof horn in more than one foot in a high percentage of the sheep. The infection may persist for more than 1 year if not treated, and chronically infected sheep may die of emaciation as a result of severe pain and lameness. Affected animals are also predisposed to flystrike. *Benign footrot*, also called "*foot-scald*," is a milder, less persistent form of the condition. It is typically characterized by moderate interdigital dermatitis which causes mild lameness and minimal production loss. The benign form has a greater propensity for self-cure.

Footrot in sheep develops approximately 10–20 days after exposure and *begins as interdigital dermatitis in the axial bulbar notch*. At this early stage, the interdigital skin is pale, swollen, and moist. Inflammation progressively extends forward and caudad around the bulb of the heel. Separation of the horn usually occurs 7 days later, beginning at the skin-horn junction and spreading to the bulb and sole. The animal is severely lame at this stage. From the sole, the process spreads to the hoof wall to involve the axial and abaxial surfaces of the digits. Exudation is minimal and consists of a small amount of gray, greasy malodorous material in the cleft beneath the underrun horn. Since the infection does not destroy the germinative layers of the horn, new horn is continually being regenerated but is rapidly destroyed as long as the infection continues. Chronically infected feet become long and misshapen.

Benign footrot is indistinguishable from the early stages of virulent footrot. However, *in benign footrot the erosions usually remain confined to the caudal aspect of the interdigital cleft*. Occasionally there is separation of the soft horn of the heel and caudal portion of the sole but there is no separation of the hard horn. Affected sheep may appear normal or exhibit mild, temporary lameness. The effect of benign footrot on production is minimal.

Diagnosis of footrot in sheep is based on clinical signs, demonstration of D. nodosus in smears from lesional material, and culture and biochemical characterization of isolates to identify antigenic and virulence variants. Because the organism is slow to grow, culture and biochemical testing is time-consuming and may require up to 10–14 days. Gene probes have been developed to identify the virulence-associated loci vap and vrl in lesional material. This testing can be completed within 48–72 hours.

Footrot of **cattle and goats** is typically a *less severe disease* and resembles the benign form of footrot of sheep. Infection with *D. nodosus* is more common than is clinical disease. Direct transmission can occur between sheep and goats in the same environment but the innate resistance of goats appears to be greater than that of sheep. The lesions in goats tend to stay confined to the interdigital skin. Underrunning lesions are not common in goats and are usually restricted to a portion of the soft horn. *D. nodosus* isolates from *cattle* with footrot tend to be relatively benign strains. Footrot in cattle usually begins at the caudal aspect of the interdigital space, spreads laterally on the bulbs of the heels, and eventually involves the entire interdigital space. *Lesions usually remain confined to the interdigital skin* which may be eroded, ulcerated, or become deeply fissured. The fissures are covered with necrotic material with a characteristic fetid odor. Lesions may extend to the heels and mild separation of the soft horn may develop. Extensive undermining of the horn, as occurs in sheep, does not typically occur in cattle. Affected animals stand on their toes. In rare severe cases, fever, anorexia, recumbency, and decreased milk production may develop.

Papillomatous digital dermatitis

Papillomatous digital dermatitis is a painful, contagious dermatitis of the feet of *cattle* that occurs worldwide. The condition is also called *footwarts* and *hairy heelwarts*; and clinically and histologically, it appears to be the same disease as *digital dermatitis, interdigital papillomatosis, verrucose dermatitis, and digital papillomatosis*. Papillomatous digital dermatitis is economically important because it frequently *causes moderate-to-severe lameness* that results in weight loss, decreased milk production, and poor reproductive performance. A similar condition has been reported in *sheep and a horse*. The condition in horses is not as rare as might be supposed from the literature, and is recognized in diagnostic laboratories where horses are commonly submitted for disease investigations.

The *vast majority of cases are in dairy cows* but it has also been reported in beef cattle. Although the disease occurs in all ages, the highest incidence appears to be in *replacement heifers*. The etiology of papillomatous digital dermatitis is unknown but it is *suspected to be bacterial* based on the favorable response to antibacterial therapy, presence of numerous *intralesional spirochetes*, lack of demonstrable viruses and other known pathogens, and evidence of a specific humoral response in affected animals to spirochetes isolated from lesions of papillomatous digital dermatitis. The spirochetes have been identified as *Treponema phagedenis*-like. Genetic analysis indicates that the organisms are related to pathogenic human treponemes associated with periodontitis. The condition is also usually associated with management conditions in which the feet of cattle remain wet for prolonged periods, such as following a rainy season, during indoor confined housing in the winter, or in muddy corrals. The condition tends to disappear when cattle are on pasture, but some outbreaks are unassociated with any apparent predisposing factors.

Papillomatous digital dermatitis most commonly affects the skin proximal and adjacent to the interdigital space at the back of the hindfeet. The front feet are less frequently involved and usually only one foot is affected. The cranial aspect of the foot and the interdigital skin are rarely involved. Lesions are painful, forcing the animal to shift its weight to the toe of the foot and resulting in clubbing of the affected foot and atrophy of the bulbs of the heels. Early lesions are well-circumscribed, round-to-oval, red plaques up to 6 cm in diameter with a moist granular surface prone to bleeding and with a very strong, pungent odor. They are partially to completely alopecic and may be bordered by hypertrophied hairs two to three times longer than normal. The lesions become progressively more proliferative and less painful with time. Mature lesions are irregular wart-like growths or filamentous papillae which measure 0.5–1.0 mm in diameter and 1 mm to 3 cm in length and are pale yellow, gray, or brown.

The early *microscopic changes* of papillomatous digital dermatitis consist of mild epidermal hyperplasia with foci of erosion, necrosis, ballooning degeneration, and microabscesses. The basal layer exhibits an increased mitotic index. The dermis contains minimal perivascular inflammation. Mixed bacteria may be present in the outer necrotic debris but only spirochetes are present in the deeper viable epidermis. Two morphologically distinct spirochetes have been demonstrated to be in large numbers in early lesions. One is a long thin type with few twists and the other is a short, thick spirochete with many twists. The spirochetes are oriented perpendicular to the epidermis and appear to invade the keratinocytes. The older lesions are composed of frond-like projections or plaques of markedly hyperplastic epidermis with parakeratosis and hyperkeratosis. Foci of necrosis and hemorrhage, ballooning degeneration, and aggregates of neutrophils are scattered throughout the hyperplastic epidermis. At this later stage, inflammation is more intense in the dermis and plasma cells may be numerous.

Skin lesions in systemic bacterial disease

Skin lesions may develop during the course of systemic bacterial infection. They frequently arise *as a result of vasculitis and/or thrombosis*. This occurs most commonly in **pigs**. Swine erysipelas, caused by *Erysipelothrix rhusiopathiae*, is a generalized septicemia that is commonly associated with *blue-purple rhomboidal plaques (diamond skin lesions)* (Fig. 5.95). These lesions are obvious on light-skinned pigs but may require palpation for detection on pigmented animals. The lesions either regress spontaneously or undergo necrosis,

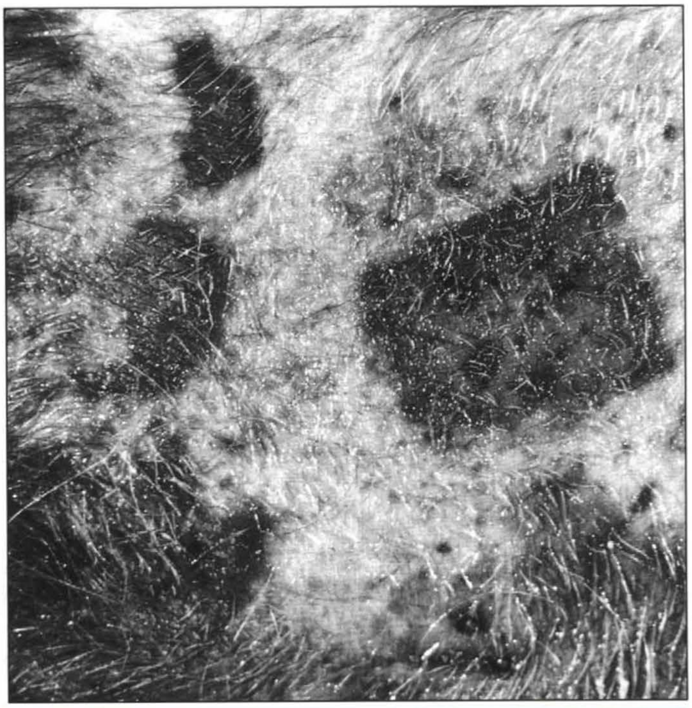

Figure 5.95 Classical "diamond skin" lesions in ***Erysipelothrix rhusiopathiae*** infection in a pig.

become hard and dry, and eventually slough. Severely affected ears and tail may also be sloughed. Microscopic findings include marked dermal congestion, neutrophilic vasculitis, cutaneous necrosis, and suppurative hidradenitis. Various gram-negative septicemias, in particular septicemic salmonellosis caused by *S. choleraesuis*, may produce blue-purple discoloration of the skin of the ears, ventral abdomen, snout, and tail primarily as a result of *endotoxin-induced venous thrombosis*. *Pasteurella multocida* may cause similar skin lesions in pigs. *Edema disease*, caused by a hemolytic *E. coli* may be associated with subcutaneous edema secondary to vascular hyaline degeneration, fibrinoid necrosis, and mural edema.

Skin lesions occur less commonly in other domestic species with systemic bacterial infection. *Salmonella dublin* infections in **cattle** may produce gangrene of distal extremities, tail, and pinnae as a consequence of vascular thrombosis. Cutaneous lesions are uncommon in **dogs** with systemic infections. Rocky Mountain spotted fever, caused by *Rickettsia rickettsii*, is most often associated with skin lesions. These consist primarily of edema and hyperemia; petechial and ecchymotic hemorrhages may also occur but typically involve mucous membranes rather than the skin. Acral dermal necrosis occurs rarely. Microscopic findings consist of necrotizing vasculitis, which may result in cutaneous necrosis. Dogs with Lyme borreliosis, caused by *Borrelia burgdorferi*, may develop a small, reddened skin lesion at the site of tick attachment. This lesion usually disappears within a week and is very inconspicuous as compared to the striking expanding, annular erythematous rash (erythema chronicum migrans) typical of the infection in humans.

FUNGAL DISEASES OF SKIN

Fungi are ubiquitous in the environment but, of the thousands present, only a few are capable of causing infection in animals. *The vast majority of fungi in nature are incapable of causing infection because they are unable to breach two major physiologic barriers to fungal growth in tissue: temperature and oxidation-reduction potential.* Many fungi have an optimal growth range considerably below the temperature of the body and cannot survive the relatively high temperature of the body. Other fungi, even if thermotolerant, cannot survive in the reduced state of living tissue. The propensity of fungi to cause infection is dependent not only on their ability to adapt to the tissue environment and temperature, but also to withstand the lytic activity of the host's cellular defenses. Some fungi are *true pathogens* with the ability to cause disease in normal individuals while many more organisms are *opportunistic pathogens* that infect individuals who have become immunologically or otherwise compromised and are unable to resist and suppress the fungal invasion. Immunocompromise by various infectious agents, such as *Human immunodeficiency virus, Feline leukemia virus, Feline immunodeficiency virus,* and *Canine distemper virus,* as well as pharmacologic immunosuppression, are important predisposing factors in development of some fungal infections. However, many mycotic infections occur in individuals without any clinically overt immune impairment. These infections are likely a consequence of an overwhelming exposure to the infectious propagules or mild immunologic defects that are not readily apparent. Mycotic infections are commonly divided into three categories: cutaneous, subcutaneous, and systemic.

- **Cutaneous mycoses** are the most common fungal diseases in veterinary medicine. The infections are generally confined to the nonliving cornified layers of the skin, hair, and claws.
- The **subcutaneous mycoses** are fungal infections that involve the skin and subcutaneous tissues. They are caused by a wide variety of saprophytic fungi that gain entry by traumatic implantation. Infection is a very indolent process and usually remains localized to the site of entry with slow spread to surrounding tissue.
- The **systemic mycoses** are infections of the internal organs. Cutaneous involvement usually occurs as a result of hematogenous dissemination. Skin lesions from direct cutaneous inoculation in systemic mycoses are rare. These infections include blastomycosis, cryptococcosis, coccidioidomycosis, and histoplasmosis. Occasionally the diagnosis of a systemic fungal infection/mycosis, particularly blastomycosis in dogs and cryptococcosis in cats, is made by biopsy of skin lesions.

Histopathology is an important diagnostic tool for fungal infections. It is a relatively rapid and inexpensive means to make a definitive or presumptive diagnosis of mycotic infection. In many cases, fungal infections are mistaken for neoplasms and the entire lesion is fixed and submitted for histologic examination. Consequently, only fixed tissue is available and the pathologist has the responsibility for the final diagnosis because the organism cannot be cultured. Some fungal organisms have distinctive enough morphologic features that, if present in sufficient numbers, they can be identified with a high degree of certainty, e.g., *Blastomyces, Cryptococcus,* and *Coccidioides*. Other mycotic infections are caused by a variety of fungi that are similar in appearance in tissues and cannot be specifically identified, although the disease can be named, e.g., dermatophytosis, phaeohyphomycosis, and eumycotic mycetoma. In some cases, fungi may be detectable in tissues but may be impossible to identify and only the conclusion that mycotic infection exists can be made. Although immunofluorescence and immunohistochemical methods for identification of fungi in formalin-fixed, paraffin-embedded tissue sections have been developed, the specific antisera are not readily available, and *culture remains the mainstay for identification of fungal pathogens.* Some fungi stain with H&E but many fungi do not stain or stain very poorly with H&E. However, even in these cases, fungal infection can be suspected because of the presence of clear circular or linear structures, representing unstained fungal hyphae, within the lesion. *Special fungal stains,* such as Gomori methenamine silver (GMS), which stains fungi black, and periodic acid-Schiff (PAS), which stains fungi pink-red, delineate the fungi so their morphology can be examined. In general, GMS is better for screening tissue because some fungal-like organisms (e.g., *Pythium*) stain poorly with PAS. Fungal stains may mask the natural color of fungi, however. To determine whether a fungus is pigmented, it can be examined in unstained cleared and mounted sections or a melanin stain, such as Fontana-Masson, can be applied to the tissue.

Cutaneous fungal infections

Cutaneous mycoses are infections in which the fungal organisms are generally confined to the nonliving keratinized tissues, i.e., *stratum corneum, hair, claw, and horn.* Pathologic changes, which occur in response to the infectious agent and its metabolic products, involve the epidermis and dermis and may vary from minimal to severe and extensive. These infections include candidiasis, *Malassezia* dermatitis, and dermatophytosis.

Candidiasis

Candidiasis (candidosis, moniliasis, thrush) is a rare opportunistic infection of skin, mucocutaneous junctions, external ear canal, and the claw bed. *Candida* spp. yeasts are normal inhabitants of the upper respiratory, alimentary, and genital tracts but are not normally present on the skin except at mucocutaneous junctions of body orifices. Factors which alter the superficial keratin barrier (such as maceration, chronic trauma, or burns), upset normal flora (such as prolonged broad spectrum antibiotic therapy), or produce immunosuppression (such as diabetes mellitus, hyperadrenocorticism, neoplasia, viral infections, cytotoxic chemotherapy, or prolonged glucocorticoid treatment) predispose to infection with the organism. Since neutrophils are a major defense mechanism against *Candida*, prolonged neutropenia renders an individual more susceptible to candidiasis. The other major mechanism for eliminating *Candida* from the skin surface is T-cell-mediated immunity.

Infections have been described in *dogs, cats, pigs, horses, and goats.* Lesions are variable and may begin as papules, pustules, and vesicles which evolve into characteristic *sharply delineated ulcers with erythematous borders and a malodorous surface with moist gray-white exudate.* Chronic lesions consist of thickened alopecic hyperkeratotic skin with prominent folds. Histologic changes include hyperkeratosis, parakeratosis, serocellular crusts, subcorneal or superficial epidermal neutrophilic pustules, and spongiosis. The dermis is edematous and contains a superficial perivascular to interstitial mixed infiltrate. *Yeasts, pseudohyphae, and hyphae may be numerous but are best visualized with PAS or GMS stains.* Generally, yeasts are most numerous on the surface of the lesions, while hyphae and pseudohyphae extend into the epidermis.

Malassezia dermatitis

Malassezia pachydermatis (formerly Pityrosporum canis) is a constituent of the normal resident flora of the skin and mucous membranes of dogs and cats and a common cause of ceruminous otitis. Its role as a cause of dermatitis has been controversial. Evidence that the organism is capable of acting as an opportunistic pathogen is provided by cases of chronic dermatitis in which large numbers of yeasts are evident on the skin surface and lesions resolve following antifungal therapy. Predisposing factors are thought to be required for the yeast to cause clinical disease. Excessive surface lipid or cerumen, high humidity, or failure of host defense mechanisms to control overgrowth of the yeast may predispose an animal to develop clinical disease. Many dogs with *Malassezia* dermatitis also have allergic skin disease, seborrhea, or bacterial pyoderma as well as a history of long-term corticosteroid or antibiotic treatment; it is unclear whether these concurrent disorders are involved in development of yeast infection or are merely coincidental. Humans with atopic dermatitis have an increased incidence of *Malassezia* skin infections. Dogs with *Malassezia* dermatitis develop high serum titers of specific IgG antibody and exhibit significantly greater skin test reactions in response to intradermal injection of *M. pachydermatis* extracts than dogs without evidence of *Malassezia* dermatitis, suggesting that *hypersensitivity may be involved in the pathogenesis of clinical disease.* Various breeds of dogs have been found to be at increased risk for *Malassezia* dermatitis in different reports. These differences in affected breeds may reflect regional variation in breed popularity or differences in regional gene pool. In several reports, however, the Basset Hound has been found to have a predilection for this disorder. When numbers of *M. pachydermatis* yeasts on the skin were examined, normal Basset Hounds were found to have higher carriage levels of the yeast as compared to normal mixed-breed dogs, a fact that may contribute to the increased incidence of the disorder in this breed. No sex predilection is evident and most cases are in adult dogs. *Malassezia* dermatitis is reported rarely in cats and has been associated with various neoplasms and other conditions that could alter the host immune response.

Lesions associated with Malassezia dermatitis include erythema, alopecia, greasiness, yellow-gray scaly plaques, lichenification, and hyperpigmentation (Fig. 5.96A). A rancid offensive odor is typical; and moderate to severe pruritus is a common feature. The face, ears, ventral neck, axilla, inguinal area, cranial aspect of the legs, caudal thighs, and feet are most commonly involved. Involvement of one or several of these areas is more common than generalized disease. *Malassezia* dermatitis in cats is seen as black ceruminous otitis externa, chronic chin acne, or generalized erythematous scaly dermatitis.

Histologic features of *Malassezia* dermatitis consist of variable hyperkeratosis, parakeratosis, scale-crusts, and irregular epidermal hyperplasia with intercellular edema (Fig. 5.96B). Exocytosis of lymphocytes, neutrophils, or eosinophils has been found in various reports. Rarely, intra-epidermal eosinophilic pustules were found in dogs without any apparent concurrent dermatosis. There is variable edema and perivascular to interstitial infiltration of mixed cells in the superficial dermis. *Malassezia* organisms are *oval to footprint- or peanut-shaped yeasts located in the stratum corneum or in crusts.* They are usually seen in focal aggregates rather than diffusely distributed and they can best be visualized with PAS or GMS stains. The organism will be missed if the skin surface was scrubbed prior to obtaining the biopsy or if the surface debris is lost during processing.

Dermatophytosis

Dermatophytosis ("**ringworm**") *is a superficial fungal infection generally confined to the keratin layers of the skin, hair, and nails.* In rare instances, deeper tissues are involved. The infection is caused by a group of fungi that are capable of using keratin as a source of nutrients and are among the few fungi that cause communicable disease. Infection can vary from mild to severe as a consequence of the host's reactions to metabolic products of the fungus, virulence of the particular species or strain, location of the infection, and local environmental factors. In general, the infection has no effect on growth rate or other measures of productivity, but economic losses may result from hide damage or inability to show infected animals.

The infection is caused by fungi of the genera *Microsporum*, *Trichophyton*, and *Epidermophyton*, which are cosmopolitan in distribution. They are commonly divided according to the host preference and natural habitat of the fungus. The **anthropophilic** dermatophytes are primarily adapted to humans and rarely infect other animals (e.g., *T. rubrum*, *T. mentagrophytes* var. *interdigitale*). Animals occasionally develop infections with these organisms as a reverse zoonosis from infected humans. The **zoophilic** species are those dermatophytes that have become adapted to animals and typically cause less inflammation in their adapted hosts than do geophilic or anthropophilic dermatophytes (e.g., *M. canis* in cats, *T. equinum* in horses). They occasionally infect humans. **Geophilic** species (e.g., *M. gypseum*) normally inhabit the soil in association with keratinous debris in the process of decomposition but they may cause human and animal infection. *M. canis*, *M. gypseum*, and *T. mentagrophytes cause the majority of infections in animals.*

Incidence and prevalence of dermatophytosis vary with individual host factors, health status, climate, season, natural reservoirs, and local environment. A variety of local and systemic factors may predispose an individual to infection. Areas of chronically warm, moist skin are more likely to become clinically infected. Long-term corticosteroid administration, cytotoxic drugs, diabetes mellitus, hematologic malignancies, and other causes of natural or iatrogenic immunosuppression are associated with susceptibility to dermatophytosis. Incidence of infection is increased with hot, humid weather and when populations of stable flies and mosquitoes are large. In confined animals, infection is common in fall and winter when animals are crowded together in wet, poorly ventilated, unsanitary conditions with decreased exposure to sunlight. Young animals appear to be more susceptible to infection than adults. Reasons for this apparent predisposition include immaturity of host immunity, lack of previous exposure, and age-related differences in biochemical properties of the skin, such as qualitative or quantitative differences in antifungal fatty acids in sebum secretions. Transmission of dermatophytosis occurs by direct contact with infected animals or indirectly by exposure to infective hair and scales in the environment (contaminated grooming equipment, bedding, saddles, cages, etc.). *Hair fragments containing infectious arthrospores are the most effective means of transmission.* They can remain infectious for more than 18 months if protected from the deleterious effects of ultraviolet light. This material is the major source of persistent environmental contamination. Certain dermatophytes are associated with specific sources. *M. canis*, despite its name, is most commonly associated with cats, and the cat is considered the reservoir for this dermatophyte. *T. mentagrophytes* dermatophytosis is typically acquired from small rodents; infection with *M. gypseum*, a geophilic dermatophyte, is assumed to be acquired from digging or rooting in contaminated soil. An animal's habitat is an important factor in the incidence and type of infection contracted. In a survey of dermatophytosis in Madras, India, a predominance of *M. gypseum* was cultured from stray dogs, which would be expected to have frequent contact with soil. In contrast, pet dogs were infected primarily with zoophilic (*T. mentagrophytes*) and anthropophilic (*T. rubrum*) dermatophytes, the latter infections suspected to be reverse zoonoses since there was a history of exposure to people known to be infected with *T. rubrum* in most of the cases.

Normal skin is relatively inhospitable to fungal growth because of low moisture conditions, antifungal substances in the surface film, and normal resident flora. Sebum contains fatty acids which are fungistatic and play an important role in resistance to infection. The process by which the stratum corneum is continually renewed may also present a form of defense against organisms because the process results in continuous shedding of the stratum corneum and thus removes infecting organisms with the sloughed keratin. Disruption of the stratum corneum, either by microabrasions or maceration, appears to be important in facilitating invasion by the fungus. Fungal cells adhere to keratinocytes and migrate to the follicular orifice. Dermatophytes produce keratinolytic enzymes, keratinases, which hydrolyze keratin and enable them to penetrate and invade the hair shaft. They grow downward within the hair shaft toward the hair bulb until they reach the keratogenous zone where they stop since they cannot grow in viable tissue. Infection continues as long as the downward growth of the fungus is in equilibrium with keratin production; if not, the fungus is sloughed and the hair is cleared of infection. When the hair enters telogen phase, keratin production stops and fungal growth ceases. Hair shafts are weakened as a result of penetration by the fungi and they become brittle and easily broken.

Dermatophytosis in healthy individuals is *usually self-limiting*, with lesions resolving in several weeks to two or three months. An inverse relationship appears to exist between the degree of inflammation produced by the fungal pathogen and chronicity of infection. Defense against infection involves both immune and non-immune mechanisms. The epidermis represents more than just a passive barrier against entry of invading microorganisms, because keratinocytes produce a variety of eicosanoids, growth factors, chemotactic cytokines, interleukins, and colony stimulating factors that can mediate inflammation. In addition, increased epidermal proliferation occurs early in infection, even before an immunologic response develops, and helps expel the organisms by desquamation. Cell wall components of the organisms activate complement via the alternative pathway. Chemotactic factors generated in the complement cascade as well as those produced by keratinocytes attract neutrophils, which are the chief effector cells. They can kill fungi with products generated in the oxidative burst and also by nonoxidative microbicidal substances within their granules. Neutrophils also have fungistatic activity via *calprotectin*, a calcium- and zinc-binding protein. Macrophages are involved to a lesser extent and produce nitric oxide, which inhibits fungal growth. Nonspecific mechanisms prevent invasion into deeper tissues even in the absence of immunity. Substances in the dermis may prevent growth of organisms. Some of these include unsaturated transferrin, which may interfere with fungal growth in the dermis by competition for iron, and α_2-macroglobulin which inhibits keratinases. Both humoral and cell-mediated immunity develop in response to infection with dermatophytes. Antibodies develop against keratinase as well as fungal glycoproteins but they apparently do not help eliminate infection since the highest titers are found in patients with chronic infections. In contrast, development of cell-mediated immunity is associated with clinical cure and elimination of the organism. In experimental *M. canis* infections in cats, there was no relationship between antibody titers and recovery; but a close temporal relationship was found between the development of increased lymphocyte proliferative responses and regression of lesions. Cell-mediated immunity is the major immunologic defense in clearing dermatophyte infections. Immunity post-infection is relative, so re-infection is possible; however, lesions are smaller and resolve more quickly when an animal is re-infected with the same organism.

Impaired T-cell function has been associated with chronic or recurrent dermatophyte infections. An increased incidence of dermatophyte carriage has been found in cats infected with feline immunodeficiency virus (FIV), and severe dermatophyte infections are common in people with AIDS. However, even apparently healthy individuals can have persistent infections. *Inhibitory factors*, which can interfere with lymphocyte blastogenesis in vitro, have been found in serum of people with chronic dermatophyte infection. In addition, *T. rubrum* cell wall mannan has been shown to inhibit lymphoproliferation in vitro and is thought to be involved in the pathogenesis of chronic infections. Chronic dermatophyte infections have also been reported in dogs. *Trichophyton* spp. and *M. persicolor* dermatophyte infections, lasting up to 5 years in some cases, have been described in dogs without any other evidence of an immunodeficiency disorder, suggesting that these organisms may also produce inhibitory substances which prevent development of an effective immune response and elimination of the organism.

The *clinical signs* of dermatophytosis are highly variable and depend on the host-fungus interaction. Well-adapted species, such as *M. canis* infection in cats, produce minimal inflammation while less-adapted species, such as the zoophilic dermatophyte *M. gypseum*, produce more significant inflammation and more prominent lesions. *Expanding circular patches of scaling and alopecia or stubbled hairs are considered the classical lesion of dermatophytosis but these are frequently the exception rather than the rule* (Fig. 5.97A, B). Follicular papules and pustules, more extensive inflammation caused by furunculosis, and crusting are prominent in many cases. Lesions are typically non-pruritic, but occasionally pruritus is intense. *Infection of nails is called* **onychomycosis** and is characterized by misshapen, crumbly or easily broken, and split nails that may be sloughed. **Kerions** are rapidly developing tender erythematous alopecic nodules that may ulcerate. They are usually solitary and most common on the face and forelimbs of dogs that dig in the dirt. These lesions result from *severe furunculosis* producing locally extensive inflammation that may be confused for a tumor. A rare form, the **dermatophyte pseudomycetoma** seen almost exclusively in Persian cats, occurs as *subcutaneous nodules* (Fig. 5.98A, B).

The microscopic lesions of dermatophytosis are as variable as the clinical lesions. *Histopathology is not considered as sensitive as culture for diagnosis*; but it can be used to confirm infection when the significance of a cultured organism is in question. It is most useful in the nodular forms, such as kerion and pseudomycetoma, which are frequently negative when superficial material is cultured. Biopsies should be taken within the outer border of expanding alopecia as this is the most active site of infection and organisms are most likely to be present. In some cases, fungal organisms are evident in HE-stained sections, but *in many instances, fungal stains (PAS, GMS) are necessary to demonstrate infection*. Dermatophytes occur as septate hyphae that

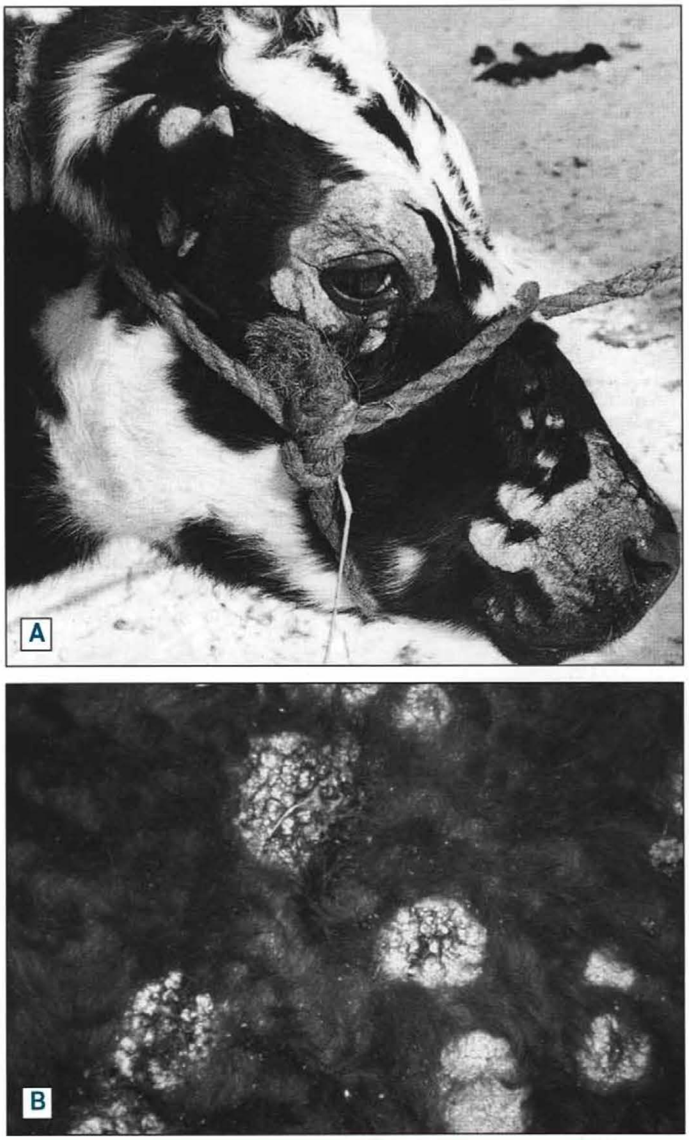

Figure 5.97 Dermatophytosis in a calf. **A.** Gray-white, rough, hairless lesions on the ear, muzzle, and periorbital skin. **B.** Classical "ringworm" lesions of expanding circular patches of scaling and alopecia.

break up into chains of round-to-oval arthrospores in the surface and follicular keratin. *Hyphae are also usually present in the hair shafts and arthrospores are formed on the outside of the hairs (ectothrix) or within the hairs (endothrix).* In rare cases, fungal organisms are present only in the surface keratin; if this material was removed in preparing the skin for obtaining the biopsy or is lost during tissue processing, the diagnosis will be missed. *Ortho- and parakeratotic hyperkeratosis* is a typical feature, and acanthosis is variable, ranging from mild to marked (Fig. 5.99A). Inflammation may be very mild and consist of low numbers of perivascular and perifollicular lymphocytes and macrophages. This is the case when infection is caused by a species of dermatophyte that is well adapted to its host (Fig. 5.99B). *Neutrophilic luminal folliculitis* is a common lesion in dermatophytosis and may result in *follicular rupture and development of discrete granulomas* surrounding fragments of hair at the base of the follicles (Fig. 5.99C). *Eosinophils* may be numerous in these trichogranulomas.

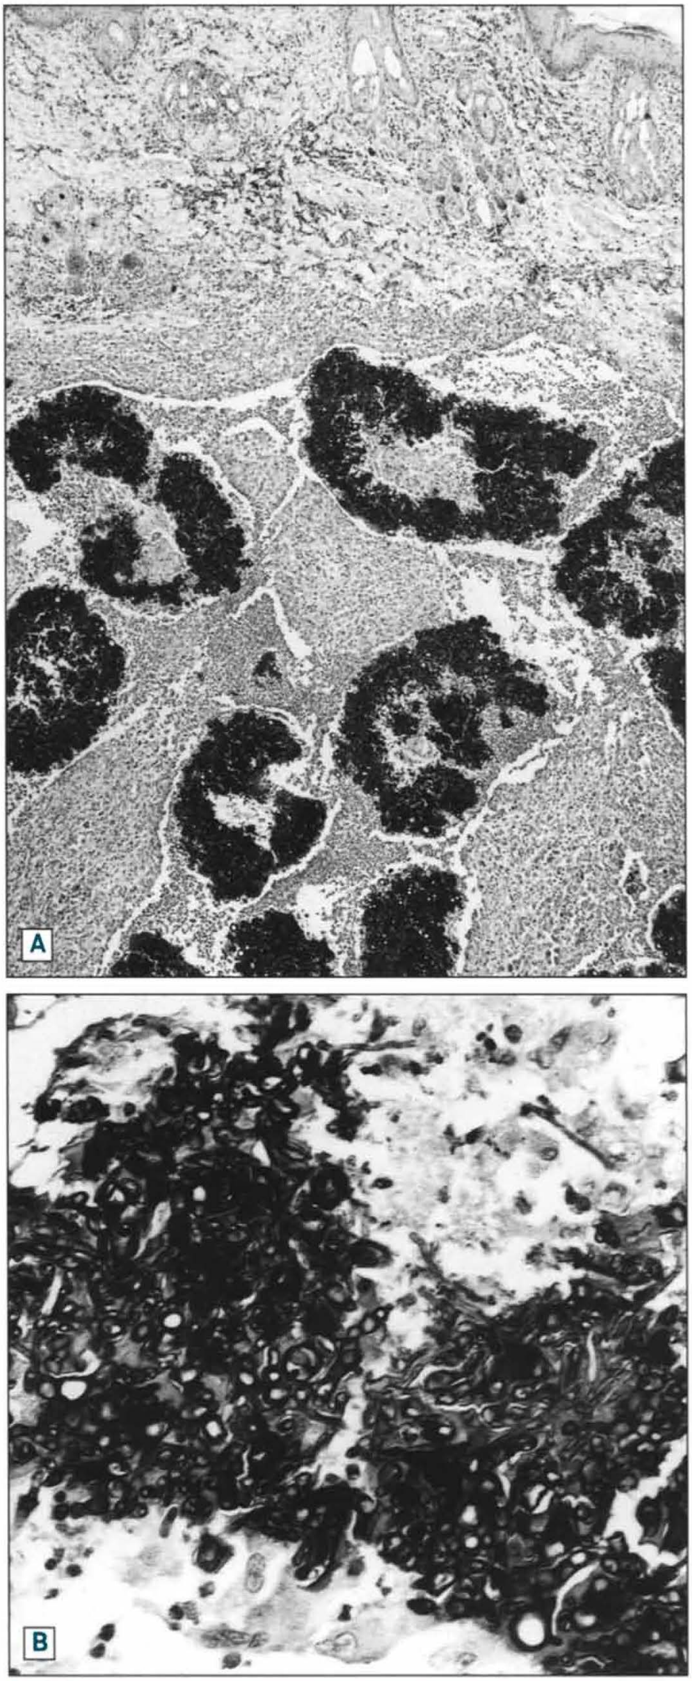

Figure 5.98 ***Microsporum canis*** **pseudomycetoma** in a Persian cat. **A.** Myriads of fungal hyphae (PAS-positive) in the panniculus surrounded by granulomatous inflammation. **B.** Higher magnification of **(A)** showing the appearance of the **hyphae**.

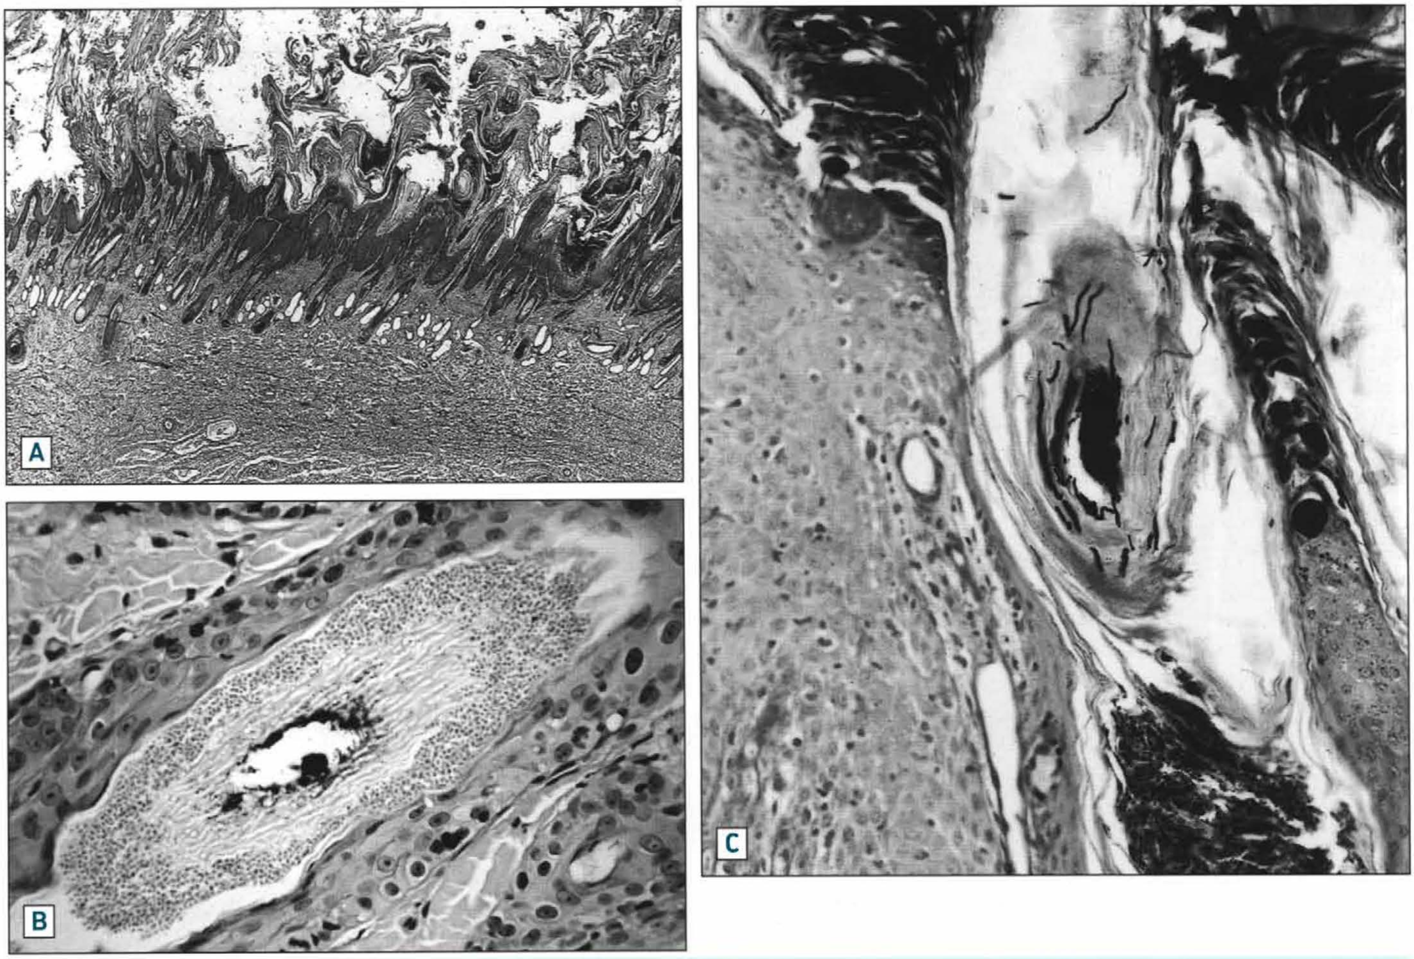

Figure 5.99 Dermatophytosis. A. Acanthosis and hyperkeratosis in a calf. **B.** Hair follicle heavily colonized by **fungal spores**, with minimal inflammation. **C. Filamentous organisms** in a follicle accompanied by leukocytes, in dermatophytosis in a calf; silver impregnation.

Kerions consist of diffuse pyogranulomatous inflammation in the deep dermis produced by extensive furunculosis. This form of inflammation is most commonly caused by poorly adapted organisms, such as the geophilic dermatophyte *M. gypseum*. Hair fragments containing hyphae and arthrospores are frequently present among the inflammatory cells but may be destroyed by the intense inflammatory reaction. *In some cases, the pattern of inflammation may be confused with autoimmune diseases.* Lymphocytic lichenoid interface dermatitis and subcorneal pustules containing neutrophils and acantholytic cells have been reported in several cases of dermatophytosis in dogs and horses; however, organisms were evident with fungal stains. The *dermatophyte pseudomycetoma* is characterized by masses of fungal elements surrounded by granulomatous or pyogranulomatous inflammation in the deep dermis and subcutis.

Cattle

Dermatophytosis is *common* in cattle and is most prevalent in calves. *T. verrucosum* is the most frequent isolate; others include *T. mentagrophytes, T. equinum, M. gypseum, M. nanum*, and *M. canis*. Outbreaks are associated with *crowding and confinement indoors during fall and winter.* Lesions occur on the *neck, head and ears, and pelvic area* most commonly. The intermaxillary space and dewlap are common sites for lesions in bulls. Lesions consist of *circular areas of alopecia with variable crusting or scaling*. In calves, the entire neck may become alopecic, crusty, thickened, and corrugated and lesions may be intensely pruritic. The disease may be of some economic significance because of damage to hides or restrictions on showing or marketing of infected animals. In very severe cases, loss of condition and decreased milk production or weight gain may result. A live attenuated vaccine for *T. verrucosum* has been effective in control of bovine dermatophytosis in Europe.

Sheep and goats

Dermatophytosis is *rare* in goats and sheep. *T. verrucosum* is the most common isolate. Lesions are usually on the *face, ears, neck, and limbs* in goats. In sheep, lesions are usually on the haired areas of the face and ears and may be intensely pruritic. *M. gypseum* infection in show lambs in the United States, called "*club lamb fungus*" by laypersons, involves wooled skin anywhere on the body but lesions are especially common on the lateral thorax. This condition is of zoonotic significance since, in approximately 50% of families with affected lambs, at least one family member had skin lesions consistent with ringworm. Outbreaks of *M. canis* dermatophytosis in sheep also involve the wooled parts of the body. In infections involving the fleece, lesions consist of circular areas of matted, discolored wool, several millimeters to up to 6 cm in diameter. Pruritus is variable.

Pigs

Dermatophytosis is *rare* in pigs. *M. nanum* is the most common isolate and infection produces little effect on the general health of the animal. *T. verrucosum* occurs in pigs housed in premises previously occupied by cattle. Infections also are also caused by *T. mentagrophytes, M. canis,* and *M. gypseum*. The lesions of *M. nanum* are especially common behind the ears and on the trunk, and consist of irregular dark patches with fine brown scales or crusts. No alopecia or pruritus occurs. Lesions may resolve spontaneously or spread slowly to involve extensive areas. An outbreak of dermatophytosis caused by *M. canis* in pigs was characterized by red alopecic patches of variable size on the backs and flanks. Pruritus was mild. The source of the infection was suspected to be rabbits, which had skin lesions clinically consistent with ringworm, or possibly from cats on the farm.

Horses

Dermatophytosis in the horse (*girth itch, tinea*) is caused by a variety of organisms but most commonly by *T. equinum*. Infections with *T. mentagrophytes* and *M. gypseum* are also common; *T. verrucosum* and *M. canis* infections are less frequent. Lesions occur most often in *areas in contact with the saddle and tack* when infection is spread by contaminated equipment or riders. In some cases, the caudal aspect of the pastern may be the only site affected and resemble "grease heel" or "scratches." Outbreaks of dermatophytosis caused by *M. gypseum* have been associated with periods of humid weather and a high incidence of mosquitoes and stable flies. In some training establishments, over 30% of the horses have ringworm and the causative agent is *M. gypseum*. The mane and tail areas are not usually affected. Initial lesions may be papular and resemble fly bites or urticaria but within several days they become the more typical scaly or crusty circular alopecic foci. The lesions of *M. gypseum* tend to be smaller than those of *T. equinum*. Pruritus varies from severe to absent. Lesions may continue to expand for one or two months and then regress as an immune response develops. Several horses with *T. equinum* dermatophytosis that resembled pemphigus foliaceus have been described. Two adult horses developed rapidly progressive painful widespread dermatitis consisting of papules, pustules, crusting, scaling, and erosions. Microscopically, lesions were characterized by prominent acantholysis. However, fungal arthrospores and hyphae were also evident and lesions resolved with antifungal therapy.

Dogs

M. canis is considered the most common cause of dermatophytosis in dogs; but in some areas, infections caused by *M. gypseum* predominate. *T. mentagrophytes* infection is less frequent. Infections with anthropophilic species *Epidermophyton floccosum* and *T. rubrum* have been reported and suspected to have been acquired from infected humans. Initial lesions are frequently on the face and forelegs. The lesions of dermatophytosis are grossly indistinguishable from demodicosis or pyoderma. Dogs with dermatophytosis frequently exhibit classic expanding annular patches of alopecia, scaling or crusting with an erythematous border. Scaling and crusting vary from mild to severe. Follicular papules and pustules are also common. Severe folliculitis and furunculosis may result in permanent alopecia and scarring. In some cases the lesions consist of generalized greasy scaling resembling seborrhea. Pruritus is usually absent but may be severe in some cases. Cases of dermatophytosis caused by *T. mentagrophytes, T. terrestre,* and *M. persicolor* with a very long duration (1–5 years) have been reported. These infections suggest that there is *little tendency for spontaneous resolution in some infections*, a situation analogous to chronic dermatophytosis in humans. Kerions are often associated with *M. gypseum* or *T. mentagrophytes* infections. Infection by *M. persicolor*, a rare zoophilic dermatophyte associated with voles, may produce lesions characterized by prominent scaling but minimal alopecia. This dermatophyte does not invade hair and thus fungal organisms are seen only in the surface keratin. *Onychomycosis is rare* and may consist of chronic inflammation of the ungual fold or infection of the claw alone, producing deformity or fragility of the claw. *Several cases of Trichophyton dermatophytosis with clinical and histologic features resembling pemphigus erythematosus have been reported.* These dogs had scaling, crusting facial dermatitis and alopecia. Microscopically, lesions included interface dermatitis accompanied by intraepidermal pustules with acantholytic cells, suggestive of an immune-mediated disease. However, fungal elements were demonstrable with fungal stains.

Cats

Dermatophytosis is a *common* disease in cats and infection may be endemic in large catteries, with up to 35% of cats being culture positive. The vast majority of cases (greater than 90%) are caused by *M. canis*, which is of considerable public health significance because of its zoonotic potential. Despite the name, this dermatophyte is well adapted to the cat and induces minimal host response. In some surveys, long-haired cats have a higher incidence of positive cultures than do short-haired cats. Geographic differences may influence the prevalence of various dermatophytes. A survey of dermatophytes isolated from cats in shelters in the United States found *M. canis* isolates to predominate in the southeastern United States; while in cats from the northern United States, anthropophilic organisms were cultured and *M. canis* was not isolated from any cat. An *M. canis* fungal cell wall vaccine developed for use in cats has been shown to induce both humoral and cell-mediated immune responses, but it does not appear to be protective against challenge exposure with a large number of fungal spores.

Lesions are extremely variable. They frequently begin on the face, ears, and forelegs and may become generalized. Pruritus is uncommon but may be moderate. Classical circular foci of alopecia and crusting or scaling are more common in kittens. In adult cats, lesions may be extremely subtle and consist of patchy mild alopecia or broken hairs with little skin change. Scaling and crusting may be absent or severe. Some cases appear as papulocrustous miliary dermatitis or as feline acne. Folliculitis with alopecia is uncommon. Microscopic findings are variable. In some cases, organisms are infrequent and only a single infected hair may be found in a biopsy, while in other cases organisms may be numerous. Pseudomycetomas are subcutaneous nodules that occur in Persian cats. They are an atypical form of dermatophytosis caused by *M. canis* in which the deep dermis and subcutis are involved. There is frequently also a history of previous or concurrent superficial dermatophyte infection. Lesions are usually focal and measure 2–3 cm in diameter; but in some instances, they are multiple and involve extensive areas. They consist of discrete masses of bizarre distorted septate fungal hyphae, larger thick-walled fungal cells resembling *chlamydospores*, and chains of round structures surrounded by a hyaline eosinophilic Splendore-Hoeppli reaction. These granules are surrounded by granulomatous or pyogranulomatous inflammation. Fungal organisms are not necessarily present in the hair and keratin of the overlying skin.

Subcutaneous fungal infections

The subcutaneous mycoses are a heterogeneous group of infections caused by a wide variety of fungi of low virulence that require mechanical introduction into tissue before they can cause disease. The organisms are common saprophytes that normally exist in soil, vegetation, or on normal skin and hair. Their ability to adapt to the tissue environment and elicit disease is variable. The clinical course is usually insidiously progressive over a period of months to years. Infection usually remains localized to the site of entry and surrounding tissues. Slow extension by way of lymphatics occurs in some diseases; but widespread dissemination is rare. Granulocytes are involved in control of many subcutaneous fungi, and granulocytopenia may render an individual more susceptible to subcutaneous mycoses.

Eumycotic mycetoma

Mycetomas are tumor-like infections of skin and subcutaneous tissues caused by two different types of organisms: actinomycetes (**actinomycotic mycetoma**) and fungi (**eumycotic mycetoma**). They are caused by a diverse group of organisms, many totally unrelated to each other, all of which elicit similar clinical disease. *Mycetomas are characterized clinically by the triad of tumefaction (swelling), draining tracts, and grains in the discharge.* Eumycotic mycetomas are those caused by fungi and they have been reported worldwide in humans, occasionally in dogs and horses, and rarely in cattle and cats. A wide variety of fungi that exist as saprophytes in the soil or on plants have been associated with mycetomas. The organisms involved may also cause other clinical diseases, e.g., phaeohyphomycosis and mycotic granulomas, when the three criteria are not present for a diagnosis of a mycetoma. Some cases reported in the veterinary literature as mycetomas are actually phaeohyphomycosis. Mycetomas usually involve skin and subcutaneous tissues and sometimes extend to involve underlying bone. *Curvularia* spp. and *Scedosporium apiospermum* (*Pseudallescheria boydii*) are most commonly involved in mycetomas in animals; *Cladophialophora bantiana* was identified as the cause of eumycetoma in one dog. These organisms are introduced by *wound contamination or implantation* by thorns and other plant material. Lesions often do not develop for many months after inoculation of the fungus. This long incubation period is thought to represent the time needed by the organism to adapt to the environment of the host tissues. All cases have become infected from sources in nature and thus *the condition is not contagious.*

Lesions in animals are widely distributed on the body but they frequently occur on the extremities and the face. In rare cases, subcutaneous lesions develop in dogs as extensions of abdominal infection. Disseminated infections have been reported rarely. Lesions are usually solitary and begin as small dermal or subcutaneous papules or nodules that enlarge gradually over a period of months to years. As the lesion slowly enlarges, deeper tissues such as muscle and bone may become involved. The reaction to the fungus is suppurative and inflammation is accompanied by prominent fibrosis that produces progressive swelling. Abscesses evolve into fistulas that emerge to the surface and give rise to the characteristic appearance of a mycetoma. The fistulas discharge serous, purulent, or hemorrhagic exudate containing grains. *The grains or granules are composed of aggregates of fungal organisms* and vary in size from 0.1 mm to several millimeters in size and may be white, yellow, pink-red, brown, or black. The color, size, shape, and texture of the grains may be sufficiently characteristic to suggest the etiologic agent, but *definitive identification of the fungus requires culture. Curvularia* spp. and *Madurella* spp. have been associated with black-grained mycetomas, while *P. boydii* is usually associated with white grains.

Microscopically, the lesions are similar regardless of the etiologic agent. *The salient histologic feature is the presence of granules in a tumor-like mass of chronically inflamed tissue.* Granules are spherical, lobular, or scroll-shaped masses of fungal hyphae that are 2–6 μm in diameter, septate, and branching. They are pigmented or nonpigmented. Chlamydospores are also frequently present, especially at the periphery of the mass. The fungal hyphae may be embedded in an amorphous eosinophilic "cement-like" substance. The granules of some mycetomas are surrounded by an amorphous eosinophilic radially arranged or smoothly contoured Splendore-Hoeppli reaction. The granules are located within abscesses composed of neutrophils and necrotic debris. *Fragments of plant material* may be seen within the lesion adjacent to the granules and are suspected to be the vehicle of infection. The abscesses vary in size and are present in the dermis and subcutis. Abscesses are surrounded by a chronic inflammatory reaction consisting of epithelioid macrophages, multinucleated giant cells, and fewer plasma cells and lymphocytes. Fibrous connective tissue of variable maturity separates the inflammatory foci. In some cases, *special stains may be needed to determine if the grains are composed of bacteria or fungi.* If the grains are hard, they may be displaced or removed altogether from the tissue because of drag on the microtome blade during sectioning. Multiple sections may be needed to find granules. The internal configuration of a granule may be suggestive of a specific fungus or group of fungi. Definitive identification of the organism can be made on tissue sections by immunofluorescence techniques but the specific antisera are not readily available and *culture is the usual means of identification.*

Phaeohyphomycosis

Phaeohyphomycosis is an uncommon opportunistic subcutaneous, cerebral, or systemic infection caused by a wide variety of fungi that are all characterized by formation of dematiaceous, or pigmented, hyphae in tissue. The pigmentation is due to the presence of melanin and results of experimental studies suggest that the pigment may act as a virulence factor in development of infection. The organisms responsible for these infections are worldwide in distribution and are widespread in the soil, on wood, and in vegetation. Some of the organisms can also be cultured from the skin of healthy people and animals. Subcutaneous infection is thought to result from wound contamination or traumatic implantation of wood slivers, thorns, sticks, and the like. The taxonomy of the organisms as well as their names and the diseases they cause have been changed frequently, causing confusion in the literature. The list of organisms identified as causative agents of phaeohyphomycosis is continually increasing. Some of the fungi that have been associated with phaeohyphomycosis in animals include *Alternaria alternata, Bipolaris* (Drechslera) *spicifera, Xylohypha bantiana (Torula bantiana, Cladosporium bantianum, Cladosporium trichoides), Curvularia geniculata, C. lunata, Exophiala jeanselmei, Ochroconis* (Dactylaria) spp., *Phialophora verrucosa*, and *Wangiella* spp.

Phaeohyphomycosis has been reported most frequently in *cats* and occasionally in *horses, dogs, cattle, and goats.* The disease also occurs in humans. Some of the cases reported in the veterinary literature as mycetomas, in which small groups of dematiaceous fungi are present within tissues but which do not otherwise fulfill the clinical criteria of mycetomas, are actually cases of phaeohyphomycosis. No underlying immune deficiency is apparent in most cases of subcutaneous phaeohyphomycosis; whereas disseminated infections have been associated with immunologic compromise or debilitating disease. Subcutaneous infection with *Staphylotrichum coccosporum*, a fungus previously thought to be nonpathogenic was described in a cat positive for *Feline leukemia virus*. Subcutaneous infection is insidiously progressive and evolves over months to years.

Lesions of pheohyphomycosis consist of *single or multiple subcutaneous nodules.* The *fungal pigmentation may be grossly visible in the tissue* and, in some cases, the nodule is so dark it may be mistaken for a melanoma. In *cats*, lesions are usually single and occur most commonly on the face and feet. Firm to fluctuant subcutaneous nodules grow slowly and may be ulcerated or have draining tracts. Multiple recurrences following surgical excision are common. The clinical course in some reported cases has been several years. Lesions in *horses* are frequently multiple and located on several different parts of the body. Occasionally nodules may be generalized. Multiple ulcerated cutaneous nodules are the usual form of the infection described in *cattle*, and lesions may also be present in the nasal mucosa. Lesions in *dogs* are also frequently multiple and may be extensive. They consist of poorly circumscribed ulcerated or fistulating nodules or plaques on the feet and legs. In one affected dog, lesions consisted of multiple nodules in the area of ascending lymphatics of a leg and an enlarged regional lymph node, a clinical appearance similar to the cutaneous-lymphatic form of sporotrichosis.

The histologic diagnosis of phaeohyphomycosis is made by demonstrating pigmented hyphae within the tissue. The lesions consist of multifocal-to-diffuse pyogranulomatous dermatitis and panniculitis. The overlying epidermis is acanthotic or multifocally to diffusely ulcerated. Microabscesses with foci of necrosis are frequently prominent. Necrosis may be extensive. Fungi are distributed throughout the lesion as scattered small aggregates and individual hyphae. *The hyphae are septate, 2–6 μm wide, and branched or unbranched.* They are often constricted at their prominent thick septations and may contain single or chains of thick-walled vesicular swellings, 25 μm or more in diameter, that resemble chlamydospores. *The innate brown pigment may not be readily apparent*, but at least some pale yellow-brown to black hyphae will be found in unstained (cleared and mounted) or HE-stained tissue sections.

If pigmentation is not readily apparent, a melanin stain , such as Fontana-Masson, has been suggested to confirm the presence of melanin in the hyphae. However, some nondematiaceous fungi have been found to be Fontana-Masson positive, calling into question the usefulness of the procedure. Fungal stains demonstrate the organisms well but can mask the natural color. The etiologic agents are so similar in appearance within tissues that they cannot be identified on the basis of their morphology. Culture is always needed for specific identification of the fungi. Phaeohyphomycosis has been confused with eumycotic mycetomas caused by dematiaceous fungi. *The fungi in mycetomas form discrete organized granules, whereas those of phaeohyphomycosis appear as individual hyphae and small aggregates scattered throughout the lesion.* The aggregates of hyphae in phaeohyphomycosis may be surrounded by Splendore-Hoeppli material but this does not constitute a granule. The fungal elements of pheohyphomycosis are frequently intracellular within epithelioid macrophages and multinucleated giant cells; granules of mycetomas are nearly always extracellular.

Sporotrichosis

Sporotrichosis is an uncommon chronic infection usually limited to skin and subcutaneous tissue caused by the opportunist fungal pathogen Sporothrix schenckii. The organism is a dimorphic fungus, growing as hyphae at environmental temperatures and in yeast form in tissue. *S. schenckii* exists as a saprophyte distributed worldwide in the soil, on plants, and on various plant materials. The organism is considered only weakly pathogenic and a great deal of variability occurs in virulence of strains isolated from soil. Disease is most common in temperate and tropical zones. Sporotrichosis has been reported in horses, mules, donkeys, cattle, goats, swine, dogs, cats, rats, mice, hamsters, domestic fowl, camels, dolphins, armadillos, chimpanzees, and humans. The infection has been *reported most often in horses, cats, and dogs*. Infection is usually acquired by wound contamination or inoculation of the organism into tissue by puncture wounds caused by thorns, wood splinters, or contaminated claws. Pulmonary infection is acquired by inhalation of spores. In humans, the disease is considered an occupational hazard for those who work with the soil, plants, or plant materials.

Sporotrichosis is subdivided into *three clinical forms*.

- The **primary cutaneous form** consists of multiple scattered raised alopecic, ulcerated, crusted nodules or plaques that remain confined to the point(s) of entry of the organism. It is thought that this form results from a *high degree of host immunity*, preventing spread of infection. Nodules may become ulcerated and associated with seropurulent exudate and crust formation. The normal grooming behavior of cats may result in autoinoculation and spread of lesions to distant sites. The cutaneous form may have a very chronic course. An unusual case of sporotrichosis in a dog consisted of otitis externa characterized by multiple cutaneous nodules which persisted for more than 5 years. A donkey with sporotrichosis had multiple slowly progressive facial lesions for 2 years before the disease was diagnosed.
- The **cutaneous-lymphatic form** involves the skin, subcutaneous tissue, and associated lymphatics. Lesions begin as firm round nodules at the site of entry, usually on an extremity, and spread proximally along lymphatics. Lymphatic vessels become thick and corded and a series of secondary nodules forms as the infection progresses. The nodules may break open and discharge seropurulent material. Lesions may cavitate and expose extensive areas of underlying muscle and bone. Regional lymphadenopathy is common. This is the most common form in *horses*. Lesions generally involve the proximal forelimbs, chest, and thigh but usually no regional lymph node involvement is evident. *Dogs* usually have the cutaneous or cutaneous-lymphatic form. The head, pinnae, and trunk are involved most frequently. In *cats*, lesions are usually located on the head, distal limbs, and base of the tail. The initial draining puncture wounds may be indistinguishable from cat-inflicted fight wound infections.
- The **extracutaneous/disseminated form** may involve a single extracutaneous tissue, such as osteoarticular sporotrichosis, or multiple internal organs. It develops as a sequela to cutaneous-lymphatic infection or following inhalation of the fungus. The disseminated form of sporotrichosis *occurs most frequently in cats*, and no immunosuppressive factors are usually identified. In experimentally induced sporotrichosis in cats, organisms were shown by culture to have disseminated to viscera in 50% of the cases. Cats with disseminated sporotrichosis are often febrile, depressed, and anorexic.

Microscopically, sporotrichosis is usually a *nodular to diffuse pyogranulomatous or granulomatous inflammatory reaction involving the dermis and subcutaneous fat*. The epidermis is acanthotic or ulcerated. Neutrophils, epithelioid macrophages, multinucleated giant cells, and fewer lymphocytes and plasma cells form discrete granulomas or extensive sheets of inflammation replacing dermal and subcutaneous tissues. Fibrosis is variable; and necrosis may be extensive. *Yeast(s) surrounded by a stellate radial corona of brightly eosinophilic material (asteroid body/Splendore-Hoeppli reaction) are seen in some cases.* The yeasts appear as round, oval, or elongated ("cigar"-shaped) single or budding cells which measure 2–6 μm or more in diameter for the round and oval forms and 2 × 3 to 3 × 10 μm for the cigar form

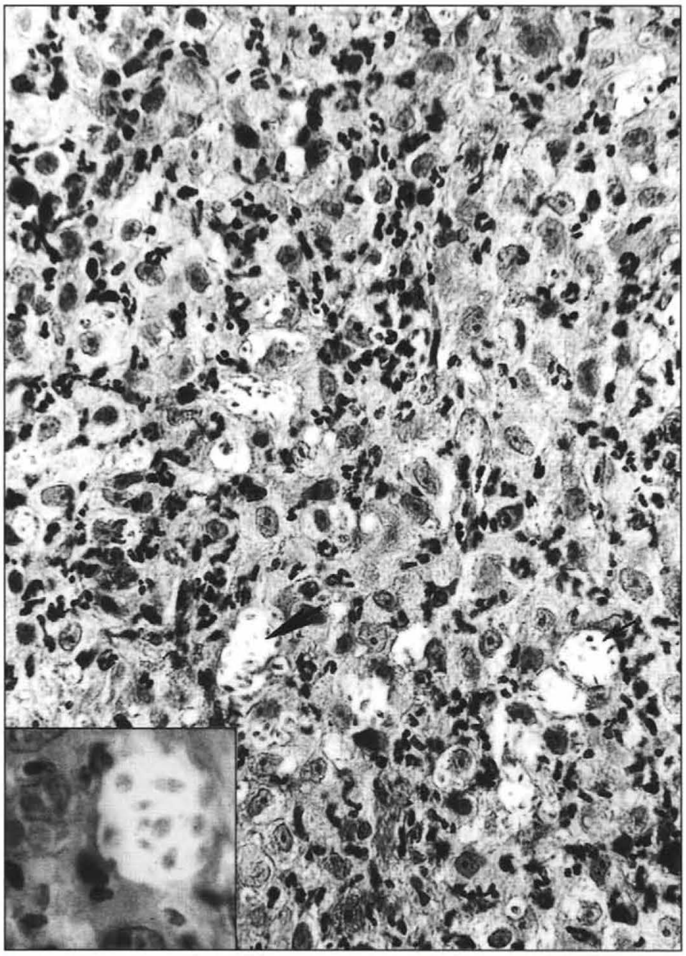

Figure 5.100 Pyogranulomatous inflammation with organisms in vacuoles (see inset) in **sporotrichosis**.

(Fig. 5.100). The cigar forms are considered characteristic of *Sporothrix* but they may not be found regularly. *In general, organisms are numerous in lesions from cats and rare in tissues from dogs and horses.* However, in immunosuppressed dogs, yeasts may be numerous. The yeasts may be extracellular or within neutrophils and macrophages. The yeasts have a refractile cell wall from which the cytoplasm may shrink during processing and give the appearance of a capsule. In such instances and when no cigar forms are evident, the organism may be mistaken for *Cryptococcus neoformans* or *Histoplasma capsulatum*. Yeasts stand out clearly with fungal stains, but serial sections may be needed to demonstrate even a single organism. Without a significant number of cigar-shaped forms, identification may not be possible. In these cases, *immunoperoxidase or fluorescent antibody staining* using specific *S. schenckii* antiserum is necessary for definitive identification of the organism. Organisms may not be found despite the use of serial sections and special stains, and diagnosis in such cases requires culture. The yeast can usually be cultured from tissue obtained from areas of active inflammation even in dogs and horses, which typically have very few organisms in tissue. In cats, cytologic examination of exudates and material obtained by fine needle aspiration of nodules is frequently diagnostic because sufficient numbers of yeasts are usually present to identify the organism.

Sporotrichosis is considered a zoonotic disease. Transmission of the infection from cats to humans has been reported many times and *infected cats pose a significant public health danger.* Veterinarians, other veterinary professionals and students, and owners exposed to ulcerated wounds or exudates from infected cats have developed infections. The organism may be able to penetrate intact skin since not all patients who develop lesions can recall having wounds or being bitten or scratched by infected cats. The large number of organisms typically present in lesions from cats is thought to be the reason for the transmission of disease from cats to humans. However, even when the lesions in cats had few organisms, transmission to humans has occurred. In contrast, infection was not transmitted from a dog with multiple cutaneous lesions containing relatively numerous organisms to several adults and children with whom the dog had had frequent contact for the 2 year duration of infection. These cases suggest that factors in addition to absolute numbers of yeasts are involved in the apparent ease of cat-to-human transmission.

Cutaneous oomycosis (pythiosis and lagenidiosis)

Oomycosis refers to infection by *Pythium insidiosum* (formerly *Hyphomyces destruens*) or *Lagenidium* sp. organisms, both of which are aquatic dimorphic water molds and members of the Oomycetes in the kingdom Protista. These opportunistic pathogens live in warm stagnant water and are most often reported in regions with tropical to subtropical environments. The organisms are thought to enter the skin through cutaneous wounds, and infection may involve the dermis, subcutis or distant tissue as described below.

Pythiosis (leeches, swamp cancer, bursattee, phycomycosis) is *a chronic cutaneous-subcutaneous, gastrointestinal, or multisystemic granulomatous infection of horses, dogs, cattle, cats, and humans living in tropical, subtropical, and temperate regions* throughout the world. *Pythium* spp. occur in the soil and aquatic environments worldwide, and some are important plant pathogens. *P. insidiosum* is unique in that it has adapted to colonize mammalian tissues. The organisms require warm weather and moisture for reproduction and thus the majority of cases occur in late summer and fall in tropical and subtropical areas. Water lilies, grasses, and debris of plants found in aquatic or humid habitats appear to support the propagation of *Pythium* spp. The infective stage of the organism is a biflagellate aquatic zoospore that is released seasonally in association with warm weather and moisture. Infection is thought to be acquired from prolonged contact with stagnant fresh water containing the newly emerged zoospores that are motile and are attracted chemotactically to injured tissue. The zoospores produce a substance that enables them to attach to host tissues during initial stages of infection and they appear to play an important role in producing infection. However, the zoospore stage is not known to form in tissue and the infection is thus not considered to have zoonotic potential.

Not all animals with pythiosis have a history of contact with permanent bodies of water, suggesting that the organism may proliferate in temporary stands of water or even on wet grasses.

Cutaneous pythiosis has been reported most frequently in **horses**. No age, breed, or sex predilection is recognized. Lesions occur most commonly on the *limbs, distal to the carpus and hock*, and on the ventral aspect of the thorax and abdomen, sites that are most likely to be in contact with stagnant water and would be traumatized by aquatic plants or vegetation (Fig. 5.101A). Affected horses frequently have a history of prolonged contact with water in lakes, ponds, swamps, or flooded areas. Lesions are usually single but occasional horses develop lesions in several separate sites. Lesions begin as nodules that enlarge very rapidly to become circular masses of granulation tissue. The masses ulcerate or develop multiple fistulous tracts that drain thick purulohemorrhagic material. The sinuses also contain characteristic gray-white to pale yellow coral-like concretions (called *leeches* or *kunkers*) that may be extruded at the skin surface (Fig. 5.101B). The colloquial name leeches is based on the initial misidentification of the masses. *These structures are unique to the horse* and are not seen in other animals with pythiosis. Lesions are frequently extremely pruritic, and biting or rubbing the lesion contributes to tissue damage. The largest lesions usually develop on the thorax and abdomen and may attain a size of 45 cm or more in diameter. In chronic cases, underlying bone may be invaded. Regional lymph nodes may be involved but visceral spread is rare. *The clinical appearance of the lesions may resemble basidiobolomycosis, cutaneous habronemiasis, excessive granulation tissue, and neoplasia (particularly sarcoid and squamous cell carcinoma).*

Cutaneous pythiosis has been reported less frequently in **dogs** than has the gastrointestinal form. The disease occurs most often in young adult, large breed dogs, and German Shepherd Dogs may be predisposed. The disease in dogs is relentlessly progressive with no proven medical treatment. Most lesions are on the extremities but they may also occur on the face, ventral abdomen and chest, and in the perineal area. In most cases, a single body region is involved. *The initial lesion is a poorly circumscribed dermal nodule that rapidly expands peripherally and extends into the subcutis to form multiple secondary nodules* (Fig. 5.101C). The nodules develop into spongy masses that ulcerate, become necrotic, and develop multiple fistulous tracts that drain purulohemorrhagic exudate. Early lesions on the legs may resemble acral lick granulomas. Pruritus is not as constant a feature in dogs as it is in horses with pythiosis. A common clinicopathologic abnormality is absolute eosinophilia.

Pythiosis has been reported infrequently in **cattle**. Most cases have been in beef calves <12 months of age. Calves of both sexes have been affected. The majority of the lesions are located on the distal extremities. They consist of irregular swellings with ulceration and multiple draining tracts. Although no concretions have been present, the tissue contains numerous yellow punctate foci. Reports of pythiosis in **cats** are rare. As in other species, lesions usually are located on the extremities. In at least two cats, the lesions progressed very slowly and the clinical course was much more protracted than is typical of the disease in dogs and horses. Moreover, nodules remained confined to the subcutaneous tissues and there was no involvement of the overlying skin.

Microscopically, the lesions consist of *granulomatous inflammation with foci of liquefactive necrosis and extensive fibrosis* involving the dermis and subcutis. The epidermis is acanthotic or focally to diffusely ulcerated. The necrotic foci consist of eosinophilic coagula containing necrotic eosinophils and sometimes degenerate collagen and small necrotic blood vessels. Necrotic foci are most expansive in lesions from horses and they correspond to the concretions seen grossly (Fig. 5.101D). The necrotic material is surrounded by viable eosinophils, epithelioid macrophages, and occasional multinucleated giant cells. The organism is located in the necrotic foci but it does not stain with H&E. However, the presence of hyphae may be detected by occasional clear, unstained circular or linear spaces within the necrotic debris. Pythium stains poorly or not at all with PAS, but it is readily stained with GMS and appears as *thick-walled, sparsely septate hyphae, 4–10 μm in diameter, with occasional branching* (Fig. 5.101E). Organisms are usually most numerous in necrotic foci and may also be seen in walls of small arterioles. They are rare in areas of granulomatous inflammation and they are not usually present in intervening connective tissue. The hyphae are similar to those of the zygomycetes *Basidiobolus* and *Conidiobolus*. The hyphae of these organisms tend to be broader, ranging from 5–15 μm in diameter, however the differentiation of *Pythium* sp. from the zygomycetes in tissue is frequently impossible.

Diagnosis of pythiosis is based on the appearance of the gross lesions, microscopic lesions, and culture of the organism. Pythium is readily cultured in most instances; but in some cases, it cannot be grown. Failure to culture the organism may be related to sample handling because refrigeration decreases its survival and freezing kills the organism. Definitive identification of the oomycete, however, requires that the cultured organism be induced to produce the diagnostic zoospores, a process that is complicated, time-consuming, and not always successful. Because of the rapidly progressive course of the disease in many animals, a more rapid means of diagnosis is preferable so that an accurate prognosis may be made and specific therapy instituted. To this end, PCR assays, immunohistochemistry, and immunoblot analyses have been developed for identification and differentiation of *Pythium insidiosum, Lagenidium* and the zygomycetes. Not all assays are available for each organism, but a combination of assays and evaluation of the clinical information and laboratory results can lead to a definitive diagnosis.

Cutaneous lagenidiosis is remarkably similar to cutaneous pythiosis in geographic occurrence and clinical and histologic lesions. Lagenidiosis has been reported only in dogs. Gross lesions consist of nodular and necrotizing lesions of the limbs and trunk that drain and may be accompanied by lymphadenitis. The disease is also very aggressive, and affected dogs frequently develop lesions of the great vessels, mediastinum, lungs, and esophagus. *Histologic lesions are indistinguishable from those of pythiosis and zygomycosis.* Again, clinical presentation, PCR assays, immunohistochemistry and immunoblot analyses are needed to differentiate these infections.

Zygomycosis

Zygomycosis refers to subcutaneous, systemic, or rhinocerebral infections caused by a wide variety of zygomycete fungi. The unifying diagnostic feature of zygomycosis is that the organisms all form infrequently septate hyphae that are typically significantly broader than other fungi with filamentous tissue forms, such as *Aspergillus* or the agents of phaeohyphomycosis. The hyphae are unpigmented and commonly range from 6–25 μm in diameter. The class Zygomycetes is composed of two orders. The order Mucorales includes *Rhizopus, Mucor, Absidia, Mortierella, Rhizomucor*, among other genera; and diseases caused by these organisms have been called **mucormycosis**. The order Entomophthorales contains the genera *Basidiobolus* and *Conidiobolus* and disease caused by these fungi is called **entomophthoromycosis**. The term phycomycosis was used when zygomycetes and oomycetes, such as *Pythium* spp., were grouped together in a single division. However, as the oomycetes have been determined not to be true fungi and their taxonomy has been reclassified, the term has become obsolete because the taxonomic equivalent no longer exists. The diseases should be referred to as zygomycosis or pythiosis. Zygomycetes are cosmopolitan in distribution and they are widespread in nature. They all occur as soil saprophytes, agents of decay, insect pathogens, or as components of normal skin and hair flora. They are common laboratory contaminants and are thus sometimes ignored when cultured from clinical specimens. The portal of entry may be cutaneous, gastrointestinal, or respiratory. Zygomycosis is not a contagious disease, the environment being the source of all infections.

Zygomycosis is a *rare disease of humans and animals*, including dogs, cats, horses, llamas, sheep, and pigs. The disease in humans usually occurs in debilitated or immunocompromised individuals. In animals, however, immune compromise is usually not evident and disease may be the result of exposure to a large number of organisms. *Traumatic implantation* is thought to be the portal of entry for the subcutaneous form. Inoculation by biting insects has also been suspected to be a means of entry for the organisms. Members of the order Mucorales usually cause disseminated disease, and *angioinvasion by hyphae is a characteristic feature*. Zygomycosis in dogs and cats is usually in the form of *fatal gastrointestinal mucormycosis*. Zygomycosis caused by *Rhizopus oryzae* has been reported in pigs in which the disease consisted of subcutaneous granulomas with draining tracts as well as lesions in the stomach, liver, and lymph nodes. *In general, fungi of the order Entomophthorales cause localized subcutaneous granulomas.* These infections occur most often in tropical and subtropical regions. The fungus *Conidiobolus* is distinguished by its predilection for the nasal mucosa, nares, and surrounding skin. Infections by various species of this organism have been reported in dogs, horses, llamas, and sheep.

Zygomycosis occurs most frequently in **horses** and infections are usually caused by *Basidiobolus haptosporus* (basidiobolomycosis) and *Conidiobolus coronatus* (conidiobolomycosis). The lesions consist of circular ulcerated nodules or swellings with serosanguineous exudate. Small irregular gritty masses of yellow-white material (kunkers, leeches) may be discharged to the surface along with the exudate. Basidiobolomycosis usually involves the chest, trunk, head, or neck. Solitary lesions are the rule and they may grow rapidly and become very large. Pruritus is a common feature. *A discontinuous undulating band of yellow-white material that sharply demarcates the superficial hemorrhagic, edematous tissue from the underlying fibrogranulation tissue characterizes the cut surface of granulomas.* The clinical lesions are similar to those of pythiosis but may sometimes be differentiated in the horse by differences in anatomic location, number and appearance of kunkers, and epidemiology. The granulomas of zygomycosis usually affect the lateral aspects of the trunk, neck, and head, and the kunkers are less numerous, smaller, and of no particular shape. In contrast, lesions of pythiosis are commonly located on the lower limbs and contain numerous, large, coral-shaped kunkers. Furthermore, pythiosis is typically associated with access to standing water. *No such association with water exists for basidiobolomycosis or conidiobolomycosis*, which are caused by agents found in soil and decaying vegetation.

Unlike the protracted clinical course typical of most cases of zygomycosis, nasal zygomycosis in **sheep** caused by *C. incongruus* results in loss of condition and death within a period of 7–10 days after initial clinical signs. This infection produces prominent asymmetrical swelling of the face, extending from the nostrils to the eyes, and marked thickening of the skin and subcutaneous tissue. In advanced cases, the nasal skin is alopecic and necrotic.

Subcutaneous zygomycosis caused by *Conidiobolus* of unknown species has been reported in a young adult **dog**. Lesions involved the skin of a hind leg and the thoracic wall but not the nasal mucosa or skin surrounding the nose. The lesions on the leg began as an ulcerated mass that progressed to circumferential swelling and induration with numerous coalescing ulcers draining serosanguineous fluid. The condition exhibited some waxing and waning, but new lesions continued to develop. No immunologic compromise or predisposing factors were apparent.

Microscopically, zygomycosis is characterized by *multifocal-to-diffuse eosinophilic and granulomatous dermatitis and panniculitis with multifocal necrosis*. Necrotic foci consist of eosinophilic coagulated material corresponding to the kunkers seen grossly. Eosinophils, neutrophils, epithelioid macrophages, and multinucleated giant cells surround the eosinophilic coagula and are separated by fibrovascular connective tissue. Fungi are usually located in necrotic foci and may be seen as clear linear or circular hyphal "ghosts" often surrounded by Splendore-Hoeppli material (Fig. 5.102). Basophilic granular protoplasm may be visible with H&E stain, but the organisms are usually better visualized with GMS stain. They frequently stain poorly with PAS. The hyphae range from 5–20.5 μm diameter for *B. haptosporus* and 5–12.8 μm for *C. coronatus*. Hyphae are thin-walled, vary moderately in diameter, and have occasional septations and uncommon branching. Folded, twisted, or compressed hyphae may be seen. The lesions of nasal zygomycosis caused by *C. incongruus* in sheep are characterized by segmental necrosis and thrombosis of subcutaneous blood vessels. Many fungal hyphae are visible in necrotic foci, in thrombi, and within vessel walls. This propensity to invade blood vessels is common with Mucorales but is an unusual feature for the Entomophthorales.

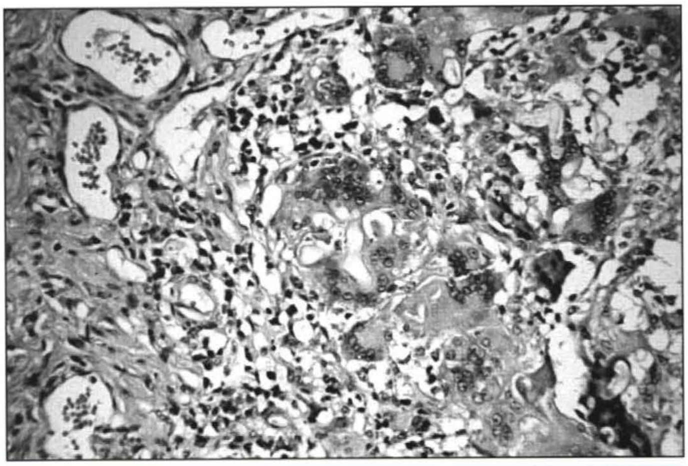

Figure 5.102 Zygomycosis. *Conidiobolus* sp. dermatitis in a dog. Note clear linear and circular hyphal "ghosts" amid granulomatous inflammation.

The microscopic lesions of basidiobolomycosis and conidiobolomycosis are similar to those of pythiosis and the diseases may be histologically indistinguishable, especially when the width of hyphae is at the narrow end of the range. All members of the zygomycetes are morphologically similar in tissue, and consequently culture is necessary for specific identification. Although immunohistochemical identification of fungi in tissue sections has been reported, the specific antisera are not readily available and culture remains the usual means of identification.

Miscellaneous fungal infections of skin

Infections with various opportunist fungi are reported sporadically in animals. These organisms are ubiquitous in the environment, common contaminants of laboratory cultures, and frequently also a component of skin and hair flora of normal animals. Thus, *diagnosis of infection is difficult to make by culture alone and requires histologic demonstration of tissue invasion by morphologically compatible organisms.* In humans, these infections are usually associated with immunosuppression and neutropenia, but predisposing factors are not usually identified in animals. A convenient means of classifying opportunistic subcutaneous mycotic infections is based on the presence or absence of pigment in mycelia. Those caused by *pigmented ("phaeoid") fungi are called phaeohyphomycosis* and have already been discussed. *Infections caused by colorless or hyaline fungi are called* hyalohyphomycosis. Organisms that cause infection with some regularity or have some particularly distinctive feature are assigned to a separate category, e.g., aspergillosis, pythiosis, etc. Reports of infection with dematiaceous fungi and the number of fungi causing phaeohyphomycosis are more numerous than those caused by unpigmented fungi. The system is artificial in that completely unrelated organisms fall into the same category. However, most of these organisms have similar tissue morphology and elicit the same pathologic response, i.e., (pyo)granulomatous dermatitis and panniculitis. Culture or immunofluorescence or immunohistochemical staining of tissue sections is necessary for specific identification of these organisms.

Cutaneous **hyalohyphomycosis** caused by *Acremonium* and *Fusarium* has been described in dogs and cats. *Aspergillus* species are not commonly associated with skin infections. Subcutaneous infection with *Aspergillus versicolor* producing a nodular mass on the upper lip was reported in an adult Saddlebred mare. The lesion recurred once following surgical excision but had not recurred one year after the second surgical excision. *A. terreus* has been associated with subcutaneous granulomas in an adult Holstein cow without any lesions elsewhere. Dogs with disseminated aspergillosis may rarely develop cutaneous lesions secondarily.

Geotrichosis is a *rare* disseminated, bronchopulmonary, oral, vaginal, cutaneous, or alimentary infection caused by *Geotrichum candidum*. Cutaneous infections have been reported in dogs, snakes, humans, flamingos, horses, and a giant tortoise. *G. candidum* is a ubiquitous soil saprophyte and is also part of normal flora of the oral cavity, intestine, skin and hair. Lesions were on the head and back in dogs and on the head and neck in horses. Gross lesions varied from well-circumscribed ulcers covered by exudate to nonulcerated nodular masses with variable alopecia and desquamation. Infection appeared to be pruritic in several affected horses. Geotrichosis has also been associated with paronychia and onychodystrophy in several dogs. Microscopically, branching septate hyphae were present in the surface keratin and exudate, necrotic epidermis, and extended into the dermis. The organism may be confused histologically with *Candida, Aspergillus*, and *Trichosporon*.

Paecilomycosis is a *rare* subcutaneous or disseminated infection of cats and dogs caused by *Paecilomyces* fungi. The organism is a common airborne contaminant that may be resistant to many sterilizing techniques. Skin lesions typically consist of focal masses or edematous swellings, frequently on the feet and legs. Lesions have also been described on the face and nasal cavity. One disseminated infection in a young adult German Shepherd was thought to originate from an external ear infection.

Trichosporon yeasts cause white piedra, cutaneous infections, systemic infections, pneumonitis, valvular endocarditis, and have been associated with abortions. In humans, disseminated systemic infections usually occur in immunocompromised patients with granulocytopenia. White piedra is a mycotic infection of hair shafts caused by *T. beigellii* (*T. cutaneum*) in humans, monkeys, and horses in temperate to tropical climates. The infection is characterized by *firm, irregular white or pale brown nodules on hair shafts*. In horses, the long hairs of the mane, tail, and forelock are affected. *The nodules consist of tightly packed septate hyphae that are held together by a cement-like substance.* Cutaneous trichosporonosis is *rare* and has been reported only in cats. One cat also had multicentric lymphosarcoma that may have caused immunosuppression. Lesions reported in cats consisted of a nodule in a nostril and an ulcerated mass on the distal leg at the site of a previous cat bite wound. Microscopically, the organisms consist of budding yeast cells and hyaline, branched septate hyphae.

PROTOZOAL DISEASES OF SKIN

Cutaneous lesions occur in several **systemic or localized protozoal** infections. Differentials for protozoal dermatitis should include *Besnoitia* sp., *Leishmania* sp., *Caryospora* sp., *Neospora* sp., *Toxoplasma* sp., and *Sarcocystis* sp. The majority of these cutaneous protozoal infections have been reported in **dogs**, however some cause serious disease in other domestic species as described below. *Toxoplasma* sp. is considered an opportunistic pathogen most often seen in dogs concurrently infected with canine distemper virus. Cutaneous infection with toxoplasma organisms has not been reported, however the morphological similarities to other protozoal organisms reported to cause dermatitis in animals warrant considering it in the differential of protozoal dermatitis. Cytologic, histologic, immunohistologic and ultrastructural studies can be used to differentiate organisms that are histologically similar. Cutaneous lesions have also been associated with *Theileria* and *Babesia* infections (see Vol. 3, Hematopoietic system). *Trypanosoma equiperdum* and dourine are discussed in Vol. 3, Female genital system.

Besnoitiosis

Members of the genus *Besnoitia* are responsible for a serious disease of *cattle and horses* and, more rarely, donkeys, goats, and sheep. In North America, opossums, caribou, reindeer, and mule deer may serve as intermediate hosts. The genus is currently classified under the family Sarcocystidae, in the subfamily Toxoplasmatinae.

Besnoitia have a *two-host life cycle*. The *definitive hosts are felids* and the intermediate hosts vary with the parasitic species. For *B. besnoiti*, the intermediate host is the ox and for *B. bennetti* it is the horse. These two organisms are morphologically identical by light microscopy and are distinguished only by their host range. Sexual reproduction occurs in the intestinal tract of the definitive host and the sporulated oocysts are passed in the feces. *The exact mode of infection of the intermediate hosts is not known*, but contamination of watering places and mechanical transmission by blood sucking insects may be involved. The life cycle in the intermediate host is characterized by release of sporozoites from sporulated oocysts and the subsequent dissemination of tachyzoites that lead to bradyzoite cyst formation. Cysts occur mostly in the dermis, subcutis, fascia, muscle, mucosa of the upper respiratory tract, pharynx, and conjunctiva. Infection, however, may be generalized and is typically so in some infections in rodents and wild animals. *The tissue cysts represent parasitized host cells* – the fibroblast in *B. wallacei* infection of rodents and the histiocyte in *B. besnoiti* experimental infection of rabbits. The bradyzoites multiply in cellular vacuoles and induce hyperplastic and hypertrophic changes in the host cells. These often divide to form multinucleated cells. The enlarging mass of crescent-shaped bradyzoites compresses the cell cytoplasm and nuclei into a thin rim forming an inner coat to the cyst. A hyalinized collagenous cyst wall is laid down around the parasitized cell. The cysts, which measure up to 500 μm with a 10–30 μm thick wall, are visible to the naked eye. Ingesting parasitized tissue from the intermediate host infects the definitive host.

Bovine besnoitiosis is a serious disease in South Africa and is associated with severe loss of condition in affected cattle, mortality up to 10% and marked damage to the hide. The disease also occurs in central and northern Africa, southern Europe, Asia, South America, and Russia. After an incubation period of ~1 week, a *pyrexic phase* develops in which animals become anorexic, depressed and reluctant to move. Approximately 1–4 weeks after the onset of the pyrexic phase and corresponding with cutaneous cyst formation, generalized lymphadenopathy, edematous swellings of the extremities and severe systemic signs develop. Pregnant cows may abort at this time. The second stage is known as the *depilatory stage* since it is characterized by marked alopecia, thickening of the skin, exudation and fissuring. *The cysts may be visible macroscopically in the scleral conjunctiva or nasal mucosa as small, round, white foci*. Animals lose condition and up to 10% mortality may occur at this point. The third phase is characterized by *dry seborrhea*. Animals remain unthrifty for an extended period and rarely regrow a normal hair coat. The skin remains alopecic, lichenified and scaly.

Histologically, epidermal hyperplasia, marked hyperemia, dermal edema and perivascular accumulations of lymphocytes, plasma cells and large histiocytes that will become hosts to the parasites accompany the acute febrile stage. *Crescent-shaped trophozoites occur in arterioles and lymphatics and free in tissue spaces*. Occasionally they may be detected in macrophages. As the parasites become encysted, inflammation and edema diminish. *The mature cysts incite little or no cellular reaction unless they rupture*; a necrotizing or granulomatous response ensues around the collapsed hyaline capsule. Numerous eosinophils are present in these reactions. The mature cyst wall has *four distinct layers*. Outermost is a condensed, hyalinized, laminated, birefringent layer of collagen fibers. Next is a very thin homogeneous intermediate zone. The third layer is the cytoplasm of the host cell and in this layer lie the several giant, vesicular but compressed host cell nuclei. A thin inner membrane, probably condensed cell cytoplasm, encloses the dense mass of 5–7 μm crescentic bradyzoites. These may be separated from the wall by an artifactual shrinkage space. *Lesions in other tissues* include focal disseminated myositis, keratitis, periostitis, endosteitis, lymphadenitis, pneumonia, periorchitis, orchitis, epididymitis, arteritis, and perineuritis.

Besnoitiosis in **horses, donkeys**, and **burros** has cutaneous lesions similar to those described in cattle. **Caprine** besnoitiosis occurs in Iran in both wild and domestic species. The *Besnoitia* cysts are observed in the skin, blood vessels, epididymis and testes. The pathological changes are comparable to those of *B. besnoiti* infection in cattle. In an outbreak affecting more than 500 domestic goats in Kenya, ocular cysts were the most common finding, but cysts were found in many body systems. Dorper **sheep** were also affected in that outbreak. A disease resembling besnoitiosis was reported in New Zealand lambs.

Leishmaniasis

Members of the genus *Leishmania* are responsible for systemic disease in man, dogs, cats, horses, and other mammals. Members of the *L. donovani* complex cause most infections. This intracellular parasite of the mononuclear-phagocytic system is *transmitted to animals and man by blood sucking sandflies*. The parasite's life cycle and manifestations of visceral disease are discussed in Vol. 3, Hematopoietic system. This zoonotic disease is endemic in Mediterranean countries and in parts of Africa, India, and Central and South America. Past reports of the disease in North America primarily involved animals with a history of foreign travel, however endemic foci of leishmaniasis now exist in Texas, Oklahoma, and Ohio. Recent reports indicate cases of canine visceral leishmaniasis have been confirmed in 21 of the United States and in southern Canada. The geographic distribution of the disease can be expected to continue to rise with the advent of increased international travel and the existence of immunosuppressive viral infections and therapeutics.

Studies in mice and dogs indicate that resistance to infection is dependent upon a Th1-type of immune response, while susceptibility is associated with a Th2-type of immune response. The alopecic form of the cutaneous disease as described below in the dog has been shown to be associated with fewer organisms and a more appropriate cellular immune response in terms of number of antigen-presenting Langerhans cells, MHCII-positive keratinocytes and infiltrating T cells. In contrast, dogs with the nodular form lacked antigen-presenting cells and had more numerous macrophages containing large numbers of organisms. It has been suggested that the clinical and histologic lesions may be useful in establishing a prognosis for remission in that the character of the lesions that develops reflects epidermal immunocompetence. Leishmaniasis is often associated with concurrent dermatoses such as opportunistic infections, parasitism, autoimmune disease, or neoplasia. This association and documented peripheral blood lymphocyte subset abnormalities *suggest that leishmaniasis may induce immune dysfunction. Cytology, immunohistochemistry, PCR, and serologic testing can help confirm diagnosis of the disease.* Currently, there is no cure for canine leishmaniasis, however, remission is possible.

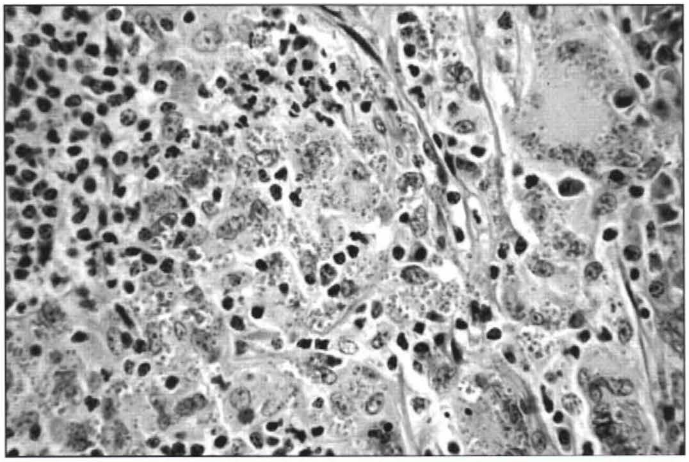

Figure 5.103 Leishmaniasis in a horse. Granulomatous inflammation. Macrophages and many multinucleate giant cells contain multiple *Leishmania* amastigotes.

The *skin* is one of the main organs affected in systemic leishmaniasis in **dogs**. Gross and histologic lesions are highly variable depending on host response and concurrent disease. Gross lesions may be alopecic, ulcerative, nodular or pustular. Onychogryposis and paronychia have also been reported. Alopecia with dry scaling on the head or entire body and multiple areas of ulceration of the skin of the head and limbs are seen most frequently. Initial lesions of alopecia are often periocular and referred to as *"lunettes."* Nonpainful, nonpruritic, variably ulcerated nodules varying from <1.0 cm to several cm in size may also be present but are less common. Nodules are most common on the ears, eyelids, and face but can be anywhere on the body. *Nodular mucosal leishmaniasis* affecting the oral cavity, tongue, nose, and penis has been reported in the dog. Unusual cases of leishmaniasis may present as a *generalized subcorneal pustular dermatitis*. Histologically, *the more common lesions consist of hyperkeratotic, nodular to diffuse superficial and deep, granulomatous dermatitis* (Fig. 5.103). Foci of inflammation may be perivascular, perifollicular, or interstitial in orientation. Perifollicular lesions frequently replace sebaceous glands. Some animals have infiltrates consisting primarily of large, foamy macrophages with numerous organisms and fewer plasma cells and lymphocytes while other animals have larger numbers of lymphocytes and plasma cells, indicating a more effective cellular immune response. Multinucleated giant cells may be present. The infiltrate in areas of ulceration includes neutrophils. *Leishmania* amastigotes are most commonly identified within macrophages, however they can occasionally be found within other leukocytes, endothelial cells or fibroblasts. In areas of necrosis, amastigotes may be free within the interstitium.

Clinical differentials for the skin lesions are numerous and vary with the types of lesions and include sarcoptic and demodectic mange, seborrhea, pemphigus foliaceus, systemic lupus erythematosus, bacterial infections, and superficial necrolytic dermatitis and zinc-responsive dermatitis, to name a few. The nodular form must be differentiated grossly from various cutaneous neoplasms, and grossly and histologically from infectious or sterile granulomas. *Leishmania* sp. *can be distinguished from other protozoa via light microscopy by recognition of the kinetoplast oriented perpendicular to the nucleus.*

Cutaneous leishmaniasis has been reported in **cats** in Europe and South America, and in a cat living in Texas; the cat was presented repeatedly with progressive, multiple, non-ulcerated cutaneous nodules on the ears, face, and nasal mucosa. Histologic lesions were described as dermal infiltrates of macrophages containing *Leishmania* amastigotes. No evidence of systemic infection was found at necropsy 7 years after the initial cutaneous lesions containing amastigotes were identified.

Cutaneous leishmaniasis has been reported in **horses, mules, and donkeys** in Europe, South America, and in a horse in North America and another in Puerto Rico. Lesions consist of crusted or ulcerated nodules on the pinna, head, and neck or less commonly the legs, scrotum and penis. Histologically, the dermis contains nodular to diffuse infiltrates of macrophages and lymphocytes or distinct granulomas with organisms identified in macrophages or free within the interstitium. Cutaneous lesions may not be associated with systemic infection.

Miscellaneous coccidian parasites

Caryospora spp., apicomplexan parasites whose primary hosts are reptiles and raptors, rarely cause *pyogranulomatous dermatitis in puppies*. Immunosuppression and concurrent disease, such as canine distemper, likely play a facilitatory role. Lesions involve skin and draining lymph nodes and comprise diffuse pyogranulomatous dermatitis. Macrophages contain large numbers of intracellular organisms, including schizonts, gamonts, oocysts, and caryocysts. Caryocysts have a thin cyst wall enclosing the host cell nucleus and contain up to three sporozoites. Not all stages of the life cycle may be present in the tissue sections, precluding a microscopic diagnosis in some cases. Immunohistochemical studies identified the agent in one case as *C. bigenetica*. Experimental oral infection of immunosuppressed puppies with *C. bigenetica* induced typical skin lesions affecting muzzle, periocular skin, footpads, ears and abdomen within 10 days of inoculation.

Neospora caninum is a cyst-forming protozoal parasite of *dogs, cattle, sheep, goats, horses, and deer*. It is best known as a cause of bovine abortion capable of transplacental transmission. It typically causes systemic and neurologic disease. *N. caninum* is considered a primary pathogen in dogs with the majority of cases occurring as neurological disease in puppies. Cutaneous lesions occur in mature dogs often with underlying immunosuppression from drug therapy or concurrent disease. It is not known whether the disease in adult dogs results from a reactivated congenital infection or from a recently acquired infection. Lesions have been described as *multifocal-to-generalized, ulcerative and nodular dermatitis*. Histologically, there is pyogranulomatous and eosinophilic, to necrotizing and hemorrhagic, dermatitis. Numerous tachyzoites, 4–7 μm × 1.5–5 μm, may be seen in macrophages, keratinocytes, and neutrophils, and rarely in endothelial cells and fibroblasts. Tissue cysts are not present in the cutaneous lesions. Identification of *N. caninum* can be confirmed by immunohistochemistry.

An unidentified ***Sarcocystis*-like protozoan** was associated with *multiple cutaneous abscesses and disseminated visceral lesions in a dog*. The skin lesions were diffuse, necrotizing, hemorrhagic and suppurative. Large numbers of protozoa were present, primarily in macrophages and neutrophils, and occasionally in fibroblasts and endothelial cells. Some vessels contained thrombi and there was associated dermal and epidermal infarction. The organism did not stain with antisera to the other apicomplexan parasites so far identified as causing dermatitis in dogs, namely *Neospora caninum* and *Caryospora* sp.

ALGAL DISEASES OF SKIN: PROTOTHECOSIS

Protothecosis is an uncommon disease caused by *Prototheca* spp. organisms, which are thought to be *colorless, nonphotosynthetic variants of the green alga Chlorella*. The organism is ubiquitous in organic matter and in fresh and marine waters. Reports of infection in humans and domestic and wild animals are worldwide, but the majority of cases are from the southeastern United States. The two most common species associated with infection are *Prototheca wickerhamii* and *P. zopfii*. *Mastitis in cows and disseminated disease in dogs are more common than cutaneous-subcutaneous infection*. In humans, the cutaneous form is the most common and is thought to be initiated by traumatic implantation, resulting in a protracted and indolent clinical course. *Cutaneous protothecosis has been reported in dogs and cats* from the USA, Australia, England, and Spain. In those cases in which the organism was speciated, *P. zopfii* is most often associated with disseminated disease, whereas the cutaneous form has been caused by *P. wickerhamii.*

Despite widespread distribution of *Prototheca* spp., *the prevalence of infection is very low* and attempts to reproduce infection experimentally have met with mixed success. This has led to speculation that the organism is an *opportunist with low pathogenicity* that requires an underlying immunologic dysfunction for the development of disease. Most humans with cutaneous protothecosis have a concurrent disease condition that may alter the immune response to the organism. Except in one dog with disseminated protothecosis, no immunologic deficit has been identified in animals with cutaneous or disseminated disease. However, there is evidence to suggest that infection may become established in an individual with minor immunosuppression and that the algae may further compromise the host immune response.

The cutaneous lesions are variable and consist of small crusty ulcerative lesions, multiple miliary nodules, firm raised nodules, or poorly demarcated subcutaneous swellings anywhere on the body. The tissue is soft and uniformly pale tan or white. Histologically, the masses consist of *diffuse infiltrates of primarily epithelioid macrophages* in the dermis and subcutis. Multinucleated giant cells, neutrophils, and lymphoid cells are in variable numbers, and foci of necrosis may be present. *Organisms are typically numerous but they are only lightly stained with H&E and therefore are poorly visualized.* The cell wall and internal contents are readily stained with fungal stains, e.g., Gridley (GF), Gomori methenamine silver (GMS), and periodic acid-Schiff (PAS). The organisms vary from 1.3–25 μm in diameter and consist of cells called *sporangia* that divide by internal cleavage to form multiple *endospores*. Identification of *Prototheca* can be made reliably by examination of tissue sections, but species identification usually requires culture or immunofluorescence methods because differences in the two species are subtle. *P. wickerhamii* sporangia are smaller and round in comparison to the larger and oval or cylindrical shape of most *P. zopfii. Protothecae must be differentiated from Chlorella algae*, whose natural green pigmentation is removed in fixation and routine tissue processing. In contrast to *Prototheca* cells, *Chlorella* sporangia contain many large starch granules that are stained by GF, GMS, and PAS.

ARTHROPOD ECTOPARASITES

Of the parasitic arthropods, only small a fraction are parasites of domestic animals, but the harmfulness of these is quite out of proportion to their number. Some, such as the mites, are pathogens in their own right, but *the majority of them owe their immense importance to their ability to act as mechanical or biological transmitters for many pathogenic viruses, bacteria, protozoa and helminths.* Their role as vectors is discussed in relation to the specific diseases throughout these volumes.

The parasites of concern to us here belong to the two large classes, Insecta and Arachnida. The class Insecta contains four important orders, Diptera (*flies*), Siphonaptera (*fleas*), Mallophaga (*biting lice*) and Siphunculata (*sucking lice*). The class Arachnida contains the order, Acarina, in which *ticks and mites* are classified. For information on biological characters and classification, reference should be made to texts on entomology.

Many **arthropod bites or stings** go unreported and are of minimal consequence. The type and number of arthropods inflicting the bite or sting and the individual host response determine the severity of the injury. In general, most arthropod bites initially appear as circular, erythematous lesions, 0.5–2.0 cm in diameter. Lesions may progress to focal areas of necrosis with ulceration, alopecia and crust formation. Histologically, the area of necrosis and inflammation may have a triangular outline with one point of the triangle in the deep dermis or panniculus. In early lesions, the inflammation is perivascular to diffuse and includes variable numbers of eosinophils, neutrophils, lymphocytes, and macrophages. Edema and hemorrhage may be present. As the lesion ages, the area may become nodular to form "*arthropod-bite granuloma*" comprised of macrophages, lymphocytes, mast cells, eosinophils and plasma cells. Lymphoid follicles may form. More specific details concerning injury inflicted by various arthropods, if known, are discussed in the following sections.

Flies

Flies belong to the insect order, Diptera. Different species have various degrees of adaptation to a parasitic existence. Adult flies feed on blood, sweat, tears, saliva, feces, urine, and other body secretions. Non-biting, nuisance flies accomplish this by feeding only at the body surface on wounds or natural body orifices, whereas biting flies puncture the skin to feed. *Musca* are facultative feeders. Some, such as the Simuliidae and parasitic species of Culicidae and Ceratopogonidae, are obligate bloodsuckers, although usually only the females draw blood. At the other end of the spectrum are the Oestridae, whose larvae are obligate parasites, and some members of the Hippoboscidae that are obligate parasites in the adult stage.

Because of the variety of parasitic modes, it is not possible to generalize on the effects of flies on domestic animals nor, with the exception of a few obligate parasites, is it possible to be specific because there is little information available on primary pathogenicity. Flies adversely affect domestic animals by *causing annoyance*, by *direct toxicity* that may be fatal following massive insect attack, by *indirect toxicity* due to the deposition of larva into damaged skin (myiasis), by *local irritant effects* causing dermatitis that may predispose to secondary bacterial infection or to myiasis, by *injection of antigens* that induce hypersensitivity reactions, by *blood-feeding activities* that cause anemia, and by the biological or mechanical *transmission of other pathogens*. It has been estimated that tabanid flies could transmit 35 pathogens including *Equine infectious anemia virus* and trypanosomes. *Musca* spp. have been implicated in the mechanical transmission of anthrax, mastitis, and conjunctivitis in animals. *Stomoxys calcitrans*, the stable fly, is thought to be the primary transmitter of habronemiasis in horses.

Animal annoyance, so-called "*fly-worry*," is an important source of economic loss to the cattle, sheep and, to a lesser extent, swine industries. Fly worry refers to the behavioral disturbances in animals brought about by the attempted feeding of flies. Biting flies inflict pain whereas non-biting flies cause annoyance by clustering around the eyes and nostrils where they feed on lacrimal or nasal secretions (*Musca autumnalis* and *Hydrotaea irritans*) or by other means such as simulating the sound of a bumble bee (*Hypoderma* spp.). Fly-worry occasionally induces such apprehension that the animals run aimlessly ("*gadding*"), and severe injury or death may result from misadventure. Deaths are usually sporadic but high levels of mortality have been reported. Of much greater economic importance is the *loss of production* associated with fly worry. When the insects are numerous, they cause very considerable annoyance to livestock, interfere with feeding and resting and cause reduced milk production and reduced weight gain. Fly worry has been attributed to biting flies such as the horn fly (*Haematobia (Lyperosia) irritans*), the stable fly (*Stomoxys calcitrans*), and horse flies (several genera in the family Tabanidae), and to non-biting species such as house flies (*Musca* spp.), *Hypoderma* spp. and the sheep-head fly (*Hydrotaea irritans*). *Culicoides* spp. biting midges can cause pruritus and restlessness in horses. Horses that develop a hypersensitivity response to *Culicoides* spp. insect bites may suffer weight loss as a result of severe pruritus and irritation (see Immune-mediated dermatoses).

Mortality may arise from direct toxic effect as well as from misadventure. Death may be the result of urticarial swelling of the head and neck or of shock. Many flies are attracted to exhaled carbon dioxide and can occasionally cause *death by suffocation* of cattle, horses, or other animals when large numbers of flies are inhaled. Mosquitoes, especially aggressive species such as *Aedes vigilex*, may cause significant mortality amongst piglets and puppies. The Simuliidae (black flies or buffalo gnats) are responsible for massive animal mortalities, particularly in temperate latitudes and river valleys following extensive flooding when the insect population expands. They feed on cattle, horses, sheep, goats, poultry, wild mammals and birds. *Simuliid flies exert systemic effects through inoculation of a heat-stable toxin*, which causes increased vascular permeability and abnormalities in cardiorespiratory function, which may cause death.

The hematophagous flies seldom cause serious loss of blood, however anemia may result from heavy infestations by *Haematobia irritans*, mosquitoes, the sheep ked *Melophagus ovinus* and *Stomoxys calcitrans*, which may ingest as much as 16 mg blood per feeding.

In dogs, stable flies (*Stomoxys calcitrans*) typically attack the face and tips or folded edges of the pinnae producing erythematous to hemorrhagic dermatitis with variable pruritus. *Simuliidae* spp. can also feed on small animals. Lesions are most often found on the head, ears, legs, or hairless areas of the abdomen and appear as papules, ulcers, or circumscribed areas of necrosis. Occasionally annular macular lesions with a central puncture surrounded by an edematous zone with a peripheral erythematous rim may be evident.

Local irritant effect results from *injection of salivary fluids into the host*. Very little is known of the nature of the cutaneous lesions produced in animals by these insects. The character and severity of the local lesions vary. Pruritus is often intense, resulting in secondary traumatic lesions. The primary lesions are usually erythematous papules or wheals often surrounding a central bleeding point (mosquitoes) or small puncture wounds (biting flies). The wheals are usually transient but may persist for several weeks. The puncture wounds often develop an exudative crust. Some flies (Simuliidae) feed by lacerating the skin until a pool of blood forms on the surface from which they feed. Histologically, there may be intraepithelial eosinophilic spongiform pustules or focal areas of epidermal necrosis indicating the penetration point. The dermal reaction is superficial perivascular in pattern and contains predominantly eosinophils, lymphocytes and plasma cells. Occasionally there is acute necrosis of the surface of the papules, including both dermis and epidermis.

The injected salivary substances are irritant and many are allergenic, and hypersensitivity reactions probably contribute to the severity of the local lesions caused by a variety of biting flies. Hypersensitivity reactions to *S. calcitrans* are recognized in cattle; affected animals develop coalescing blisters on the forelimbs. An important allergic dermatitis of horses is caused by hypersensitivity to *Culicoides* spp.

Rather more important than the bloodsucking or biting flies are those species whose larvae are highly destructive facultative or obligate parasites. Infestations with such larvae cause *myiasis*, which is discussed below.

Myiasis

Myiasis is the infestation of the tissue of living animals with the larvae of dipterous flies. The larvae are referred to as *maggots* or *grubs* and may be facultative or obligate parasites. The important families are Cuterebridae, Sarcophagidae (*Wohlfahrtia* spp.), Gasterophilidae (stomach bots of horses), Oestridae (nasal bots, warbles), and Calliphoridae (blowflies). Only those flies whose larvae cause cutaneous or subcutaneous lesions are discussed here. Nasal and stomach bots are described elsewhere. Agents of facultative myiasis affecting the skin live in decaying organic matter, and the females oviposit in wounded, infected, or heavily soiled skin of warm-blooded vertebrate hosts. The larvae feed on host tissues and eventually drop to the

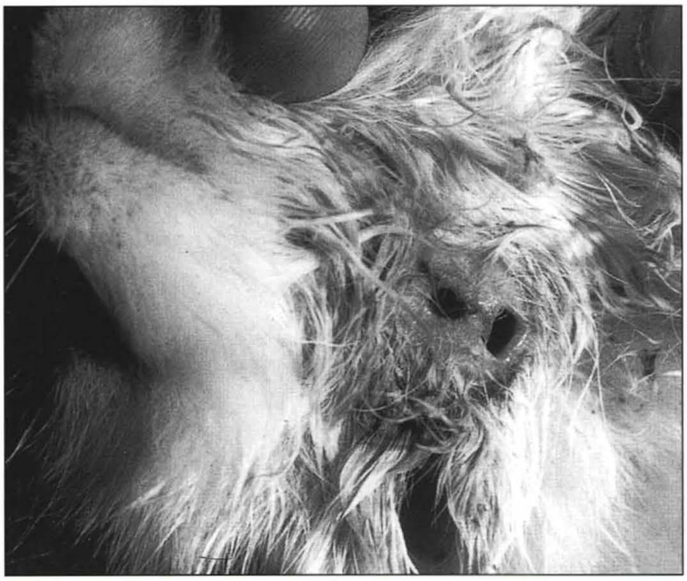

Figure 5.104 ***Cuterebra* infestation** with draining lesions in a cat.

ground to pupate. *Cochliomyia hominovorax,* the screwworm fly, produces larvae that are obligatory parasites and are discussed separately.

Cuterebra

The larvae of ***Cuterebra*** spp. (Diptera; Family: Oestridae; sub-family: Cuterebrinae) are obligate parasites of rodents and rabbits but occasionally aberrant infestations occur in cats and rarely in dogs, pigs, and humans. Larvae attach to the host's fur and either enter via ingestion through grooming, direct skin penetration or through natural orifices to migrate to the subcutaneous tissues to produce an initially firm, then fluctuant, cyst-like subcutaneous abscess in which the larvae mature. The larvae breathe through a fistulous pore in the skin through which they are visible, and feed off tissue debris. Wounds heal slowly after larvae are removed or released and secondary bacterial infection may occur. The majority of infections occur in late summer or fall. *In cats, the larvae have a predilection for the neck area* (Fig. 5.104), often over the submandibular salivary gland, but swellings also occur in the scrotal region. Larvae may locate in aberrant locations such as the pharynx, nasal cavity, eye, and brain.

In South and Central America, ***Dermatobia hominis*** (Diptera; Oestridae; sub-family: Cuterebrinae) affects cattle, sheep, goats, pigs and people and, rarely dogs and cats. It is also known as the *human bot fly*. The adult fly captures another carrier insect to which it attaches its eggs. The eggs hatch when the carrier insect visits a host. The larvae then attach to the host and penetrate the skin to form local cutaneous nodules that can be pruritic. The mature larvae exit the nodule through holes that leave the host susceptible to fly strike. A case report of an infected dog from the Netherlands described lesions as painful, erythematous, exudative nodules with a central pore.

Wohlfahrtia

Wohlfahrtia magnifica (Diptera; Superfamily: Oestoidea; Family: Sarcophagidae) is an *obligate larval parasite of warm-blooded vertebrates* in the Mediterranean basin, eastern and central Europe and Asia minor. The female fly deposits larvae on the host near body orifices or in wounds. Larvae mature and drop to the ground to pupate in 5–7 days. *W. magnifica* causes myiasis in sheep, camels, poultry and to a lesser extent in cattle, horses, pigs, and dogs. Fecal soiling in sheep is a predisposing condition. *W. vigil* is a parasite of mink, foxes, rabbits, and occasionally dogs and cats in North America. The larvae can penetrate the tender skin of young animals, hence the young are most often affected. *W. nubia* is a secondary facultative invader of wounds in camels in North Africa and the Middle East.

Warbles

Warbles caused by ***Hypoderma bovis*** and ***Hypoderma lineatum*** (Diptera; Family: Oestridae; sub-family: Hypodermatinae) *occur chiefly in cattle*, although the parasite is not host specific; horses, sheep and humans are affected occasionally. *H. bovis, H. lineatum*, and *H. sinense* are present in Europe and Asia. Intensive eradication programs have eliminated *Hypoderma* spp. from the UK and Ireland and have greatly reduced their populations in much of the USA and Canada. *Przhevalskiana silensus* affects sheep and goats in Asia and Eastern Europe. *H. diana* is an important parasite of deer and possibly sheep in the Palaearctic. *H. tarandi* parasitizes reindeer in northern Eurasia and North America. There are no warble flies in Australia.

Warble flies are also known as heel flies because the eggs are deposited predominantly on the hair of the legs. Larvae emerge 4–6 days later and burrow directly into the skin or into hair follicles causing minimal irritation. Larvae migrate along fascial planes leaving tracks of green gelatinous material known as "butcher's jelly." The first instar larvae of *H. bovis* overwinter in the epidural fat, whereas those of *H. lineatum* develop in the esophageal submucosa. In the esophageal lesions, collagen bundles around the first instar larvae of *H. lineatum* appear fragmented, as if undergoing enzymatic digestion. A collagenase has been isolated from *H. lineatum*. In the epidural lesions of *H. bovis*, it is the fat tissue that appears necrotic. In the spring, the larvae migrate dorsally to the subcutaneous tissue of the back to form subcutaneous nodules ~3 cm diameter with a central pore for respiration. The lesions, which are known as "warbles," last for 4–6 weeks, during which the larvae undergo 2 molts. The mature third-instar larvae emerge from the breathing hole and pupate in the soil. In horses, the lesions occur in the saddle region and are often "blind" in that the larvae do not complete their development. Fatalities resulting from aberrant migration into the central nervous system are reported in horses.

Histologically, the cellular reaction is predominantly eosinophilic and lymphocytic. It is the eosinophilic infiltrate that gives "butcher's jelly" its green coloration. However, the most intense inflammatory reactions occur at sites of previous migration rather than around the viable larvae, suggesting that in naive hosts the parasites depress any effective host responses. Proteinases with the capacity to cleave the third component of bovine complement have been isolated from the first instar larvae of *H. lineatum*. Such enzymes could well ablate the host's inflammatory responses. The actual "warble" is lined by a wall of granulation tissue that matures to form a connective tissue capsule in which lie islands of eosinophils. The cystic cavity between the cuticle of the parasite and the granulation tissue fills with fibrin and a few inflammatory cells, chiefly eosinophils. Cuticle sloughed during ecdysis, or remnants of dead larva, incite a marked foreign body giant cell reaction. Once the larvae emerge, the cavity is repaired by fibrosis, but small foreign body granulomas may persist for months.

Warbles are economically important. The buzzing of the adult *H. bovis* (*H. lineatum* is silent) disturbs cattle causing considerable loss in milk and meat production. Larval tracks in the tissues decrease carcass value and the larval-induced holes markedly depreciate the value of the hide. Larval rupture, either accidental or deliberate, may induce a fatal anaphylactic reaction. This may result from systemic effects of the warble toxin, from type I hypersensitivity reactions, or a combination of both.

Calliphorine myiasis

This occurs in all animal species but is *most common in sheep*, particularly in Australia where it is of major economic importance. The flies involved are members of the subfamily Calliphoridae (**blowflies**). Important blowfly genera are *Lucilia, Calliphora, Protophormia, Phormia* and *Chrysomia*. The larvae (*maggots*) adopt a *facultative parasitic mode*, which is an adaptation of their beneficial and important role in the breakdown of carrion. Adult flies lay eggs on moist, warm skin of weakened or debilitated animals, in wounds or areas of heavy soiling with feces, urine or other body fluids. Hence, any species of animal can be susceptible.

Moisture, whether provided by rain, dew, urine, sweat or inflammatory exudate, predisposes to bacterial proliferation. These bacteria are often of fecal or urinary origin. The odor induced by the bacterial proliferation and resultant inflammatory exudate attracts the primary flies, which deposit batches of 50–200 ova. The larvae of primary flies emerge within 12–24 hours and grow rapidly, feeding on inflammatory exudates. *The primary larvae secrete proteolytic enzymes*, including collagenases, which liquefy the host tissues and provide predigested nutrients. The *cutaneous necrosis* that results attracts the secondary flies to oviposit. The resulting larvae *tunnel into the adjacent viable tissue* and markedly expand the lesion. The putrefactive odor attracts more flies, and the process is further exacerbated. The lesions of fly strike are often extensive and *leave large areas of undermined skin with punched-out holes*. The subcutaneous tissues may become cavitated. Muscle may be destroyed and body cavities invaded. Lesions may result in death from *shock, debilitation, toxemia or bacterial septicemia*.

The species of fly involved in fly strike differs with geographic location: *Lucilia cuprina* is the most important primary fly in Australia, *Phormia regina* in USA and Canada, and *Lucilia sericata* in Great Britain. Several different species of flies are involved in the development of the lesion of cutaneous myiasis. Primary flies, such as *L. cuprina*, are capable of initiating a strike on living sheep. Secondary flies, such as *Chrysomia rufifaces*, are not able to initiate a strike, but greatly exacerbate the lesions initiated by the primary fly. They may also displace the maggots developing from the eggs laid by the primary fly. Tertiary flies, such as the housefly *Musca domestica*, attack at a later stage and do not contribute significantly to the skin damage.

The development of fly strike in sheep depends upon abundance of primary flies, susceptible sheep, and moisture. The prevalence of the disease tends to follow the rise and fall in the population of primary flies, which in turn depends upon the climatic zone. In general, the flies require warm and moist but not hot conditions. Thus there is usually a double wave of primary flies, peaking in the spring and autumn. Certain breeds of sheep, in particular the fine-wooled Merino, have an inherent predisposition to attract fly strike. The character of the fleece and conformational features, such as skin wrinkling, allow retention of moisture or predispose to fecal or urinary soiling which are all initiating factors in fly strike. *Pseudomonas aeruginosa* (of "fleece rot") proliferation in soiled wool of sheep is of major importance. *Dermatophilus congolensis* may be involved occasionally.

In sheep, the lesions are most common in the perineum ("*breech strike*"), particularly in sheep with a narrow conformation and/or marked skin wrinkling which favor urine or fecal soiling. Lesions may affect the preputial orifice ("*pizzle strike*") particularly in animals with narrow urethral orifices, which predispose to urine soiling. Rams with deep head folds may develop "*poll strike*," possibly predisposed to by fight wounds. "*Wound strike*" occasionally follows castration or tail docking and "*body strike*" follows prolonged wetting, which in turn predisposes to "fleece rot" or dermatophilosis.

The initial *gross lesion* is a patch of dark-brown, moist wool, which has a foul smell. The wool is often very hot as a result of putrefaction and inflammation caused by the larvae. As the process advances, the maggots burrow under the skin causing irregular ulcers with scalloped edges. The lesions are irritating and pruritic. Occasionally the maggots migrate deeper into the muscle.

The economic losses of fly strike in sheep result from death, disfigurement, and depreciation of the fleece and costs associated with prevention and treatment.

Screwworm myiasis

Members of the Calliphoridae also cause myiasis; however, they differ from the blowflies in that *screwworm fly larvae are obligate parasites, invading edges of fresh, uncontaminated wounds on live animals*. The American species of screwworm flies are ***Cochliomyia hominivorax*** and ***Cochliomyia macellaria*** (the secondary screwworm fly), which is usually a carrion breeder but can act as a secondary invader of fly strikes. The African and Asian screwworm fly is *Chrysomyia bezziana*. The disease occurs in Africa, Asia, Central and South America and Mexico but has been virtually eradicated from the USA and Mexico, following a program in which release of massive numbers of irradiated male flies rendered the annual breeding a sterile one. An outbreak of screwworm in Libya in 1988, seen as a major threat to the livestock of southern Europe and Africa, was dealt with in a similar fashion. International air travel proffers a source of spread to susceptible countries.

Screwworm myiasis affects all domestic animals and humans and is an important cause of mortality in wildlife. The flies oviposit in cutaneous wounds, such as those caused by castration, dehorning, branding or accidental injuries. The navel of neonatal calves, the perineum of recently calved cows and tick bites are also favorable sites for oviposition. The larvae feed in groups, to penetrate and liquefy fresh, live host tissue with the aid of proteolytic enzymes. Blood-stained fluid, often containing incompletely digested shreds of tissue, oozes from the wound, which contains clusters of voraciously feeding larvae. A distinctive and particularly evil odor emanates from the lesion. The lesions are extremely painful and may expand rapidly, leading to death in untreated animals. Screwworm infestation is a reportable condition in many countries.

Sheep ked infestation

Melophagus ovinus (Diptera: Hippoboscidae) *is a wingless fly that causes a chronic, pruritic dermatitis of sheep*. Goats are also affected. Of worldwide distribution, the disease's chief economic importance is the associated *loss of wool production*.

Melophagus ovinus is an obligate ectoparasite. The eggs develop into larvae within the female until they are ready to pupate. After parturition, the female attaches its larva to wool fibers with the aid of a sticky substance. The immotile larva transforms into a chestnut-brown pupa ~3–4 mm long. The pupal stage lasts 3–5 weeks and the adult keds live 4–5 months. They prefer the sides of the neck and body and are difficult to detect in fully-fleeced animals. The adults feed actively on blood. While anemia may develop in severe ked infestations, the more significant lesions are the result of the *severe pruritus*, which causes the sheep to rub and bite, and thus damage the fleece. The adult fly's excreta stains the wool, further reducing its value. Wool loss and vertical ridging of the skin leads to a condition referred to as "cockle." The irritation induced by the bites also affects weight gain. The US sheep industry has estimated losses attributed to sheep keds to be about $40 million per year.

Histologic lesions reported are superficial and deep perivascular dermatitis with eosinophils and lymphocytes predominating. Fibrinoid necrosis of small arterioles is also described.

Hornfly dermatitis

While mainly an obligate parasite of cattle, the **horn fly (*Haematobia irritans*)** is one cause of *seasonal ventral midline dermatitis in the horse*. In **cattle**, the flies feed in groups primarily on the back, withers, and head. They leave the animal only briefly to mate and lay eggs. Horn flies require fresh bovine feces to lay eggs. Large numbers of horn flies in cattle can result in significant loss of blood, wounds that attract other flies, and in loss of production. *H. irritans* is also thought to transmit the skin parasitic nematode of cattle, *Stephanofilaria stilesi*.

In **horses**, horn flies, cluster on the ventral abdomen (and occasionally on the neck or periocular region), producing bites marked by tiny drops of dried blood. A few days later pruritic, scaling, alopecic patches develop. These become lichenified and heal with either leukoderma or melanosis. The lesions are often single, usually well-circumscribed and occur near the umbilicus. Histologically, lesions are perivascular and eosinophilic, typical of many insect bite-induced dermatopathies. If ulcerated, lesions predispose to infection by *Habronema* spp. nematodes. Lesions of *Culicoides* hypersensitivity (see Immune-mediated dermatoses) and onchocerciasis may also occur on the ventrum, but these are diffuse, often extending from the axillae to the groin. Both *Culicoides* hypersensitivity and onchocerciasis are sporadic diseases whereas up to 80% of horses in a group may be affected with horn-fly bite dermatitis.

Mosquito-bite dermatitis

Mosquito bites in animals are common and the bite itself is of little consequence most of the time. Mosquitoes serve as *vectors* for a number of important diseases, including malaria in humans, canine and feline heartworm disease, equine viral encephalitis and equine infectious anemia, and rabbit myxomatosis. In **cats**, mosquito bites can induce a severe papular, crusting dermatitis characterized by dense eosinophilic infiltrates. Experimental studies in cats utilizing intradermal skin tests and Prausnitz–Kustner tests indicate that these lesions develop only in cats hypersensitive to mosquito bite antigens and are initiated by a type I hypersensitivity reaction. The disease is seasonal and often pruritic. Clinically, cats initially develop wheals progressing to erythematous papules and plaques that eventuate into crusted, ulcerated and sometimes hypopigmented lesions (Fig. 5.105). Sparsely haired regions of the body are most often affected such as the bridge of the nose, the pinnae, and footpad margins. The pinnae may develop symmetrical lesions of miliary dermatitis. The severity of lesions varies by individual, leading to scar formation in the more severe cases.

Histologic lesions include intraepidermal eosinophilic microabscessation and perivascular to diffuse interstitial infiltrates of eosinophils, mast cells, macrophages and lymphocytes. The epidermis is often spongiotic and acanthotic. Eosinophilic granulomas around focal areas of collagen degeneration, and perifollicular to intrafollicular eosinophilic infiltrates with furunculosis, may be present. Cats may have regional lymphadenopathy and peripheral eosinophilia. *Clinical differential diagnoses* include lesions of the eosinophilic granuloma complex, other cutaneous hypersensitivities such as atopy or food allergy, actinic dermatitis or squamous cell carcinoma, and pemphigus foliaceus. *Histologic differentials* include *Felid herpesvirus-1*-associated dermatitis, other cutaneous hypersensitivities mentioned above, and feline eosinophilic granulomas. Eosinophilic folliculitis and furunculosis are not usually seen in feline eosinophilic granulomas and are less prominent in food allergy than in mosquito bite hypersensitivity. Ballooning degeneration, viral inclusions, and marked necrosis are usually present in herpesvirus-induced lesions. Careful evaluation of histologic lesions and circumstantial evidence are essential keys to the diagnosis.

Lice

Lice are host specific, obligate parasites of the class Insecta. Two orders of lice are recognized. The Mallophaga are *biting lice,* which have mouth parts specially adapted for chewing the epithelial scales, feathers, and sebaceous secretions of birds and mammals. The Anoplura have piercing mouth parts and are the *blood-sucking lice* of mammals. Lice cannot live away from their hosts for more than a few days. Consequently, spread of infestation occurs mainly by direct contact among hosts. Pigs and humans are parasitized only by sucking lice, birds and cats are parasitized only by biting lice, and both types parasitize other domestic animals. Because various species of lice have adapted to different microenvironments within the host pelage, it is possible for an animal to carry several species at once.

Infestation with lice is called **pediculosis**. It tends to be a seasonal problem, being worse in winter. The signs associated with pediculosis are extremely variable. In most instances, lice do not pose a significant threat to the host. *Heavy infestations signal an underlying contributing condition such as poor sanitation, overcrowding, ill thrift, or poor nutrition.* Low infestations may be unaccompanied by clinical signs in carrier animals. *Most lesions result from skin irritation and resultant pruritus.* They include alopecia, papules, crusts, and damage to wool or hide caused by rubbing or biting. *Sucking lice may induce anemia,* which is occasionally fatal in heavily infested animals. Weight loss and decreased milk production are associated with the constant irritation seen in some lice infestations.

Lice are almost always host specific, but *Heterodoxus longitarsus*, normally parasitic on kangaroos, has become an important ectoparasite of Australian dogs. *Phthirus pubis*, the human crab louse, has been reported to infest dogs living with infested humans. Because of host specificity, it is advantageous to consider pediculosis of the different hosts in turn.

Louse infestation occurs in **cattle** more often than in other domestic species. *Haematopinus eurysternus*, the short-nosed louse; *H. quadripertusus*, the tail-switch louse; *H. tuberculatis*, the buffalo louse; *Linognathus vituli*, the long-nosed louse; and *Solenoptes capillatus* are sucking lice of cattle. *Damalinia bovis* is the one biting species. The various species have preferred habitats. *Damalinia bovis* tend to cluster about the poll, forehead, neck, back, and rump; *Linognathus* and *Solenoptes* prefer the head, neck, and dewlap. There may be antagonism between the species; in dual infestation with *D. bovis* and *L. vituli*, the former tends to occupy the dorsal half and the latter the ventral areas. Some lice are widely distributed, others tend to cluster in groups. Infestations are quite common, particularly in colder weather or seasons, but, unless heavy, are not particularly deleterious. Poorly fed, overcrowded, and unthrifty animals are more susceptible to heavy infestations. Conversely, heavy infestations may indicate underlying disease as debilitated or ill animals cease normal grooming activities. Lesions reflect pruritus. Heavy periorbital infestation of heifers by *Haematopinus quadripertusus* has caused keratoconjunctivitis and periorbital papillomatosis. Bovine pediculosis usually has little deleterious effect on weight gain and other production parameters. Economic consequences are due to deterioration of hide quality, damage to fences, and costs of treatment. The exception is *Hematopinus eurysternus* infestation, which may cause anemia and death in some uniquely susceptible cattle. *H. eurysternus* feed most often around the poll, neck, brisket, and tail but may become generalized.

The species of sucking lice affecting **sheep** include *Linognathus ovillus* (the face or blue louse), *L. africanus* (also called the blue louse) and *L. pedalis* (the foot louse). *L. ovillus* is not very pathogenic. *L. pedalis* characteristically infests the hairy skin on the legs. Infestations are frequently light and may be confined to one limb, as the lice form localized clusters. Rarely, heavy infestations spread to adjacent scrotal or abdominal skin, causing irritation and dermatitis secondary to self-trauma. While goat and sheep lice are considered host specific, there are reports of naturally occurring transmission of the goat louse *Damalinia caprae* to sheep and experimental transmission of *D. ovis* to goats.

Damalinia ovis, a biting louse, is a common and serious ectoparasite in sheep. Populations of *D. ovis*, on an individual or in a flock, can build up very quickly. The numbers of lice fluctuate with the season, increasing usually in late winter and early summer. The population declines in the summer probably because the lice, which are sensitive to heat and low humidity, cannot survive in the body fleece where temperatures at the tip of the staple may reach 48°C. There are also unexplained individual differences amongst sheep in their susceptibility but, in general, unthrifty sheep carry the heaviest infestation. The size of louse populations may be in part regulated by the sheep's immune response. The lice feed on loose skin scales and sebaceous secretion and there is a correlation between the degree of scurf and the size of the louse population. The highest concentration of lice occurs along the dorsal midline, chiefly over the withers, but the parasites range over the entire body. Eggs are attached to the wool fibers close to the body surface. The infestation has serious consequences because of the *marked pruritus* it induces. The cause of the pruritus is unknown but is thought to be more than simple mechanical irritation. Affected sheep rub, scratch and bite at the skin resulting in severe damage to the fleece. Focal crusting may be associated with some louse infestations. Economic loss is due to reduced fleece quality, cost of prevention, and mortality from secondary myiasis. There is, however, no evidence to support the claim that sheep louse infestation leads to unthriftiness.

In **goats**, the sucking louse, *Linognathus stenopsis*, is more pathogenic than the biting lice, *Damalinia caprae*, *D. limbata* and *Holokartikos crassipes*. The haircoat of Angora goats may be seriously damaged by the irritation induced by pediculosis.

Two species of lice occur on **horses**, namely *Haematopinus asini*, a sucking louse, and *Damalinia equi*, a biting louse. The populations of lice fluctuate considerably, being highest when the hair is long as in winter or in debilitated animals which have not shed their hair. In warm weather, the populations decline but some lice persist in the long hair of the mane and tail. Both species of louse induce skin irritation. The lesions of pediculosis, rough coat, variable alopecia and self-excoriation, result from the animal rubbing or biting at the irritated areas.

One species, *Haematopinus suis*, a sucking louse is parasitic on **pigs**. Preferential sites include the ears and skin folds of the neck, axillae and inguinal areas. Infestations are often severe but, with the exception of nursing piglets, anemia is not severe. In white-skinned animals, numerous small puncta may be seen, especially in scalded carcasses. Constant irritation from lice also interferes with growth rate and efficiency of food conversion. The lice are vectors for *Swinepox virus*, *African swine fever virus*, and *Eperythrozoon suis*.

Linognathus setosus is a sucking louse and *Trichodectes canis* and *Heterodoxus spiniger* are biting lice of **dogs**. *Trichodectes canis* may serve as an intermediate host for the tapeworm, *Dipylidium caninum*. Pediculosis is a rare disease in pet dogs. Breeds with moderately long, fine hair may provide a more favorable environment for lice, and the disease is more prevalent in the cooler winter months. The biting lice cause pruritus, which may be associated with mild to moderately severe dermatitis with papules and crusts or with patchy alopecia. Infestation in the absence of pruritus may be an incidental finding.

Only one species, the biting louse, *Felicola subrostratus*, occurs on **cats**. Infestation may be an incidental finding or it may be associated with mild pruritus in the absence of lesions. Occasionally there is generalized scaling (seborrhea sicca) or multifocal or generalized papular, crusting dermatitis.

Fleas

Fleas are ubiquitous and obligate parasites. They are intermittent parasites and their survival depends upon temporary episodes of feeding and a habitat where the host is periodically available. Fleas primarily parasitize hosts that return on a regular basis to a nest, burrow, bedding, or lair. Hence, animals such as ungulates rarely have fleas and carnivores, rabbits, rodents, and bats often do. Most fleas can parasitize a range of hosts. An exception to this general rule, is the more recent finding that cat fleas spend more of their lifetime on the cat than fleas infesting other species. Fleas are chiefly a problem in cats, dogs, pigs, and humans. Flea bites damage the host from the irritation, pruritus, blood loss, and possible transmission of infectious agents. *Ctenocephalides felis*, the cat flea, *Ctenocephalides canis*, the dog flea, and *Pulex irritans*, the human flea, are vectors for the dog tapeworm, *Dipylidium caninum*. Fleas are also vectors of tularemia, bubonic plague, and rabbit myxomatosis. Flea saliva is injected into the host as the flea feeds leading to hypersensitivity reactions in some animals.

Fleas are the most common ectoparasites of **cats** and **dogs**. The most important species are *Ctenocephalides felis*, the cat flea, and *Ctenocephalides canis*, the dog flea. However, infestations also occur with *Pulex irritans* (human flea), *Leptopsylla segnis* (rat flea), *Echidnophaga gallinacea* (chicken stick-tight flea), *Spilopsyllus cuniculi* (European rabbit flea), and *Ceratophyllus* spp. (bird and hedgehog fleas). *C. felis* is the most common flea found on both dogs and cats in North America and northern Europe.

The clinical manifestations of flea infestation are highly variable. Some animals, despite heavy infestations, remain asymptomatic carriers. Some animals may develop **flea bite dermatitis**, which is a reaction to the many irritant substances in the flea's saliva, but the vast majority of animals that develop lesions do so because of hypersensitivity reactions to allergenic components of the flea saliva. **Flea allergy dermatitis** is an extremely common and very important disease of the dog and cat; it is discussed in detail under Immune-mediated dermatoses. Finally the blood-sucking activities of fleas may induce blood-loss, iron deficiency anemia in heavily infested animals, particularly in kittens, puppies or debilitated adults.

Lesions affecting the pinna of cats may be caused by *Spilopsyllus cuniculi*, the flea of rabbits and hares. Typically, hunting cats acquire the infestation from their prey. Macroscopic lesions are crusted, alopecic patches on both aspects of the pinna. Histologically, eosinophils are prominent in the dermal inflammatory cell infiltrate.

The two fleas most commonly associated with **swine** are the human flea (*P. irritans*) and the chicken stick-tight flea (*E. gallinacea*). Infestation with *C. felis* and *C. canis* have also been reported. In Africa, *Tunga penetrans*, the chigoe flea, has been associated with swine infestations although it is chiefly a human parasite. The female flea burrows into the skin causing ulcerative lesions. The skin around the coronary band, on the scrotum and snout are favored sites. Infestations of the teat canal have been associated with agalactia in sows. Fleas may act as vectors for *Swinepox virus*. Heavy infestations with *Ctenocephalides* spp. in Africa lead to anemia, reduced weight gain and even death in **sheep** and **goats**, particularly in the young. Fleas may also trigger allergic dermatitis in sheep. *C. felis* has been rarely reported in **cattle**. Heavy infestation with *C. felis* was reported to cause mortality in calves, lambs and kids in Israel. Rarely, **horses** may become infested with *Echidnophaga gallinacea* or *Tunga penetrans*. Papules, crusts, pruritus, and alopecia may develop.

Mites

Sarcoptic mange

Sarcoptes scabiei (Acarina: Sarcoptidae) is responsible for scabies in man and sarcoptic mange in domestic animals worldwide. Scabies has also been reported to cause severe disease in a number of wildlife species. *It is a common ectoparasite in swine.* The disease occurs in *cattle* and goats but is not as important as psoroptic mange. The disease is rare in horses and sheep. Ovine sarcoptic mange has not been reported in North America. Sarcoptic mange is *common in the dog* and may be underdiagnosed. It occurs rarely in the cat. So-called feline scabies is caused by *Notoedres*. The economic importance of sarcoptic mange in food-producing animals is due to depressed growth rate and decreased rates of food conversion. Production studies in experimentally infected pigs and sheep demonstrating the effect of therapy, support the contention that *the disease is of economic significance*. Sarcoptic mange is a notifiable disease in many countries.

Through host-adaptation, *S. scabiei* has become divided into morphologically indistinguishable varieties, which rarely cross infect. Each variety is named for its host; thus *S. scabiei* var *equi* is usually confined to the horse but may live temporarily on cattle or humans. People are quite readily parasitized by most of the animal-adapted varieties. However, in most cross-infestations, the parasites remain on the skin surface and do not complete their life cycle.

In the normal host, the parasite completes it life cycle in tunnels burrowed into and under the stratum corneum. After mating in a "molting pocket" close to the surface, the female burrows through the stratum corneum to feed on cells of the stratum granulosum and stratum spinosum. Cutting mouthparts and tarsal claws on the legs of the mite achieve the excavation. In swine, this phase of infestation takes ~3 weeks. Epidermal cell damage induces proliferative changes in the surrounding keratinocytes so that the surface openings of the tunnels become sealed with thick parakeratotic scale-crust. In swine this process takes a further 3–4 weeks. After 7 weeks of infestation, the crust falls off and the mites vacate the tunnels. Approximately 40–50 ova are laid in the burrows at a rate of 1–3 per day. They develop through the larval and nymphal stages in the same tunnel or in new ones, to reach maturity in 10–15 days depending on the host species. In general, both parasites and ova have poor viability in the external environment, however, low temperature and high humidity may allow some mites and nymphs to persist in the environment up to 21 days. The disease, which is *highly contagious*, is transmitted largely by direct contact, but may occur following indirect contact with contaminated objects such as bedding.

The *pathogenesis* of lesions in *S. scabiei* infestation is due to *direct damage* inflicted by the parasite mechanically, by the *irritant effects* of its secretions and excreta, and by an *allergic reaction* developed against components of the mite or one or more of the extracellular products of the parasite. Evidence for an allergic pathogenesis in animals comes chiefly from experimental infestations of swine. Initial lesions in pigs are due to parasite invasion and are localized and non-pruritic. After 7–11 weeks, there is generalized urticarial eruption associated with extreme pruritus. This eruption coincides with the development of immediate and delayed hypersensitivity reactions and peripheral eosinophilia. The delayed hypersensitivity response is dependent on antigen dose, whereas the immediate hypersensitivity response is independent of the degree of antigen exposure. Lesions regress between 12–18 weeks after the initial infestation.

The variability of the clinical manifestations of sarcoptic mange probably reflects individual variations in the duration and intensity of the hypersensitivity reaction and in the related capacity of the host to limit parasitic multiplication. Asymptomatic carriers exist. Most *S. scabiei*-related diseases are caused chiefly by the allergic reaction, and the lesions are the result of self-trauma induced by severe pruritus. However, animals with a weak hypersensitivity reaction may exhibit severe crusting dermatitis characterized by the presence of large numbers of mites. This type of disease is typically seen in poorly nourished animals or animals debilitated by coexisting disease. An

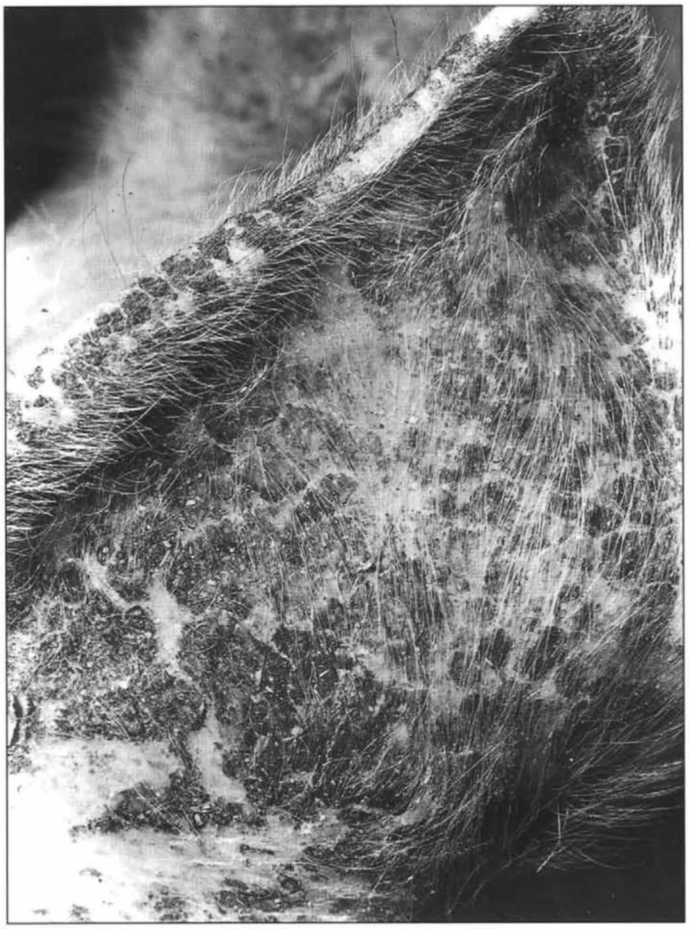

Figure 5.106 Sarcoptic mange in a pig.

example is the chronic form of scabies in dogs associated with long-term corticosteroid therapy. This has been referred to as *Norwegian-type scabies*, following the human nomenclature for severe scabies in immunosuppressed people. Diminished levels of hypersensitivity are correlated also with the development of chronic infestations in swine, known as *hyperkeratotic mange*. This manifestation of mange is sporadic and chiefly affects breeding adults.

The primary parasite-related lesions of sarcoptic mange are erythematous macules or papules, which develop a local scale-crust in reaction to the burrowing mites. The thickness of the overlying scale-crust is proportional to the number of tunnels beneath. In poorly nourished or immunosuppressed animals, which develop massive mite infestations, the lesions are characterized by alopecia, marked lichenification, accumulation of thick gray scale-crust and fissuring. Excoriations, hemorrhagic crusts and patchy alopecia follow the early lesions of erythematous papules. Chronic hypersensitivity lesions include marked alopecia, scaling and lichenification.

The distribution of the lesions is characteristic in the various species. In **pigs**, the mites have a predilection for the *inner surface of the pinna* where they cause primary lesions (Fig. 5.106). The papular lesions associated with the allergic reactions are located chiefly on the rump, flank and abdomen, and the secondary changes due to chronic self trauma follow a similar pattern. In the chronic hyperkeratotic form of the disease, heavily crusted lesions develop over the whole body but are most severe on the head, neck, and legs. In **dogs**, the preferred sites are the lateral elbows, hocks, ventral thorax, and lateral margin of the pinna. There may be an associated peripheral lymphadenopathy. The lesions may become generalized in untreated dogs or dogs inappropriately treated with corticosteroids. In **cattle**, the lesions chiefly affect the neck, head and sacral areas but may become generalized. The disease in **goats** also has a predilection for the head but may involve the whole body. In **sheep**, only the haired areas develop lesions, particularly the lips, nostrils, external surface of the pinna and occasionally the legs. Generalized lesions occur in the more hairy desert sheep of the Sudan. Lesions in the **horse** begin on the head and neck and may extend to involve most of the body, but seldom the legs or mane.

Histologically the lesions vary with the balance between allergic reaction and parasitic infestation and chronicity. *Definitive diagnosis requires demonstration of the parasite.* Rarely, sections of mites or ova may be present within the epidermis or surface crusts. Lesions consist of a mild to severely acanthotic epidermis with variable orthokeratosis to patchy parakeratosis. In fully developed lesions, there is marked spongiosis, mixed leukocytic exocytosis, serocellular crusts, and possibly intraepidermal eosinophilic pustules. Vasodilation, endothelial swelling, and edema may also be present. Immunosuppressed animals with large numbers of adult mites in epidermal burrows often have a markedly parakeratotic stratum corneum. Dermal lesions consist of a mild-to-moderate superficial to mid-level perivascular infiltrate with a variable ratio of lymphohistiocytic cells and eosinophils. The chronic allergic lesions reflect continued trauma with dermal fibrosis, epidermal hyperplasia with prominent rete ridge formation, hyperpigmentation and a predominantly mononuclear cell perivascular infiltrate.

Diagnosis of the typical allergic form of the disease depends chiefly on the clinical signs of extreme pruritus and the nature and distribution of the cutaneous lesions. Mites are characteristically difficult to demonstrate, either in skin scrapings or in microscopic section. Approximately two-thirds of affected dogs fail to yield parasites even when multiple scrapings are performed. Mites are more commonly recovered from puppies than adult dogs. *The microscopic lesions are not diagnostic, being indistinguishable from other allergic dermatoses.* The most useful diagnostic procedure is response to appropriate therapy. In the chronic form of sarcoptic mange associated with poorly developed hypersensitivity reactions, mites are plentiful in scrapings and in tissue section. *Clinical differential diagnoses* include other causes of pruritic dermatitis such as atopy, contact, food, or flea-bite hypersensitivity, infestation by other parasites, *Malassezia* dermatitis, or superficial pyoderma.

Notoedric mange

Notoedres cati (Acarina: Sarcoptidae) is the cause of *feline scabies* and is also a parasite of the rabbit, and occasionally foxes, dogs, and humans. *The disease in cats is uncommon to rare*, although there are some endemic areas of higher prevalence. The mite has a life cycle similar to that of *S. scabiei*. The infestation is *highly contagious*, with transmission chiefly by direct contact. The major clinical sign is *pruritus*. The lesions in cats commence on the head and ears, particularly on the margin of the pinna but may extend to the neck, paw or become generalized. Lesions include partial alopecia, thickening and wrinkling of the skin and, in chronic cases, the formation of tightly adherent yellow-gray crusts (Fig. 5.107A). There may be accompanying regional lymphadenopathy. Lesions in dogs are indistinguishable from sarcoptic mange. Histologically, the lesion is a hyperplastic, eosinophil-rich, superficial perivascular dermatitis with focal parakeratosis. *The diagnosis is based on history, clinical signs and demonstration of typical mites in section* (Fig. 5.107B) *or skin scrapings*. Mites are readily found in skin scrapings and histologic sections from cats.

Psoroptic mange

The psoroptic mites (Acarina: Psoroptidae) infest *sheep, cattle, horses, rabbits, and goats* as well as other nondomestic species. Human beings are not susceptible. There are actually fewer species of ***Psoroptes* mites** than originally thought, as mites from one host can often infect another host, and morphologic distinctions overlap. Based on critical literature review and molecular genetic analyses, the *Psoroptes* mites are conspecific, and, by rule of priority, belong to the one genus *P. equi* (Hering, 1838). Traditionally, *Psoroptes ovis* infests sheep, cattle and horses; *P. natalensis* infects cattle in South Africa, South America, and Europe; and *P. cuniculi* affects the ears of several species including rabbit, horse, donkey, goat and sheep.

Psoroptic mange is a serious disease in cattle and sheep and is a reportable disease in several countries. Bovine psoroptic mange showed a recrudescence in North America during the 1970s and early 1980s but has been brought under control by the effective use of ivermectin. Ovine psoroptic mange has been eradicated from many countries including Australia and New Zealand. The *economic importance* in sheep and cattle results from a marked decrease in weight gain, reduced milk production, reduced fleece weight and quality, occasional mortality and costs related to prevention and eradication campaigns.

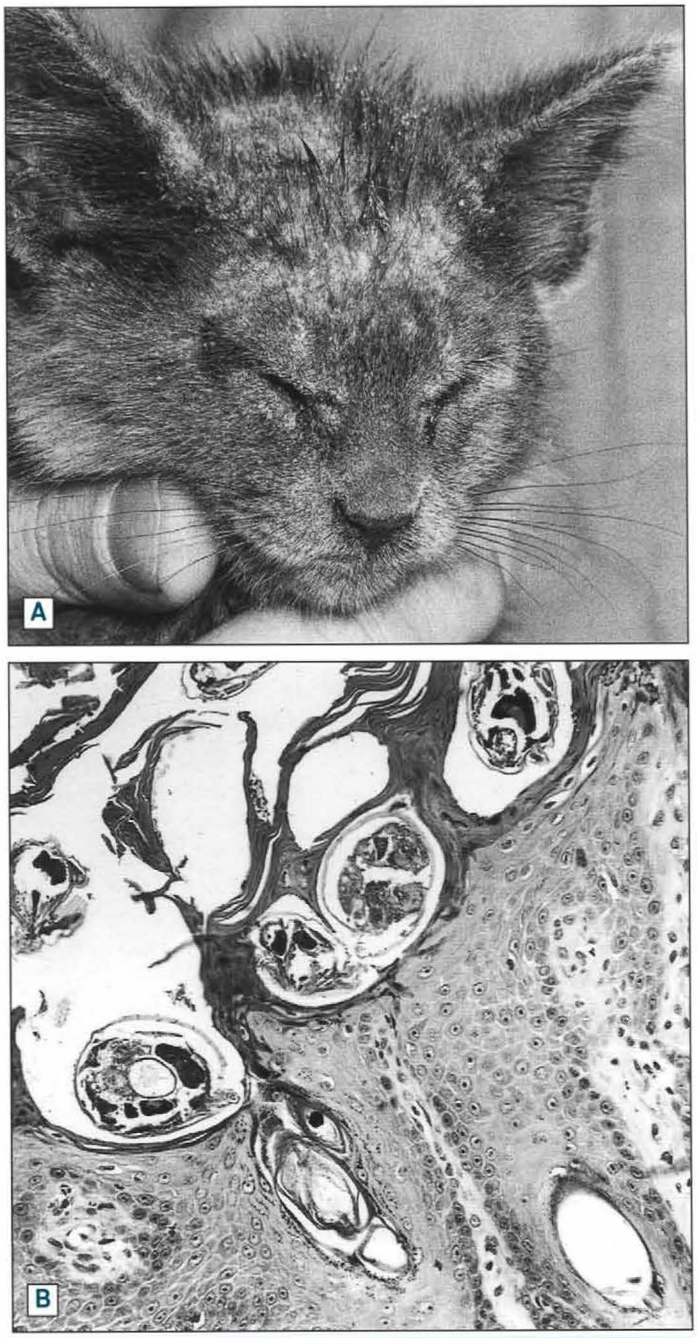

Figure 5.107 Notoedric mange in a cat. **A.** Gross photo **B.** Mites embedded in the surface keratin of the hyperplastic epidermis.

Psoroptic mites do not burrow into the outer epidermis, as do the sarcoptic mites, but instead complete their life cycle on the skin surface. Lipids from the stratum corneum provide a major source of nutrients in the early stages of infestation, probably supplemented by serous and hemorrhagic inflammatory exudates in the later stages.

Psoroptic mange is characterized by *intensely pruritic dermatitis*. The pathogenicity of the mite has been attributed to its local irritant effect on the epidermis, but this does not readily explain the marked loss of condition induced by *Psoroptes* infestation in some species, particularly cattle. The detrimental systemic effects may derive directly or indirectly from a *chronic hypersensitivity reaction* rather than from local dermatitis. The histologic lesions, in which the predominant inflammatory cells in the superficial dermis are eosinophils, mast cells, and lymphocytes, are consistent with an *allergic pathogenesis*. Constant pruritus resulting from allergy markedly reduces feed intake, and secondary bacterial infection or myiasis may further contribute to loss of condition. There is little evidence to support the hypothesis that the mites inoculate a toxic compound along with their saliva.

Histologically, the lesions are similar in all species. The pattern of inflammation is superficial perivascular dermatitis with predominantly spongiotic, exudative or hyperplastic reactions depending on chronicity. The eosinophil is the most numerous of the infiltrating leukocytes, followed by lymphocytes, other mononuclear cells and mast cells. Dermal edema is usually marked. Mites are present both on top of and under the surface scale-crust. Sebaceous gland hyperplasia has been described in lesions in sheep and cattle.

Psoroptic mange in **sheep**, also known as "*sheep scab*," may occur as a latent infection in which mites persist in the ears, infraorbital fossae, inguinal and perineal folds and at the base of the horns. In rams, mites may be found on the scrotum or prepuce in small, dry lesions. Latency occurs in the summer months when the fleece microclimate is less favorable to parasite proliferation. In autumn and winter or with debilitation of the host, the parasitic population explodes and lesions are induced. The withers and sides are particularly affected. The initial lesions are papules ~0.5 cm in diameter covered with a yellow serous crust, which may mat the fleece. The individual lesions expand at the periphery and may coalesce to become diffuse over most of the body surface. The main damage to the fleece is caused by self-trauma induced by the severe pruritus. Affected sheep scratch, kick, rub and tear out the fleece with their teeth.

In **cattle**, psoroptic mange is sometimes referred to as "*cattle scabies*." Lesions also diminish in the summer months as a result of decreasing mite populations, attributable to increased self-grooming. Previous exposure to mites, while not conferring solid resistance to reinfection, also limits the mite population, chiefly by reducing the rate of oviposition in the females. Lesions in reinfested cattle, while occurring earlier, progress more slowly, reflecting the decreased mite population. Lesions in naturally affected cattle usually commence about the poll, withers or at the base of the tail (Fig. 5.108) and chiefly result from persistent licking, rubbing and scratching induced by pruritus. Infested areas are fairly well defined as areas of alopecia. Alopecic areas become lichenified and covered by dry gray crusts and scales. Severely affected calves may develop mild anemia, lymphopenia and marked neutropenia.

In **goats**, *P. cuniculi* is known as the *"ear canker" mite* because of its predilection for the external auditory meatus. Mite infestation induces head shaking and occasionally crusted lesions on the inner surface, and alopecia on the outer surface of the pinna. In debilitated or stressed animals, thick brown-yellow, dry scale-crust accumulates on the inner aspect of the pinna and, rarely, spreads to involve the poll, body and the legs. Concurrent *Mycoplasma* and *P. cuniculi* infections have been described in the ears of goats; however, *Mycoplasma* may be cultured from the ears of clinically normal animals, placing some doubt on the significance of the finding.

In **horses**, *P. cuniculi* is found quite frequently in the ear. Infestations have been associated with "head shakers" in the United Kingdom and Australia, but are often subclinical. *Psoroptes ovis* infestations are rare; lesions are crusted papules with alopecia and the preferred sites are at the base of the mane, forelock and tail.

Chorioptic mange

Chorioptic mange, caused by ***Chorioptes bovis*** *(Acarina: Psoroptidae), affects horses, cattle, sheep, and goats. Not host specific, C. bovis is an obligate parasite that lives on the surface of the skin.* The mite populations tend to fluctuate considerably as a result of host and environmental factors. Inapparent infections allow persistence in the population. Clinically affected animals are pruritic and have papular, crusted, scaly, alopecic and/or lichenified lesions depending upon the duration of the disease and the degree of self-trauma inflicted.

The disease in **cattle** predominantly affects *housed dairy cows* and is most prevalent in winter. Subclinical infections are probably quite common. The major clinical sign is *pruritus*, but this is not as severe as in sarcoptic or psoroptic mange. Chorioptic mange is, in general, a less serious condition than psoroptic mange in cattle, although a syndrome of highly irritant coronitis was associated with falling milk production. The typical distribution of lesions is perineum, tail, scrotum, udder, and caudal areas of thigh, hindlimbs and rump. Lesions are predominantly alopecia, erythema, lichenification, and wrinkling of the skin.

The disease in **horses** is uncommon. As indicated by the colloquial name "leg mange," lesions occur preferentially on the lower limb around the fetlock but may extend proximally to the thigh and ventral abdomen. Draft horses, with thick-feathered fetlocks are affected more often. The lesions are most severe in winter, as in cattle.

In **goats**, lesions originally were described as commencing on the neck and spreading to the back, base of tail, and lateral body. Another pattern, in which lesions affect the coronet, pasterns, and lower limbs, appears to be more typical. The face, udder, and scrotum also may be affected.

In **sheep**, *C. bovis* mites prefer the distal extremities, particularly the pastern and interdigital skin of the hind limbs. The scrotum may be affected and the resultant scrotal dermatitis may lead to temporary infertility. Chorioptic mange has been eradicated from the sheep population in the United States. It is a reportable disease in some countries.

Otodectic mange

Otodectes cynotis (Acarina: Psoroptidae) is an obligate parasite of the external skin surface of *dogs and cats*. While the mite may be found at several body sites, its preferred habitat is the *external ear canal*. The major lesion is thus *otitis externa* (see Vol. 1, Eye and ear). Focal, erythematous, alopecic, or excoriated lesions occur occasionally on the face, feet, neck, or tailhead. Self-trauma and head shaking can lead to aural hematomas. The mites are contagious, particularly in young animals and can live off the host for extended periods of time. *Diagnosis is by direct visualization*; however, mites may be difficult to demonstrate in some cases.

Cheyletiellosis

Members of the genus ***Cheyletiella*** (Acarina: Cheyletidae) affect *dogs, cats, rabbits, wild animal species, and, incidentally, humans*. There are three species involved: *C. parasitivorax* is chiefly a parasite of rabbits although formerly considered as a canine pathogen; C. *yasguri* is the major canine cheyletiellid; and, the species most commonly associated with feline infestation is *C. blakei*. Host specificity is weak and cross infestations are not uncommon. The mites are obligate parasites, completing their life cycle on the skin surface in ~35 days. The infestation is transmitted by direct contact, frequently from a carrier female to her litter. The mites originally were thought to survive for only 1–2 days away from the host, but more recent observations suggest longer survival may permit indirect transmission.

The pathogenicity of cheyletiellid infestation is controversial. The presence of the mite on naive hosts usually, but not always, induces hyperkeratosis, which may or may not be associated with pruritus. Adults, possibly because of acquired immunity, usually have asymptomatic infestations.

The gross lesions in both the dog and cat reflect the mite's *predilection for the dorsal midline*. Lesions often commence over the caudal back and progress cranially but may become generalized. The typical lesion is a moderate to marked exfoliation of small, dry, white scales (seborrhea sicca). The mites crawl in "pseudotunnels" in the loose keratin debris and their movement has produced the colloquial name "*walking dandruff*" for cheyletiellosis. Cats may develop, in addition, focal, multifocal or generalized erythematous papules or crusted lesions. Occasionally animals show pruritus in the absence of scaling. *Diagnosis depends upon demonstration of the mites* via skin scraping, acetate tape, vacuum cleaning, or brush techniques. Biopsy, which shows a spongiotic hyperplastic superficial perivascular dermatitis with variable numbers of eosinophils, is nondiagnostic since mites are usually not demonstrable. *Clinical differentials* should include other pruritic dermatoses and idiopathic or primary seborrhea. Humans in contact with affected animals often develop a pruritic maculopapular rash on the arms and trunk. As the mites do not complete their life cycle on human skin, these lesions regress once the animal is treated.

Psorergatic mange

Psorergates ovis (Acarina: Cheyletidae) is a parasite of the integument of *sheep*. The disease occurs in Australia, New Zealand, South Africa, and South America. It is thought to have been eradicated from the USA and has not been reported in Europe. The mite, which is much smaller than sarcoptid mites, is an *obligate parasite and goes through its life cycle on the skin surface in the loose keratin debris*. The mite does not penetrate deeper than the stratum corneum. Infestations occur predominantly *on the dorsum*. Seasonal influences greatly affect mite populations, with lowest numbers occurring in the summer and highest in the spring.

Mite infestations induce *pruritus*; the pathogenesis of which is not known, although hypersensitivity reactions have been postulated. Lesions result from the sheep biting and pulling at the fleece. Fleece damage is more severe in the fine-wooled Merino than in the coarse-wooled breeds. The lesions occur on the flanks, thighs and lateral body wall, and comprise bleached, twisted tufts which give the fleece a ragged, tasselled appearance.

A mite named *P. bos* has been isolated from nonpruritic, scaling and alopecic lesions in cattle in the USA, Canada, Australia, New Zealand, and South America.

Demodectic mange

Demodex mites *(Acarina: Demodicidae) are normal inhabitants of the hair follicles and sebaceous glands in most species of domestic animals and in humans.* The cat also hosts a species of *Demodex*, *Demodex felis*, that lives in the superficial stratum corneum rather than in the follicles. The mites found in the different hosts are regarded as separate species, although they are similar morphologically. The mites are generally named for the host species, as in *D. canis* of dogs and *D. bovis* of cattle. *D. phylloides* of swine, *D. ghanensis* of cattle, *D. caballi* of horses and *D. aries* of sheep are exceptions in the nomenclature. A short form of Demodex species mite is also reported in dogs. It has been considered unusual for an animal to host more than one species of *Demodex*, but synhospitality may in fact be the rule rather than the exception.

Demodex spp. are *obligate parasites*, completing their life cycle in the hair follicle or its adnexae. They are rapidly killed by desiccation on the surface of the skin, but mites move from follicle to follicle and it is probably at this time that transmission to another host takes place. Transmission usually occurs by direct contact from the dam to her offspring during nursing in the neonatal period.

Demodex mites are part of the normal fauna of the skin in most, if not all, mammalian species. This implies that small numbers of mites exist in harmony with the host, and it is only when the equilibrium between the host and parasite is altered in favor of the mite that excessive proliferation occurs and lesions of demodectic mange are produced. The most severe expression of demodectic mange is seen in the dog as *generalized dermatitis* (Fig. 5.109A), which is, on occasion, fatal. Multiple lesions occur commonly in cattle, less commonly in pigs and goats, but with no systemic consequences. The demodectic mites of sheep rarely assume pathogenicity.

Demodicosis is one of the most common skin disorders of **dogs** *in North America.* In active infections, mites are first observed on skin scraping from the muzzles or feet of newly infected animals. Lesions may remain localized and self-limiting or become generalized. Generalized demodicosis is more prevalent in particular breeds of purebred dogs and often affects successive litters of certain clinically normal bitches or sires. *It has been postulated that puppies genetically predisposed to develop demodectic mange have a form of cell-mediated immune dysfunction that alters the body's recognition and reaction to the mites allowing massive proliferation of the mite population.* Immunophenotypic and histopathologic studies in the dog indicate active lesions of demodicosis produce *mural lymphocytic folliculitis with infiltration of the follicular wall by primarily CD3+ and CD8+ T lymphocytes.* The mural folliculitis is often associated with apoptosis or degeneration of keratinocytes and perifollicular pigmentary incontinence consistent with a lichenoid tissue reaction similar to epidermal lesions of lupus erythematosus or graft vs. host disease. Current research suggests lymphocyte-mediated follicular wall injury may be directed against keratinocytes expressing either altered self-antigens or *Demodex* antigens. It is not known whether or not the presence of cytotoxic T lymphocytes indicates an appropriate host reaction to eliminate the parasite or if it represents an inappropriate and self-damaging host response. *The disease itself, in its complicated form, appears to induce a secondary immunodeficiency state*, especially in the presence of *S. intermedius*. Dogs with chronic generalized pustular demodicosis show reduced cell-mediated immune responsiveness as measured by depressed lymphocyte blastogenesis reactivity. Evidence of humoral immunosuppressive factors also exists in dogs with generalized demodicosis. It is not yet clear whether this change is attributable to the secondary bacterial infection or to the mite infestation itself. A dog exhibiting generalized demodicosis at the time of rabies vaccination later developed rabies after exposure to a rabid skunk. This dog also failed to receive the recommended rabies vaccine booster but nevertheless suggests the dog may not have been able to mount an appropriate immune response to the vaccine.

Demodicosis in the dog has two forms, *squamous or pustular* and may be *localized or generalized*. Erythema, alopecia, scaling, and comedones characterize the squamous form. *Pustular demodicosis* occurs when secondary bacterial infection ensues and furunculosis and cellulitis develop. Papules, pustules, draining tracts, and edema may be evident. Perifollicular hypermelanosis manifest as pinpoint hyperpigmentation is suggestive of demodicosis.

Localized demodicosis (limited to one body region) occurs in young dogs 3–10 months of age and is usually self-limiting. These dogs do not have depressed cell-mediated immune responsiveness and can respond to intradermal challenge with a crude *Demodex* antigen. The lesions are single or multiple, well-circumscribed, erythematous, scaly, and alopecic patches usually affecting the head around the lips, eyes, ear canals, or on the extremities. Approximately 10% of cases of localized juvenile demodicosis progress to the generalized form of the disease.

The *generalized form* may be of juvenile onset (dogs 3–18 months of age) or adult onset (dogs >12–18 months of age). *Juvenile-onset generalized demodicosis* is familial in many breeds. *Adult-onset generalized demodicosis* has no breed predispositions. Adult-onset, severe demodicosis has been reported to occur concurrently with hyperadrenocorticism, corticosteroid administration, hypothyroidism, and chemotherapy and other serious internal or infectious diseases. It is not known if these conditions predispose the dog to generalized demodicosis or if the affected dogs were initially already immunologically predisposed to develop demodicosis. The lesions of generalized demodicosis may be particularly severe on the face, forelimbs and feet. In some dogs, lesions may be confined to the feet (Fig. 5.109B). Lesions include patchy to diffuse alopecia, erythema, scaling and crusting, with or without lesions of secondary bacterial pyoderma. Peripheral lymphadenopathy occurs in ~50% of affected dogs. Often the dogs with generalized pustular demodicosis are depressed, febrile and debilitated, and may die.

Histologically, demodicosis has a variable appearance depending on the stage of the disease and presence of secondary bacterial infection. Early, uncomplicated lesions are characterized by a predominantly *lymphocytic mural interface folliculitis*. Lymphocytic infiltration of the isthmus and infundibulum accompanied by various degrees of vacuolar degeneration and apoptosis of keratinocytes of the outer root sheath, follicular melanosis or pigment clumping in the outer root sheath, and perifollicular pigmentary incontinence are present.

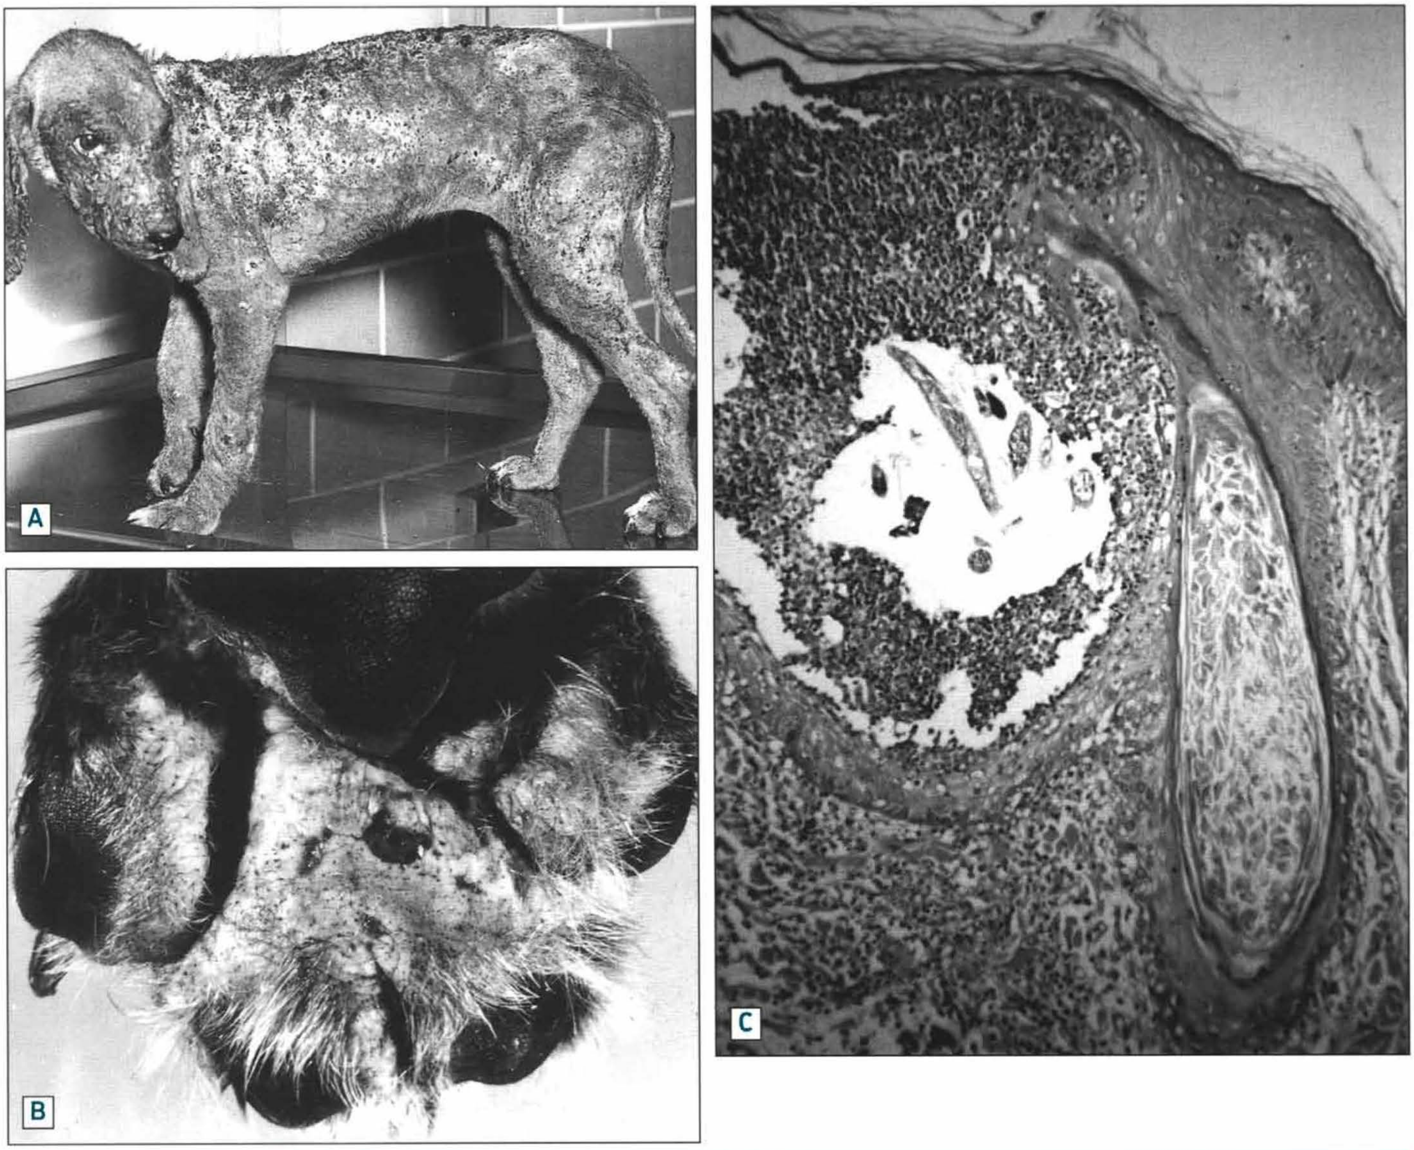

Figure 5.109 Demodicosis in a dog. **A.** Generalized demodectic mange. **B. Pododermatitis** in demodicosis. **C.** Folliculitis and **furunculosis** releasing *Demodex* mites into the dermis.

Immunophenotyping has identified infiltrating lymphocytes as CD8+ cytotoxic T cells, while the perifollicular infiltrates was found to be comprised of approximately equal numbers of CD4+ and CD8+ lymphocytes. The external root sheath may be hyperplastic. *Perifolliculitis* is also a consistent feature with infiltrates of plasma cells, macrophages, and lymphocytes in periadnexal regions. Mast cells and eosinophils may be present in smaller numbers. Marked follicular hyperkeratosis is associated with variable numbers of mites in the upper third of the follicle. Mural folliculitis is also consistently present at later stages and in cases with secondary bacterial infection but may not be the predominant pattern. In some cases, follicles may contain numerous mites but have no evidence of folliculitis of any type. This is especially true in cats. *Suppurative folliculitis and furunculosis* may be present depending on the presence and extent of secondary bacterial infection and the generation of deep pyoderma. Typically, large numbers of mites occupy the hair follicles at all levels and also occlude the opening of the sebaceous gland into the pilar canal. Marked follicular hyperkeratosis and build up of mite products causes follicular plugging. Bacterial proliferation within the plugged follicle often induces neutrophilic folliculitis. The combined effects of *follicular keratosis*, mite proliferation and folliculitis lead to *follicular rupture* and release of mites, bacteria, keratin, sebum, and other irritant products into the dermis (Fig. 5.109C). The bacteria, chiefly *Staphylococcus* spp., induce neutrophilic dermatitis often with abscessation. The keratin and other irritant substances stimulate a granulomatous reaction, chiefly of epithelioid macrophages, but a few multinucleated giant cells may be present. This *pyogranulomatous furunculosis* of demodectic mange differs from most other types of furunculosis in that eosinophils are rare or absent in the reaction. Epidermal lesions include hyperplasia, orthokeratotic and parakeratotic hyperkeratosis and variable spongiosis, neutrophilic exocytosis, ulceration and inflammatory crusting. Longer-standing lesions consist of perifollicular mid-to-deep dermal or occasionally subcuticular granulomas sometimes containing remnants of mites. Chronic lesions also have marked dermal fibrosis, often with obliteration of adnexa. Mites or fragments of mites are found in the subcapsular zone of regional lymph nodes associated with a local granulomatous inflammatory response. These do not indicate active invasion but rather passive transport to the node, via lymphatic channels.

Demodectic mange in **cattle** occurs worldwide. Three species are responsible: *D. bovis, D. ghanensis,* and *D. tauri.* Economic significance lies largely in the damage that mite infestation produces in hides. In some parts of Africa and Madagascar, demodectic mange in cattle may become generalized and fatal, this outcome contributed to by other debilitating conditions such as malnutrition, tick-worry and tropical heat.

Typical gross lesions are *multiple cutaneous papules or nodules*, usually between 2–4 mm diameter and occasionally reaching 1 cm or more. Nodules vary in number from a few to several hundred (Fig. 5.110A, B). The nodules are visible in smooth-coated cattle, often indicated by overlying tufts of erect hairs. In rough-coated cattle such as Herefords, detection usually requires palpation. The preferred sites are the shoulders, neck, dewlap, and muzzle but, in heavy infestations, nodules may be present over most of the body. The content of the nodules is thick, waxy or caseous material, sometimes stained with blood. The contents may liquefy and discharge to the surface forming a thick crust, or rupture of the nodule into the dermis may generate an abscess or a granulomatous reaction.

Histologically, the nodules are follicular cysts lined by a flattened squamous epithelium and filled with keratin squames and large numbers of demodicid mites. Adult parasites occur occasionally in sebaceous glands and rarely in apocrine sweat glands. A mild mononuclear cell infiltrate may occur around the epithelial lining. Rupture of a follicular cyst induces a marked nodular granulomatous reaction in which degenerating and occasionally mineralized segments of parasites and keratin debris are surrounded by epithelioid macrophages, multinucleated giant cells, lymphocytes, plasma cells and eosinophils.

The lesions in **goats**, caused by *D. caprae,* are similar to those described for cattle in both distribution and morphology. Some affected goats are mildly depressed, inappetent and have decreased milk production. Generally, the chief economic significance of caprine demodicosis lies in damage to the hides.

Demodectic mange is rare in **sheep**. *D. ovis* infestation is probably not uncommon in the medium to coarse-wooled sheep, affecting the Meibomian glands of the eyelid and the sebaceous glands of the primary follicles on the body, particularly the neck, flank and shoulders. *D. aries* infests the large sebaceous glands of the vulva, prepuce and nostrils. Grossly, lesions may be papular, nodular and rarely pustular. *D. ovis* infestation has been associated with matted fleece ("stringy wool"). Histologically, the mites are present in sebaceous glands or the pilar canal, occasionally inciting folliculitis or furunculosis.

While *Demodex* spp. are found commonly in the eyelid glands of the **horse**, demodectic mange is a very rare disease. *D. caballi* parasitizes the pilosebaceous units of the eyelids and muzzle, while *D. equi* infestation occurs over the body. Lesions associated with the latter occur on the head, neck and shoulder but may become generalized. They include papules, nodules and occasionally pustules. A patchy to diffuse alopecia with marked scaling occurs in the "squamous" form of the disease.

Demodex phylloides of **pigs** is not uncommon but is relatively unimportant in comparison to sarcoptic mange. The mites reside in the pilosebaceous units on the eyelids and snout with no clinical effect. The principal economic loss results from extensive trimming of affected carcasses. The lesions typically involve the ventral abdomen, ventral neck, eyelids, and snout. They commence as small red macules, developing into cutaneous nodules covered by surface scale. Incision of the nodules releases thick white caseous debris that is full of mites. The histologic lesions are as described in cattle.

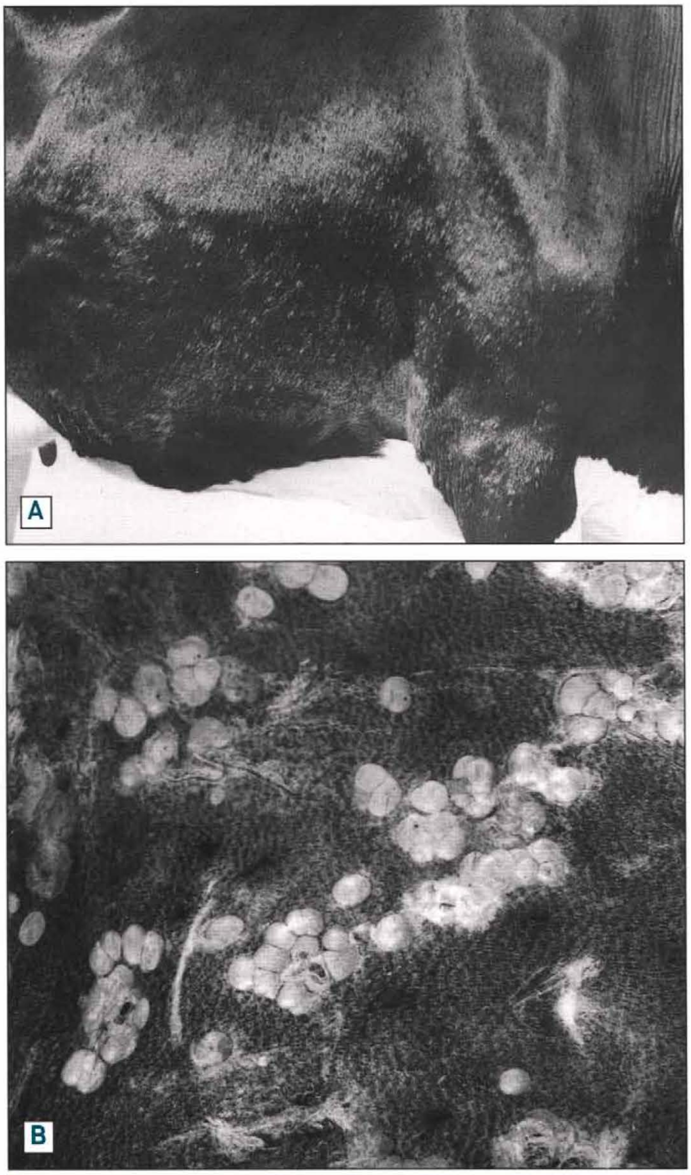

Figure 5.110 Demodectic mange in a cow. **A.** Multiple cutaneous nodules. **B.** *Demodex bovis* nodules beneath the hide.

Cats may develop demodectic mange. Two species of *Demodex* mites have been associated with feline demodicosis. One is *D. cati* that resides in the hair follicles and sebaceous glands; the other, *D. gatoi*, is found on the skin surface in pits in the stratum corneum. *D. gatoi* is shorter and broader than *D. cati*. Unlike dogs, there is no age or clear breed predisposition.

Demodex gatoi is associated with alopecia, scaling, hyperpigmentation, erythema, and excoriations due to pruritus and excessive grooming. Lesions are most often on the head, neck, groin, and extremities. Ceruminous otitis may be present. Clinical reports suggest this species of mite may be transmitted horizontally between cats. *Differentials* include atopy, food allergy, flea-bite hypersensitivity, dermatophytosis, feline psychogenic alopecia, or other ectoparasitism.

Demodex cati infestation results in single or multiple areas of alopecia, erythema and scaling that resemble the localized form of canine demodicosis. Lesions have a predilection for the chin, eyelid, head, and neck. Generalized lesions may occur in association with systemic disease, such as feline leukemia virus or feline immunodeficiency virus infection, hyperadrenocorticism, or diabetes mellitus, which presumably suppress normal cell-mediated immune responses. *D. cati* infestation of lesions of multicentric squamous cell carcinoma in situ (Bowen's disease) suggest that a localized alteration in the cutaneous immune response may allow mite proliferation. The lesions of *D. cati* are multifocal to generalized areas of alopecia and erythema, with variable degrees of scaling, and papules and crusts. Secondary pyoderma is not a common accompaniment. A third syndrome, otitis externa, has also been associated with *D. cati* infestation.

Histologic lesions tend to be limited to follicular and surface hyperkeratosis, sometimes with follicular atrophy. Inflammatory cell infiltration is minimal in *D. cati* lesions. Some eosinophil, mast cell and neutrophil infiltrates have been described in infestations with *D. gatoi,* but the reaction was never severe and concurrent allergic disease could not be ruled out.

Trombiculiasis

The nymphs and adults of the trombiculid mites are free-living or parasitize plants or other arthropods; the larvae are parasitic and are known as "harvest mites," "chiggers," or "red bugs." The parasitic larvae are six-legged and resemble minute red or yellow spiders just visible to the naked eye. The mites attach themselves to the skin and make a channel into the epidermis, called a *stylostome*, through which salivary enzymes are injected and digested tissue fluids are withdrawn. The mites engorge to twice their original size over a period of 3–5 days, after which they drop off and complete their life cycle in the soil. *Intensely pruritic dermatitis* develops at the sites of attachment, probably as a result of an allergic reaction to the salivary secretions delivered through the stylostome; the allergic reaction caused by larval trombiculid mites is known as *trombidiosis*.

Wild vertebrates are the usual hosts for the trombiculid mite larvae, but food-producing domestic animals, pets and people may be accidentally infested. The disease tends to have a seasonal incidence, occurring in the *late summer and autumn* when climatic conditions favor an expansion of the mite population. Factors such as soil-type also influence the prevalence of trombiculiasis in different geographical regions. Animals exposed to fields and woodlands are more often infested.

Trombicula autumnalis, the European harvest mite, attacks most domestic species. *T. sarcina*, an Australian species known as the leg-itch mite, is an important parasite of sheep although its principal host is the gray kangaroo. *T. alfreddugesi* (North American chigger), and *T. splendens* are some of the species implicated in trombiculiasis in cats, dogs and horses. *Straelensia cynotis* normally reside on foxes, but can infest dogs.

Lesions tend to occur in areas close to ground contact in animals exposed to wild or semi-wild areas. Lesions are extremely pruritic. In **sheep**, the larvae attach preferentially on the skin of the caudal pastern. The interdigital web is the predilection site in the **dog**. In a massive infestation reported in two dogs, temporary hindlimb paresis developed. The mite in **horses** is known as the "heel-bug" because of its tendency to parasitize the feathered area of the pastern. Lesions may also occur along the mane and at the tail-head. Face, particularly lip, involvement is not infrequent. The lesions are intensely pruritic. In **cats**, lesions affect the paws, head and ears, but an atypical generalized form of the disease may occur in association with *W. americana* infestation.

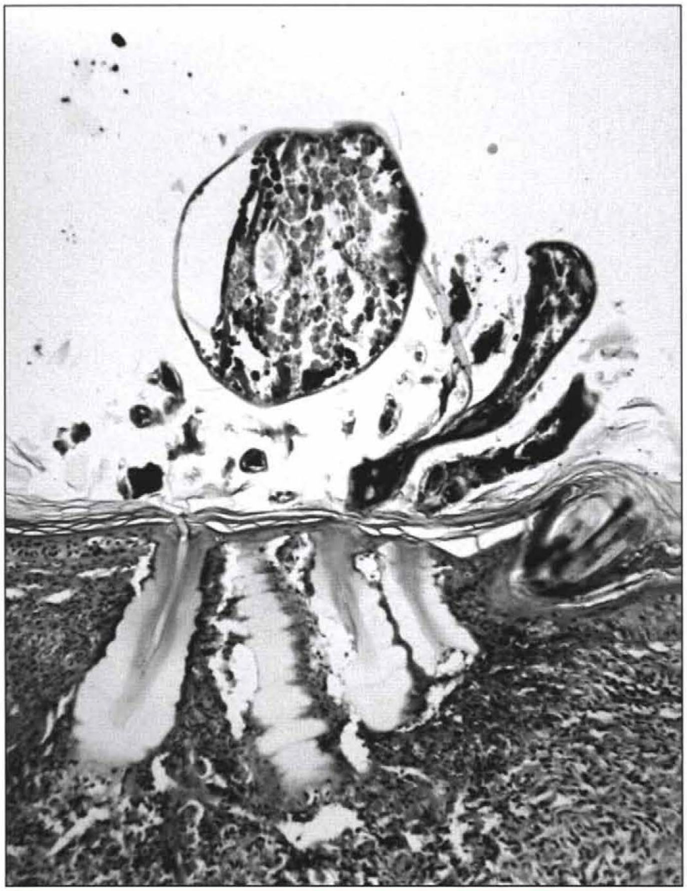

Figure 5.111 Trombiculiasis in a black bear. Section of skin showing mites within the surface keratin and multiple stylostomes oriented vertical to the skin's surface and extending into the dermis.

The gross lesions in all species are small, erythematous papules on which are clustered tiny (0.2–0.4 mm) bright red, orange or yellow mites. The mites leave a small, shallow ulceration that oozes a serous discharge and becomes crusted. Pruritus induces marked self-trauma, which may incite secondary bacterial infection. Histologically, *the mite is present in tunnels within the stratum spinosum or in the stratum corneum*. The presence of the mites induces both hyperplastic and degenerative changes in the epidermis. The stylostome appears as a pale staining, hyalinized tube with undulating margins oriented vertical to the skin's surface and extending into the dermis (Fig. 5.111). A large zone of necrotic cellular debris usually surrounds the stylostome. The surrounding dermis has a superficial perivascular infiltrate, with eosinophils and mast cells predominating.

Other mite-induced dermatoses

The **cat fur mite**, *Lynxacarus radovsky*, infests cats in the USA, Australia, Fiji, South America, and the Caribbean. The mite attaches to the hair shafts rather than to the skin surface. Predilection sites include the tail tip, tail head, and perineum. The mite infestation mimics seborrhea sicca, giving the coat a characteristic "salt and pepper" appearance. The infestation is not usually associated with lesions, although crusted, exudative and pruritic lesions and alopecia have been described.

The **straw-itch mite** (*Pyemotes tritici*) is normally found in straw or grain where it parasitizes the larvae of soft-bodied grain insects. The parasite may occasionally infest humans and other mammals causing pruritic dermatitis. Mildly pruritic lesions may develop in horses fed infested hay. Multiple papules and wheals may occur on the neck, withers and thorax. *Acarus (Tyroglyphus) farinae* and *A. (Tyroglyphus) longior* may cause a pruritic, exudative, crusting and alopecic dermatosis in horses exposed to contaminated grain or hay.

Cats and dogs may be infested on rare occasions with the **poultry mite**, *Dermanyssus gallinae*. The infestation resembles that of cheyletiellosis but pruritic eruptions have been described.

Sheep may, on rare occasions, become infested with the **stored product mite**, *Sancassania berlesei*. These mites cannot infest dry skin; infestations are secondary to other conditions such as myiasis.

Ticks

Ticks belong to the class Arachnida, sub-class Acari. They are divided into two families, the Argasidae and the Ixodidae. *The*

Argasidae are the so-called soft ticks, lacking the scutum that characterizes the Ixodidae. Included in this group is *Argas persicus*, a complex of tick species that are important parasites of birds. *Otobius megnini*, known as the "spinose ear-tick," is parasitic to all domestic animals causing severe parasitic otitis externa and predisposing to bacterial infection or myiasis. Most of the pathogenic species of tick are found in the Ixodidae.

Ticks are most important as vectors for a large number of serious viral, bacterial and protozoal diseases of domestic animals. Babesiosis, Rocky Mountain spotted fever, Lyme borreliosis, heartwater disease, Q fever, louping ill, and anaplasmosis are a few examples of tick-transmitted diseases. Ticks also are small, attach firmly to their hosts, utilize multiple hosts, live for prolonged periods of time, and can often survive without feeding for long periods of time. These factors make ticks important in the possible transport and transmission of diseases from one host to another and between countries or continents. Importation of animals harboring ticks can pose a threat to animals in areas free of certain diseases. Ticks also harm their hosts more directly by causing *local injury* at the site of attachment. If infestation is heavy, fatalities may result. The local injury may predispose to myiasis and secondary bacterial infection, particularly to staphylococcal cutaneous abscesses or septicemia. Heavy infestations are also capable of causing *anemia* as a result of the bloodsucking activities of the ticks, but the Ixodidae, which engorge only once at each instar, are much less important in this respect than are the argasid ticks, which as adults engorge repeatedly. Tick bites may also induce hypersensitivity reactions. Several species of ixodid ticks have neurotoxins in salivary secretions that can cause *paralysis* of the host. These species include *Ixodes rubicundus* and *Rhipicephalus evertsi* of South Africa, *I. holocyclus* of Australia, *Dermacentor andersoni* in western North America, and *D. variabilis* in eastern North America.

The *local reaction to ticks is variable*, depending on properties of the tick, for example its ability to secrete prostaglandins, and on host factors such as the level of tick resistance. Primary tick bite lesions are papules and wheals, which proceed to focal areas of necrosis with crusts, erosions and ulcers and lead to focal alopecia. In contrast, tick-sensitized hosts produce extremely erythematous reactions. Histologically, the primary lesions are less severe and develop more slowly than those of sensitized animals. For example, in experimental *Ixodes holocyclus* infestations of cattle, the inflammatory cell reaction to the tick mouthparts embedded deeply into the dermis is not marked, even at 40 hr post-attachment. The lesions are restricted to the immediate feeding site and are predominantly neutrophilic. By contrast, previously sensitized cattle show epidermal spongiosis and vesiculation at some distance from the actual point of penetration as early as 1 hour post-attachment. By 12 hours, intraepidermal vesicles, bullae and microabscesses containing basophils with eosinophils and neutrophils are prominent. Basophils, many degranulated, are numerous in the edematous dermis from 1 hour post-attachment, reflecting the important role cutaneous basophil hypersensitivity plays in tick immunity. Severe hypersensitivity reactions to *Boophilus microplus* have been described in horses in Australia. Within 30 min of reinfestation, sensitized horses develop intensely pruritic papules and wheals, chiefly on the lower legs and muzzle. As tick bite lesions progress, they are often typified by the "arthropod-bite granuloma" described earlier in this section.

Tick infestation in lambs leading to secondary staphylococcal septicemia can result in high mortality.

HELMINTH DISEASES OF SKIN

The skin is the natural portal of entry of a number of metazoan parasites that have their final habitat in the gastrointestinal tract or elsewhere. As a rule, those infective larvae that can invade percutaneously are not host specific, thus infection of aberrant hosts occurs. Such parasites are quite varied in their nature and include infective larvae of trematodes such as *Schistosoma*, and of the nematodes of various genera including *Strongyloides, Gnathostoma, Ancylostoma, Bunostomum, Uncinaria*, and others. Infective larvae of the filariids such as *Dirofilaria* and *Setaria* are deposited in the skin by the biting insects that are their vectors. The first percutaneous invasion of one of these parasites in its natural hosts takes place very quickly (for example, the larvae of *Strongyloides* and *Bunostomum* reach the dermis in 15 min) and provokes little reaction. Repeated invasions in a natural host or single invasion in an unnatural host are met with some resistance that is manifested as acute dermatitis limited to the invaded area. The cutaneous lesions are, except under experimental circumstances, seldom observed in animals. It is on the glabrous nonpigmented skin of people that they are easily observed and well recognized as the so-called "creeping eruption." There the larvae produce acutely inflamed, serpiginous, vesicular to papular tracts that may advance several centimeters a day. Usually, aberrant larvae die in the skin, but some enter the vessels and become lodged in the lungs or other tissues. Nematode larvae most often incriminated are *Ancylostoma braziliense* and *A. caninum*, the canine hookworm larvae. *Uncinaria stenocephala, Bunostomum phlebotomum, Gnathostoma spinigerum, Dirofilaria* sp., *Strongyloides procyonis*, and *Strongyloides westeri* are nematode parasites of other domestic and wild animals that have also been reported to cause cutaneous larval migration in humans.

Hookworm dermatitis occurs in dogs kept on grass or dirt and subjected to poor sanitation. Lesions consist of pruritic red papules on parts of the body exposed to the ground. The footpads and interdigital regions of the feet may be erythematous, edematous and painful. Claw deformities may occur. Histologically, hyperplastic spongiotic perivascular dermatitis with eosinophils and neutrophils is present. Larval tracts may be present in the epidermis or dermis lined by degenerating leukocytes. Inflammation is thought to be due to hypersensitivity reaction to migrating larvae.

The cutaneous lesions produced by the blood flukes and those nematodes that pass through the skin on the way to the gut are discussed elsewhere with the mature parasites (Vol. 2, Alimentary system). To be discussed in more detail here are those helminthic infestations that remain more or less localized to the dermis. The dermatitis produced by the larvae of *Elaeophora* is discussed in Vol. 3, Cardiovascular system.

Cutaneous habronemiasis

The aberrant deposition of the larvae of the spirurid nematodes *Habronema majus* (*microstoma*), *H. muscae* and *H. megastoma* by transmitting flies at cutaneous or mucocutaneous sites causes this *common disease of* **horses**. The adult worms normally develop in the stomach of horses following the ingestion of infective larva (see Vol. 2, Alimentary system). The cutaneous disease occurs sporadically in horse populations in temperate or tropical climates during the summer when the transmitting flies, *Musca* spp. and *Stomoxys calcitrans*, are active. Horses with a hypersensitivity response to the larvae are affected and the condition is recurrent each summer, hence the term, "*summer sores*." Lesions are consistently pruritic.

The location of the lesions is in the moist exposed areas of the body that attract flies. The most common sites are the *medial canthus of the eye* (Fig. 5.112A), *the glans penis and prepuce, and any cutaneous wound*. Since lacerations are more common on the distal extremities, these too are predilection sites for habronemiasis. Fly bites alone are sufficient to initiate an infestation. Ulcerative diseases initiated by other causes can be complicated by habronemiasis.

The gross lesions are rapidly progressive and proliferative in nature, comprising *ulcerated, tumorous masses of red-brown granulation tissue*. The surface is friable and hemorrhages readily. Lesions may be single or multiple and range in size from 5–15 cm in diameter and from 0.5–1.5 cm in depth. They are often irregular in shape in the early stages but become circular as they enlarge. On cut section, multiple small (1–5 mm) yellow-white, caseous, and occasionally gritty foci are scattered through the granulation tissue. These are often confused with the "kunkers" of pythiosis, but lack the characteristic branching pattern of the true kunker. In the deeper parts of the lesion, the more mature connective tissue has a dense, white appearance. The lesions on the conjunctiva and eyelids do not usually exceed 2 cm. Commencing with a serous conjunctivitis, small ulcerated, proliferative nodular lesions develop on the mucous membrane of the third eyelid and at the medial canthus. Lacrimal duct involvement characteristically produces a lesion 2–3 cm below the medial canthus. The entire conjunctiva may be affected resulting in profuse lacrimation, photophobia, chemosis, and inflammation of the eyelid. On cut section, *the nodular lesions of brown-red granulation tissue contain the typical caseous or mineralized foci*. Involvement of the penis and prepuce may cause prolapse of the urethral process and dysuria. On rare occasions, *Habronema* granulomas are found in the lung.

Histologically, multiple aggregates of degenerate eosinophils are scattered randomly throughout a collagenous connective tissue stroma of variable maturity. Epithelioid macrophages, multinucleated giant cells and degenerating eosinophils often surround longitudinal or cross-sections of degenerating larvae, which may be mineralized (Fig. 5.112B). However, *larvae may be rare or absent in many caseous foci*. The fibrous connective tissue is heavily and diffusely infiltrated with eosinophils and with fewer numbers of mast cells, lymphocytes and plasma cells. The surface of the lesion is usually covered with fibrinonecrotic exudate overlying highly vascular granulation tissue infiltrated with neutrophils.

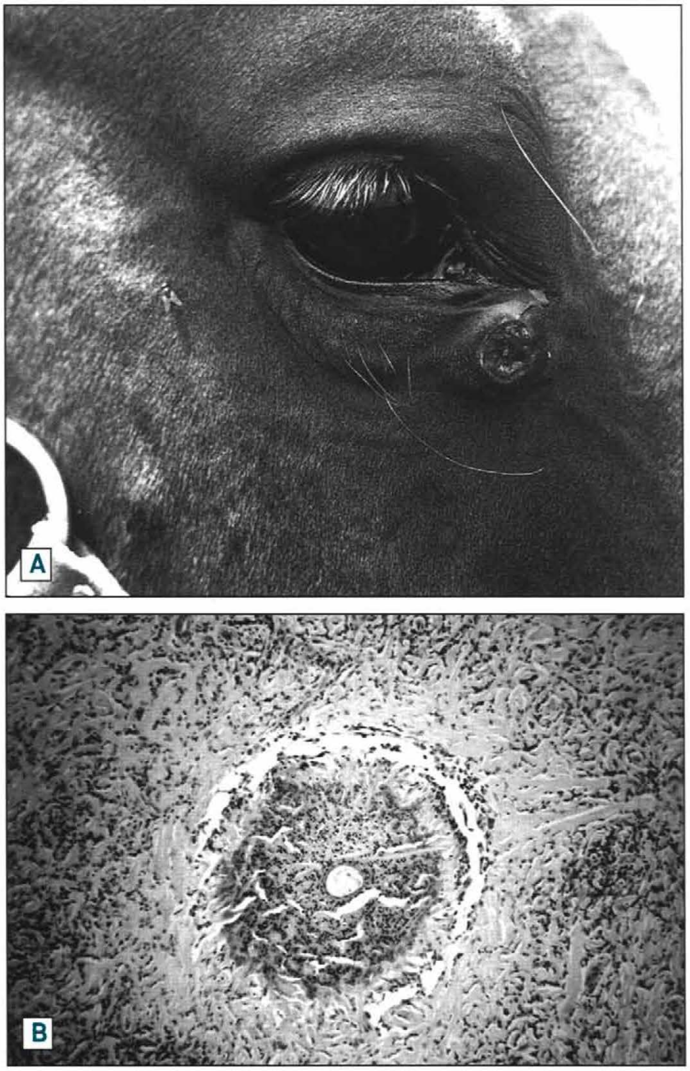

Figure 5.112 Cutaneous habronemiasis in a horse. **A.** Ulcerated nodule below medial canthus. **B.** Clusters of degranulating eosinophils surround a cross section of a *Habronema* sp. larva.

Since the gross lesions of cutaneous habronemiasis may resemble those of exuberant granulation tissue, botryomycosis, pythiosis, equine sarcoid and squamous cell carcinoma, the diagnosis requires biopsy and histologic evaluation. Squamous cell carcinoma and equine sarcoid are readily distinguished histologically. Exuberant granulation tissue lacks the caseous foci of degenerating eosinophils and larvae. Special stains will reveal the causative agents in botryomycosis (see Bacterial diseases of skin) and pythiosis (see Fungal diseases of skin). Nodular collagenolytic granuloma (nodular necrobiosis) presents a different clinical appearance but may be confused histologically with habronemiasis (see Miscellaneous skin conditions). Habronemiasis may complicate a pre-existing lesion; secondary *Habronema* infestations occur with pythiosis, *Corynebacterium pseudotuberculosis* infection and in skin tumors, particularly squamous cell carcinoma of the penis.

Cutaneous habronemiasis has been reported in a **dog**. Lesions developed on the face but, unlike the equine disease, were not characterized by rapid proliferation of granulation tissue. The dog was housed under unsanitary conditions in the company of several heavily parasitized ponies.

Stephanofilariasis

Members of the genus ***Stephanofilaria*** (Spirurida: Setariidae) are parasites of **cattle**. All stephanofilarid parasites cause similar cutaneous lesions, but the species are geographically separated and the lesions occur on different parts of the host's body. *Stephanofilaria stilesi* occurs in North America, affecting the abdominal skin near the midline; in Australian cattle, initial lesions develop at the medial canthus of the eye; *S. dedoesi* in Indonesia causes dermatitis, known locally as "cascado," on the sides of the neck, dewlap, withers and around the eyes; *S. assamensis* causes "hump-sore" of Zebu cattle in India and the Soviet Union; S. *kaeli* causes dermatitis of the legs of cattle from the Malay Peninsula; *S. dinniki* affects the shoulder of black rhinoceros; *S. boomkeri* causes severe dermatitis in pigs in Zaire; *S. zaheeri* causes dermatitis of the ears of buffalo, and *S. okinawaensis* causes lesions on the teats and muzzle of cattle in Japan. *Stephanofilaria kaeli, S. assamensis,* and *S. dedoesi* cause crusting dermatitis in **goats.**

Flies transmit stephanofilariasis. The hornfly, *Haematobia irritans*, is the vector of *S. stilesi* and the buffalo fly, *Haematobia irritans exigua*, is the major vector for stephanofilariasis in Australia. *Musca conducens* transmits *S. assamensis* and *S. kaeli*. The flies ingest microfilariae when feeding on cutaneous lesions. After a period of development in the fly, the infective larva is deposited on the skin by the biting species of fly or onto cutaneous wounds in the case of the nonbiting vectors such as *M. conducens*. The adults of *S. stilesi* live in cystic diverticula off the base of the hair follicles. The parasites are very small, with males reaching 3 mm and females 8 mm in length.

The *initial macroscopic lesions* in *S. stilesi* infections are circular patches 1 cm or less in diameter in the skin of the ventral midline, in which the hairs are moist and erect and the underlying epidermis is spotted with small hemorrhages and droplets of serum. These initial foci enlarge and coalesce, sometimes to produce a lesion 25 cm or more in diameter. As the foci enlarge, new spots of hemorrhage and exudation develop at the periphery while, in the central areas, the hair is shed and the exudate builds up into scabs or rough dry crusts through which the few remaining hairs penetrate (Fig. 5.113). The lesions are mildly pruritic and rubbing may aggravate them. In the healing stage, the affected areas remain as alopecic, lichenified plaques (Fig. 5.114).

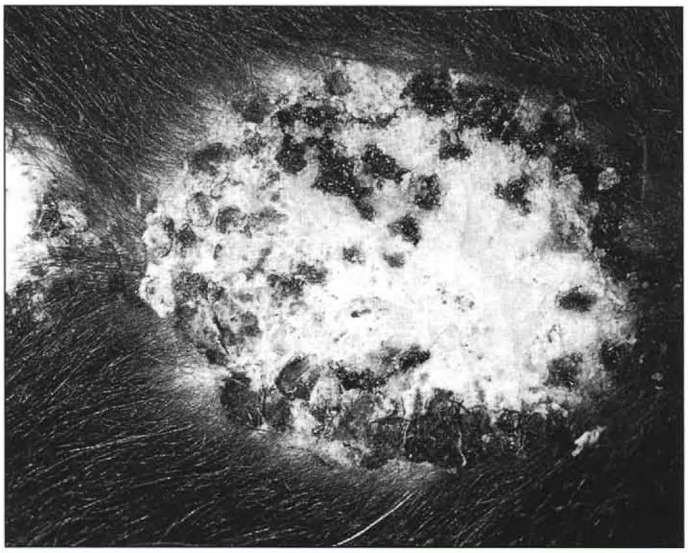

Figure 5.113 Early lesion on the ventral midline in **stephanofilariasis** in a cow.

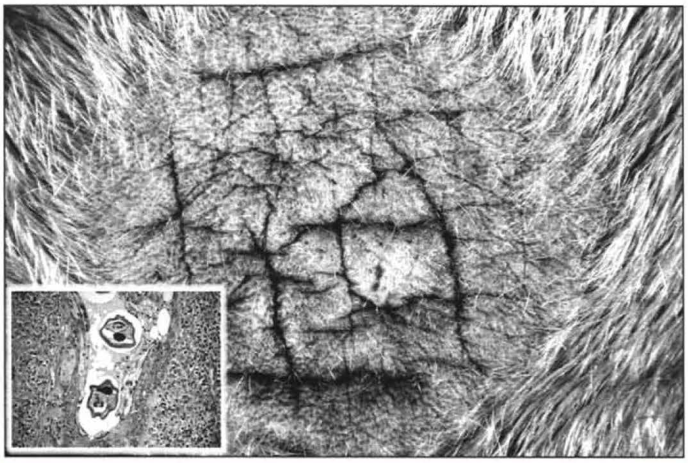

Figure 5.114 Chronic lesion of lichenified, alopecic plaque in **stephanofilariasis**. Nematode within a hair follicle (inset).

Histologically, sections of adult parasites may be seen in the cystic diverticula from hair follicles or lying free in the adjacent dermis. They may be identified as *Stephanofilaria* spp. with some confidence if microfilariae are seen in the uteri of females since this parasite is viviparous; if ova rather than larvae are found, it is more likely for the parasite to be of the genus Rhabditis. Microfilariae occur free in the dermis or in dermal lymphatics, enclosed within their own vitelline membranes (*S. stilesi*), or may be found free or unhatched in surface exudate (*S. kaeli*). There is little dermal reaction to the microfilariae or to the adults enclosed in cystic hair follicles, but the presence of adults in the dermis stimulates a mononuclear inflammatory reaction. There is accompanying superficial and deep perivascular dermatitis characterized by accumulations of eosinophils and mononuclear cells, chiefly lymphocytes. The epidermis is hyperplastic, spongiotic and often covered by orthokeratotic and parakeratotic hyperkeratosis and inflammatory crust. Spongiform microabscesses containing eosinophils and mononuclear cells are also described; such lesions are more typically associated with the bites of arthropod ectoparasites. It is difficult to assess the relative contributions made to the lesion by the stephanofilarial parasite and by the bites of the fly that acts as the vector.

Diagnosis is usually made on the basis of the typical gross lesions, by histologic examination of biopsy specimens or by demonstration of microfilariae by deep scrapings.

Onchocerciasis

Onchocerca spp. are filarial nematodes (Spirurida: Onchocercidae) which affect cattle, horses, sheep, goats and man. *The adult worms reside in various connective tissue locations*, chiefly ligaments, tendons and subcutaneous nodules, but also perimysial sheaths, cartilage and the aorta. The microfilariae migrate to the dermis where they lie free in tissue spaces or lymphatics. In man, blindness caused by migration of microfilariae into the chambers of the eye has been a serious health concern in Africa and Central America. Microfilariae in the dermis of any host are aspirated by the intermediate hosts, which are insects of the families Simuliidae (black flies, buffalo gnats) and Ceratopogonidae (biting midges). The prevalence of infection is very high in cattle and horses, ranging up to 100% in some studies.

Onchocerca cervicalis occurs worldwide and is the major species affecting the horse in North America; adults reside in the ligamentum nuchae and range from 27–75 mm in length. *Onchocerca reticulata* occurs in horses in Europe and Asia; adults live in the flexor tendons and suspensory ligaments, particularly of the forelimbs. *Onchocerca cervicalis* and *O. reticulata* are primarily transmitted by *Culicoides* sp.

Onchocerca gutturosa more commonly affects cattle but also is recovered from horses. *Onchocerca gibsoni* infects cattle in Australia, Asia, and Africa; *O. ochengi* infests cattle in Africa. *Onchocerca armillata* occurs in cattle, sheep, and goats in Africa and Asia; the adults live in the aorta.

Most animals show no reaction to the presence of living microfilariae in the dermis. The reason for the lack of host reaction to the living microfilariae is unknown. Dead microfilariae are, however, highly phlogistic and an intense inflammatory reaction may occur after treatment with microfilaricides in some animals. *Onchocerca* microfilariae cause cutaneous lesions in some horses; in cattle, the adults cause the cutaneous lesions.

In dogs, onchocerciasis has been reported involving the palpebral conjunctiva, third eyelid, sclera, cornea, and retrobulbar space. Dogs were presented for evaluation of periocular or ocular masses. Degenerating or mineralized adult *Onchocerca* spp. parasites were found in the center of pyogranulomas comprising the masses.

Equine cutaneous onchocerciasis

The pathogenicity of *Onchocerca cervicalis* and *O. reticulata* microfilariae, originally questioned because the parasites could be readily demonstrated in the skin of clinically normal horses, became accepted when it was shown that ivermectin treatment induces rapid and concurrent disappearance of cutaneous lesions and microfilariae. The prevalence of adult parasites in horses has not diminished despite the widespread use of avermectins. It has been postulated that individual hypersensitivity to microfilarial antigens is the reason for the sporadic occurrence of equine skin lesions.

Areas affected are the face, neck, medial aspects of the forelimbs, ventral thorax, and abdomen. Lesions on the face may be diffuse, periorbital or central. *The central lesions, which often involve the facial markings, are very characteristic of onchocerciasis.* The lesions on the neck are focal and tend to occur at the base of the mane. Lesions on the ventral thorax and abdomen are often diffuse, in comparison with the localized lesions of horn fly-induced ventral midline dermatitis. The ventral lesions are indistinguishable grossly from those of *Culicoides* hypersensitivity, but onchocerciasis does not cause lesions at the base of the tail. It is likely that onchocerciasis and *Culicoides* hypersensitivity can exist simultaneously.

Cutaneous lesions include partial or complete alopecia, scaling, crusting, and leukoderma. Secondary excoriations or ulcerative dermatitis are induced by self-trauma in pruritic animals. Ocular lesions are discussed in Vol. 1, Eye and ear. The microscopic lesions associated with microfilarial infection vary from none to superficial and deep perivascular lymphocytic and eosinophilic dermatitis. Microfilariae may be present in large numbers or may be very sparse. They are best recovered from unfixed biopsies that are minced and incubated in saline at 37°C. *Differential diagnoses* include other fly-bite-associated dermatitides, staphylococcal folliculitis, occult sarcoid, and infestation with lice, mites, or ticks. Lesion distribution should be helpful.

Viable adult parasites in the nuchal ligament are not associated with significant lesions; in older horses, there is an increased frequency of caseated, mineralized and granulomatous lesions, associated with death of the parasite. *Onchocerca gutturosa* is also found in the nuchal ligament of horses in Australia. Histologic examination revealed that this parasite does not penetrate the elastic tissue of the ligament and the inflammatory reaction is localized around the worm. Mineralization is the fate of degenerate *Onchocerca gutturosa* worms, in contrast to caseation with *O. cervicalis.*

Bovine cutaneous onchocerciasis

Cattle can be infected by three species of *Onchocerca*. Cattle infested with *O. gibsoni* develop multiple subcutaneous papules and nodules of ~2 cm diameter, although lesions up to 9 cm are recorded. Lesions may be hard or soft depending on the degree of mineralization and fibrosis or the degree of caseation and suppuration. Lesions predominantly affect the brisket but also the stifle and hip. Histologic assessment of *O. gibsoni* nodules revealed dead worms and associated degenerative changes such as mineralization in ~30% of nodules. Eosinophilic infiltration was more marked around viable worms, with eosinophils apparently adherent to the cuticle. In *O. gutturosa* infections, the worm is found in the nuchal ligament and connective tissue around tendons and ligaments of the shoulder, hip, and stifle. It does not form nodules and is thus easily overlooked. In *O. ochengi* infections, scrotum, udder, flanks, lateral thorax, and head are affected.

Pinworms

Oxyuris equi infection of the equine large intestine can be associated with *pruritic dermatitis of the perineal region* leading to self-induced excoriations and alopecia of the tail known as "*rat tail*." The adult parasite crawls out of the anus to deposit eggs on the hair and skin using a gelatinous material that can induce pruritus. *Diagnosis* is made by using the tape method in the perianal region for identification of characteristic operculated eggs.

Parafilariasis

Parafilaria multipapillosa occurs in horses in Eastern Europe. *Parafilaria bovicola* is endemic in cattle in Africa, India, and parts of Europe. *Parafilaria bassoni* has been reported in African buffalo and springbok in Namibia. The parasites are thin, thread-like worms, 2–7 cm long. The adults inhabit subcutaneous and intermuscular connective tissues producing nodules 1–2 cm in diameter. In the spring and summer, the nodules rapidly enlarge, burst open, hemorrhage, and heal. This coincides with the migration of the fully gravid female into the more superficial dermis to oviposit and to release the infective microfilariae. The vectors, flies such as *Haematobia atripalpis* in Russia and *Musca* spp., are infected when they feed from these bleeding points, known as "blood nodules." Secondary subcutaneous abscesses may occur.

Pelodera dermatitis

Some of the biological characteristics of the Rhabditidae have been discussed with the principal parasitic genus, *Strongyloides*, in Vol. 2, Alimentary system. Here it is necessary only to describe the cutaneous lesions produced occasionally by the small free-living worms of this family. Those worms that are found in the lesions are usually classified as ***Pelodera (Rhabditis) strongyloides***.

Pelodera dermatitis occurs most commonly in dogs, occasionally in cattle and rarely in horses and sheep. The condition has been reported in humans. The development of dermatitis to a clinical degree probably requires exposure to many larvae. These worms live as saprophytes in warm moist soil that is rich in organic matter, and significant infections probably require that the host's skin should be continually moist and filthy. The lesions develop on contact areas, particularly at the margins of areas caked with dirt. Affected **dogs** often have a history of being bedded on straw. Acute dermatitis develops, commonly with neutrophilic folliculitis and is due to the combined stimuli of the parasites, bacterial folliculitis, and of the scratching, rubbing, and licking prompted by severe pruritus, probably induced by an allergic reaction to the parasite. The gross lesions include erythema, papules, excoriations, scaling, exudation and crusting with partial to complete alopecia. Pustules may occur, particularly in dogs. Histologically, the worms are in the lumina of the hair follicles or in the dermis, surrounded by an intense eosinophilic inflammatory reaction (Fig. 5.115). *Differential diagnoses* based on gross lesions in dogs include hookworm dermatitis, dirofilarial dermatitis, dermatophytosis, demodicosis, bacterial folliculitis, scabies, strongyloidiasis and contact dermatitis. Definitive diagnosis is based upon environmental history and deep skin scrapings or biopsy. *Pelodera* dermatitis in **sheep** may result in complete loss of wool, hyperkeratosis and lichenification in affected areas.

Miscellaneous helminths

Dracunculus medinensis (Spirurida: Dracunculidae) is the "guinea worm" of humans in Asia and Africa. It has been introduced into America, the West Indies, and Fiji. The parasite has been reported in *dogs, cats, horses, and cattle* as well as other species in endemic areas. *Dracunculus insignis* is the species of the nematode that occurs in dogs and wild carnivores in North America. Infection is particularly prevalent in raccoons and mink that appear to be the natural definitive species. The intermediate host is a crustacean copepod but frogs may act as paratenic hosts. Ingesting the intermediate host, infected frogs, or water containing infected copepods infects the final host. The larvae are released during digestion and proceed to migrate through the body. The adult worms mature in the connective tissue of the host in approximately 1 year. The parasite occurs typically in the subcutaneous tissues of the limbs. The mature female may measure up to 70 cm in length, resulting in the formation of a 2–4 cm nodule. The gravid female produces an intraepidermal bulla with her anterior end by means of toxin secretion. Rupture of the bulla forms a shallow ulcer from which a milky exudate drains. When these lesions contact water, the worm is stimulated to release very large numbers of larvae that are ingested by copepods in the water. Fine needle aspiration of the cutaneous nodules reveals rhabditiform *Dracunculus* larvae, approximately 500 μm long and covered by a striated cuticle. The adults lie in a pseudocyst lined by fibrous connective tissue and infiltrated with eosinophils, lymphocytes and multinucleated giant cells. Ulcerated lesions are seen as draining fistulae that may be painful or pruritic. *Differentials* include foreign body, neoplasia, infected wound, or cutaneous dirofilariasis. The parasite can be identified by morphologic features.

Dirofilaria immitis microfilariae can occasionally lead to cutaneous lesions in dogs harboring the adult parasite. A series of five cases document a scabies-like, papular to nodular, variably ulcerated, pruritic dermatitis of the skin of the head, trunk, and extremities in dogs infected with *D. immitis*. Histologic examination of affected skin revealed angiocentric and pyogranulomatous dermatitis with intralesional microfilariae. A type II hypersensitivity response was proposed as a pathogenic mechanism based on positive immunoreaction of microfilariae with anti-IgG serum. Lesions resolved with antiparasitic treatment. Ectopic adult *D. immitis* have been recovered from cutaneous abscesses and interdigital cysts in parasitized dogs. In addition, a generalized cutaneous syndrome characterized by a pruritic papular and crusting dermatitis without intralesional microfilariae has been apparently associated with infection with *D. immitis* and was thought to be a manifestation of an unusual hypersensitivity reaction. Parasites are not present in the cutaneous tissues. Lesions also resolved with antiparasitic treatment. *Dirofilaria repens* occurs in the subcutaneous connective tissues of dogs in Mediterranean countries and tropical parts of the Orient. The intermediate hosts are probably mosquitoes. The microfilariae occur in dermal lymphatics. This parasite is not known to be pathogenic. *Dipetalonema reconditum* occurs in the subcutis of dogs and coyotes. Its only significance is in the differential diagnosis of *D. immitis* infections by identification of microfilariae in peripheral blood.

Dermatitis associated with nematode microfilariae of **undetermined species** has been associated with a pruritic, papular, or plaque-like dermatitis of the head and limbs in dogs determined by multiple assays to be free of adult *Dirofilaria immitis* and *Dipetalonema reconditum*. Lesions were single to multiple, erythematous, alopecic, ulcerated, and crusted. Histologic changes included ulceration and perivascular, periglandular, or interstitial mixed inflammatory cell infiltrates with variable eosinophils and plasma cells. Microfilariae were free within the dermis or subcutis and within microgranulomas. No microfilariae were present within vessels. One adult nematode was also present in the cutaneous tissues and was determined to be *Acanthocheilonema* sp.

Incidental subcutaneous parasitism by the free-living form of the helminth, ***Gordius robustus*** has been reported in the cat. The cat developed a 1–2 cm firm subcutaneous nodule on the back. Histologically, the nodule consisted of an adult nematomorph surrounded by granulation tissue and pyogranulomatous to eosinophilic to lymphoplasmacytic infiltrates. *G. robustus* has a free-living adult form as well as a parasitic larval form that resides in the body cavity of freshwater or terrestrial insects. *Differentials* include many causes of solitary cutaneous nodules. Definitive diagnosis is dependent upon recognizing morphologic features of the parasite.

Suifilaria suis occurs in pigs in South Africa. The worms are 2–4 cm long and live in the subcutaneous and intermuscular connective tissues, sometimes producing small white nodules. The female is oviparous and the eggs are released to the surface via small vesicular eruptions in the epidermis. The remainder of the life cycle is unknown.

Parelaphostrongylus tenuis, a common parasite of white-tailed deer, is an occasional cause of neurological disease in goats. Some affected goats also develop an unusual dermatitis, often restricted to one side of the body. Lesions are vertically oriented, alopecic, ulcerated, crusted or scarred, linear tracks on the shoulder, thorax or flanks. The lesions have been explained tentatively on the basis of ganglioneuritis leading to irritation of dermatomes. Histologically, the lesion is a fibrosing dermatitis with focal areas of basal keratinocyte hydropic degeneration.

MISCELLANEOUS SKIN CONDITIONS

Canine juvenile cellulitis

Canine juvenile cellulitis (juvenile sterile granulomatous dermatitis, puppy strangles, juvenile pyoderma) is an idiopathic disease typically affecting puppies less than 4 months of age. The condition can affect one or more puppies from a litter of any breed but golden and yellow Labrador Retrievers, Dachshunds, Lhasa Apsos, and Gordon Setters are most often reported. A condition clinically and histopathologically identical to juvenile cellulitis has also been reported in adult dogs. Immunologic, infectious, traumatic, parasitic and environmental conditions have all been proposed as possible etiologies. The fact that the lesions are sterile when cultured, nontransmissible, and respond to corticosteroids better than antibiotics alone eliminates infectious agents as probable causes. Special stains and electron microscopy have also failed to identify intralesional infectious agents. Immune system tests have not revealed abnormalities in affected animals. Depressed in vitro lymphocyte blastogenesis responses have been reported but likely represent the result not the cause of the disease.

Cutaneous lesions comprise papules, pustules, crusts, alopecia, and very marked edema (Fig. 5.116). Skin of the muzzle, face, ears, and occasionally the feet, abdomen, vulva, prepuce, and anus are affected. Otitis externa is common. Lymphadenopathy of the mandibular nodes is common and may precede the onset of the skin lesions. Lymphadenitis may also occur in nodes distant to the skin lesions and may occur in the absence of skin lesions. The cutaneous lesions are bilaterally symmetric, painful but not pruritic. Anorexia, fever, malaise and arthritis affecting multiple joints are not uncommon. *Histologically, the lesions are pyogranulomatous nodular to diffuse dermatitis with furunculosis and pyogranulomatous lymphadenitis.* Inflammation often extends into the panniculus. The differential diagnoses include severe bacterial dermatitis, demodicosis, and adverse drug reactions or other cause of angioedema. The condition resolves with proper treatment in 1.5–6 weeks and rarely recurs.

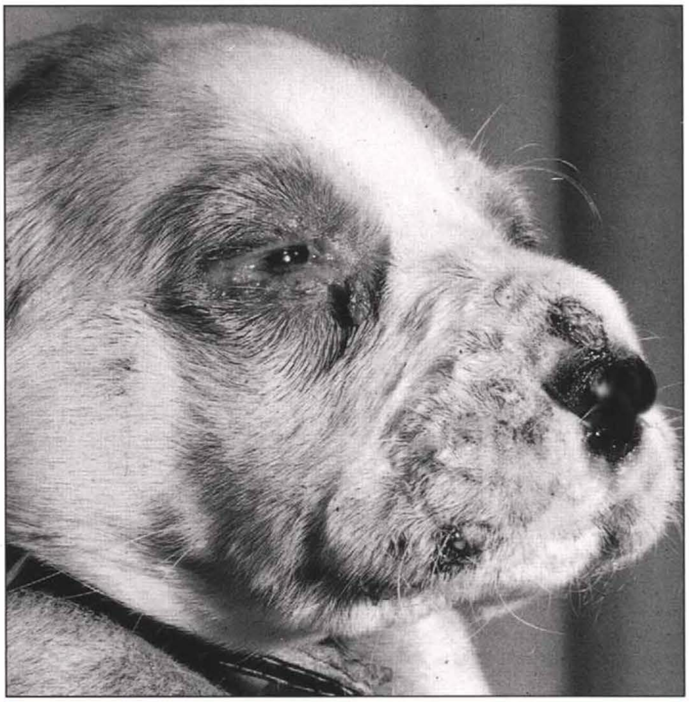

Figure 5.116 Marked soft tissue swelling in **juvenile cellulitis** in a puppy.

Cutaneous paraneoplastic syndromes

Cutaneous paraneoplastic syndromes are dermatoses associated with internal neoplasms. The neoplasms may be malignant or benign but are most often malignant. In keeping with the definition of a paraneoplastic syndrome, *these conditions cannot be directly attributed to the anatomic location of the neoplasm.* The skin or mucosal lesions may precede, concur with, or follow the diagnosis of the underlying neoplasm. Removal or elimination of the tumor should alleviate the cutaneous lesions, while relapse of the dermatosis signals recurrence of the underlying neoplasm. The majority of cutaneous paraneoplastic syndromes in animals do not have a defined pathogenesis and often have only been reported a limited number of times. These syndromes are better documented in humans, but the increased recognition and clinical significance in domestic animals warrants mention in this chapter. The well-recognized cutaneous lesions seen with functional pituitary, adrenal or testicular tumors are discussed elsewhere (see Endocrine diseases of skin). Cutaneous lesions associated with the cryoglobulinemia associated with multiple myelomas have been discussed elsewhere (see Other immune-mediated dermatoses).

A unique dermatosis reported in aged cats is characterized by symmetrical ventrally distributed alopecia affecting the trunk and limbs (Fig. 5.117A) has been reported to be associated with a concurrent **pancreatic carcinoma** or **bile duct carcinoma**. The alopecia is due to *marked follicular atrophy* (Fig. 5.117B). Adnexal structures are also markedly atrophic. The epidermis lacks a stratum

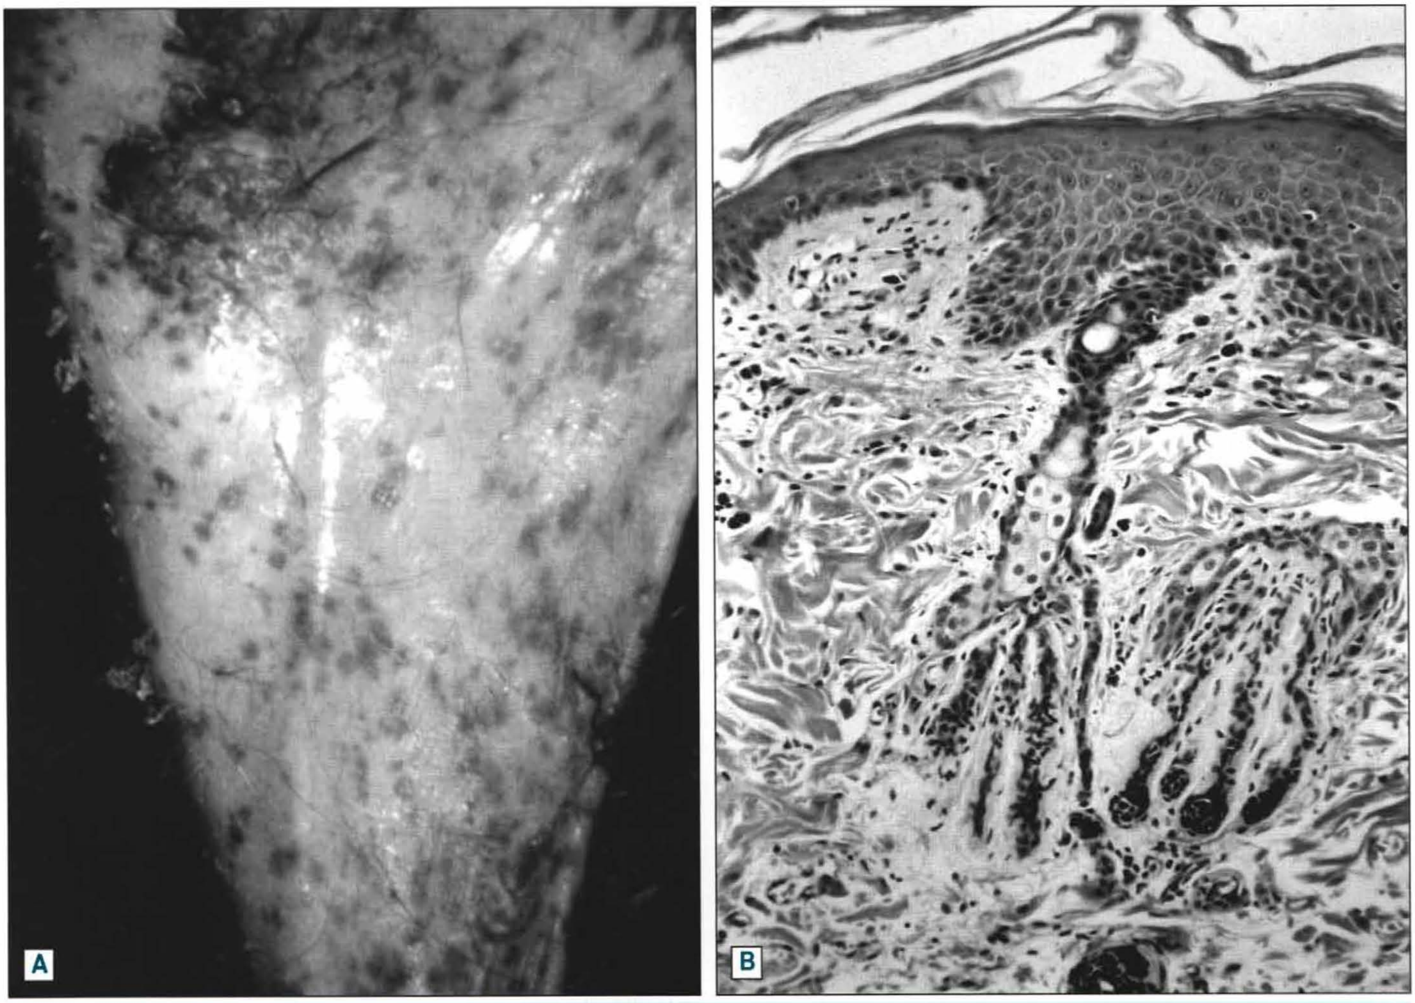

Figure 5.117 Feline paraneoplastic alopecia. (Courtesy of B Dunstan.) **A.** Glistening appearance of the skin on the medial aspect of the limb. **B.** Marked follicular atrophy.

corneum, giving the regions of affected skin the characteristic "glistening" or moist appearance. The lack of the stratum corneum may be due to licking by the cat. Inflammation is not a feature unless complicated by secondary infection. Footpads may be softened and hyperkeratotic. The pancreatic carcinoma is usually in an advanced stage, often with hepatic metastasis at the time of diagnosis and the prognosis is grave. The condition must be differentiated from hyperadrenocorticism and feline psychogenic alopecia.

Thymoma and concurrent **exfoliative dermatitis** has been reported in cats. Cats are usually aged and have signs such as dyspnea and coughing referable to an intrathoracic mass. Cutaneous lesions may be well developed prior to onset of respiratory signs. The cutaneous lesions consist of generalized, dry exfoliative dermatitis with multifocal ulceration, easily epilated hairs and variable pruritus. Histologically, marked orthokeratotic hyperkeratosis with patchy parakeratosis is usually present. The epidermis is hyperplastic with multifocal spongiosis and exocytosis of lymphocytes and variable neutrophils into the surface and follicular epithelium. The dermal component has been reported as either a perivascular mixed infiltrate or a lichenoid, lymphocytic dermatitis with hydropic changes in the basal epidermis and outer follicular root sheath. Epidermal and follicular keratinocyte apoptosis with lymphocytic satellitosis may be present. Some cases have been reported to also have a overgrowth of *Malassezia pachydermatis* and bacteria. It has been speculated that the presence of a thymoma initiates abnormal immunological responses responsible for the dermatitis, which at times can resemble erythema multiforme or graft vs. host dermatitis histologically.

Superficial necrolytic dermatitis (hepatocutaneous syndrome) has been reported in dogs and occasionally the cat. The condition is sometimes associated with **endocrine tumors of the pancreas** (see Nutritional diseases of skin).

Multiple **nodular dermatofibromas** of the distal limbs have been reported in middle-aged German Shepherd Dogs and occasionally other breeds (Golden Retriever, Boxer, Belgian Shepherd, mixed breed) in association with **renal cysts**, **renal cystadenocarcinomas** and/or **uterine leiomyomas** in the bitch. Both kidneys are often affected. The cutaneous lesions range from 2 mm to several centimeters and are comprised of mature, sparsely cellular bundles of collagen within the subcutis or occasionally the dermis (Fig. 5.118A, B). Animals may be presented for examination of the cutaneous lesions prior to signs referable to the internal neoplasms. Death occurs most often due to complications of the renal lesions. Nodular dermatofibrosis is suspected to be inherited in an autosomal dominant manner in German Shepherd Dogs.

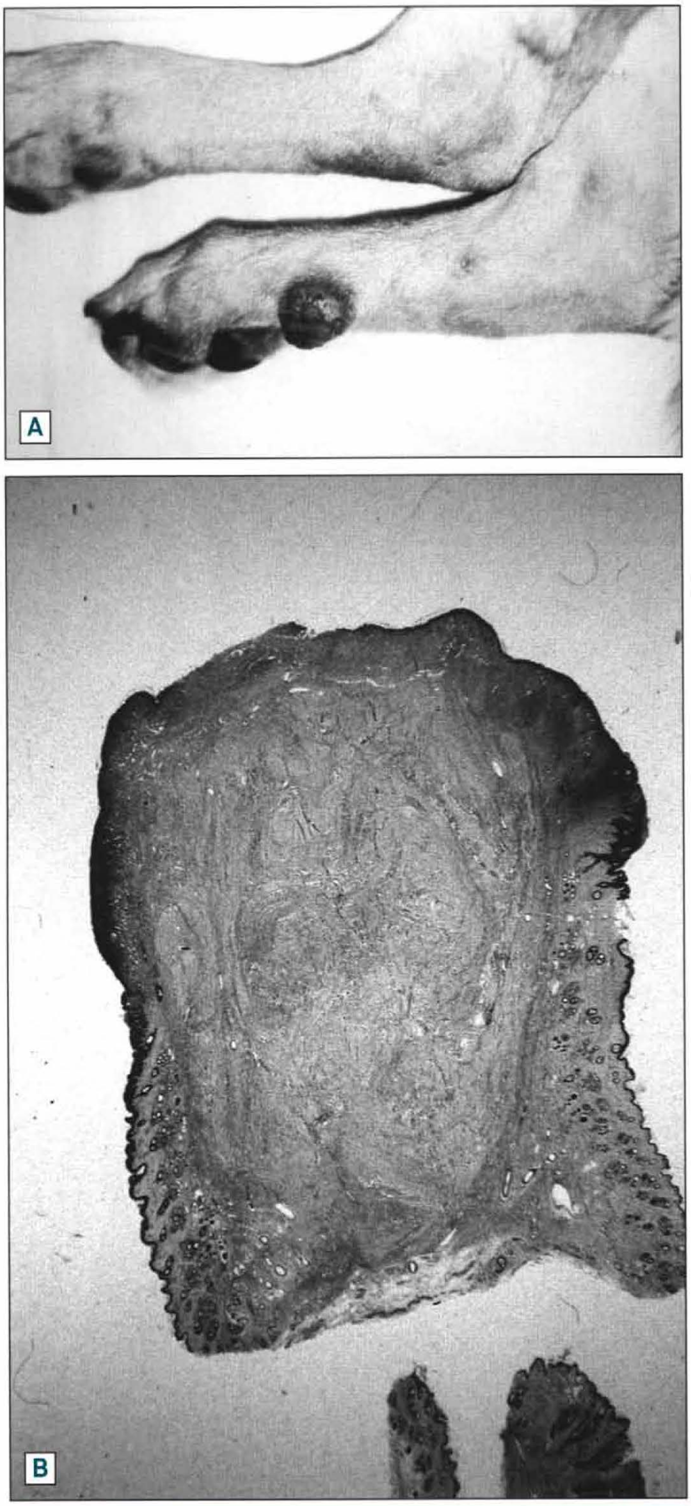

Figure 5.118 Dermatofibrosis in a German Shepherd Dog. (Courtesy of University of Florida Clinical Dermatology Service.) **A.** Protruding fibrous nodule on the distal limb. **B.** Nodule from **(A)** comprises sparsely cellular bundles of mature collagen.

Severe **generalized pruritus** without primary gross or histologic cutaneous lesions or other identifiable cause for pruritus has been reported in the dog and horse in association with underlying **malignant lymphoma**. Self-trauma can lead to extensive excoriations and secondary infection. This condition is also reported in humans with lymphoma and a variety of other internal malignancies. The mechanism of the development of pruritus is not understood but is speculated to be related to tumor-induced release of chemical mediators. Pruritus can only be relieved by successful treatment of the malignancy.

Paroxysmal **cutaneous flushing** of extensive areas of the skin without pruritus has been reported in a German Shepherd Dog with an intrathoracic mast cell tumor and pulmonary adenocarcinoma. Functional pheochromocytomas upon rare occasion can lead to cutaneous flushing in the dog. Flushing is due to vasodilation and is usually caused by vasoactive mediators.

Occasionally, vesicular, pustular or bullous dermatoses virtually identical to idiopathic autoimmune skin diseases may be associated with an underlying malignancy. The tumor is suspected to trigger the production of autoantibodies. These types of paraneoplastic dermatoses must be differentiated from true autoimmune skin diseases as the prognosis may vary. Differentiation is based on ruling out the presence of an underlying neoplasm and resolution of the skin lesions with tumor removal. A **subepidermal bullous stomatitis** microscopically identical to bullous pemphigoid has been reported in a horse in association with a hemangiosarcoma. Immunoprecipitation studies indicated the horse had antibodies to desmoplakin I and II, the bullous pemphigoid 230 antigen, and a 190 kDa antigen. This immunoprecipitation profile was consistent with that reported for **paraneoplastic pemphigus** as reported in humans and the dog. Paraneoplastic pemphigus is a form of pemphigus that is sometimes associated with an underlying malignancy and has been previously discussed (see Immune-mediated dermatoses).

Eosinophilic and collagenolytic dermatitides

The presence of eosinophils in inflammation is usually considered to be an indication of a hypersensitivity reaction or parasitic infestation, however eosinophils can be seen in many diseases and complete understanding of the role of this leukocyte remains to be elucidated. Eosinophils produce lipid mediators that contribute to an acute allergic response, and also TGF-β that is associated with chronic inflammation and fibrosis. Eosinophil cytoplasmic granules contain four cationic proteins that are essential in host defense against parasites, however in the process of this defense the contents of the granules also cause severe tissue damage and contribute to the collagen degeneration and collagenolysis which are so common in many eosinophilic dermatitides. Eosinophilic inflammation in the horse and cat is a common tissue reaction and it seems that the chemotactic stimuli that attract neutrophils in most species attract both eosinophils and neutrophils in these two species.

Feline eosinophilic dermatoses

Cats have several distinct eosinophilic dermatitides, some of which have been previously collected under the term **eosinophilic granuloma complex**. These conditions include *feline eosinophilic granuloma, eosinophilic plaque, and indolent ulcer.* The collective term has been useful as a grouping since these conditions respond to similar treatments. Histologically these three conditions are distinct, although occasionally the features overlap. In addition, allergic dermatitis in cats, such as hypersensitivity to ectoparasites, atopy, and food allergic dermatitis, can demonstrate overlapping features, especially with eosinophilic plaque and occasionally with feline eosinophilic granuloma. Indeed eosinophilic plaque has been established as a hypersensitivity, and although not as yet fully characterized, eosinophilic granuloma and indolent ulcer may well eventually be shown to have an allergic basis. Cats with eosinophilic granuloma can also have eosinophilic plaque or indolent ulcer.

Feline eosinophilic plaque *is a common condition in cats and is a hypersensitivity reaction to food, fleas, or may be associated with atopy.* The condition can occur alone or together with miliary dermatitis, and in some cases the two conditions can form a continuum. It occurs most commonly in the inguinal, axillary, perineal or lateral thigh areas, although it can occur anywhere. *Lesions are pruritic, and affected cats lick them constantly*, resulting in raised, red, ulcerated plaques and patches that can develop peracutely. *Histologically the lesions are characterized by epidermal acanthosis and spongiosis with exocytosis of eosinophils* (Fig. 5.119A, B). In some cases there is epidermal and follicular epithelial mucinosis characterized by pale basophilic or gray mucin between keratinocytes. Inflammation in the dermis is diffuse or perivascular, markedly eosinophilic, and may extend into the subcutis. Mast cells, lymphocytes, and macrophages are present in smaller numbers.

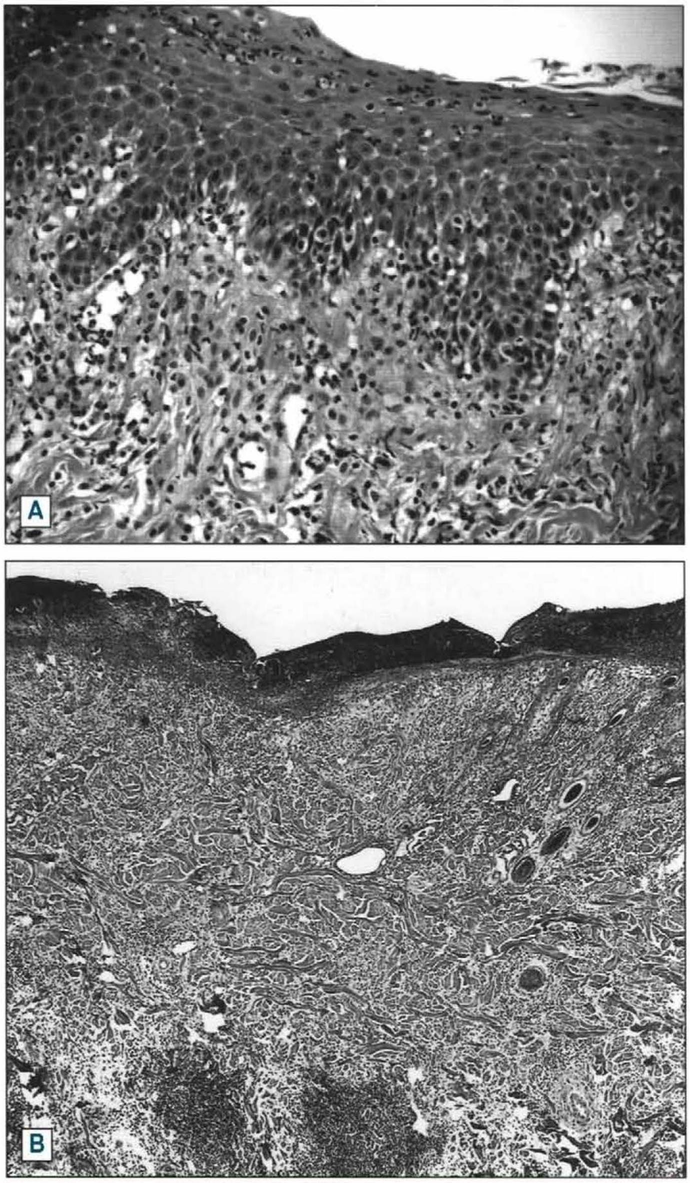

Figure 5.119 Feline eosinophilic plaque. A. Hyperplastic, spongiotic epidermis. **B.** Dermal infiltrate of eosinophils and mast cells.

Feline eosinophilic granuloma (feline collagenolytic granuloma, linear granuloma) is a common condition in cats. It can occur at any age, however is *more common in young cats.* Spontaneous regression can occur. An underlying hypersensitivity has been suggested as the cause however the condition may also occur in cats with no other evidence of allergic disease. A genetic predisposition has been documented in some cases. The lesions can be nodular or linear, and occur on the skin, footpads, mucocutaneous junctions, and in the oral cavity. Linear lesions are more common on the caudal or medial thigh and nodular lesions are more common on the lips, chin, oral cavity and face. The lesions are raised, pink and frequently alopecic. Histologically the lesions are characterized by *diffuse dermal inflammation composed primarily of eosinophils*, with fewer mast cells, macrophages, and occasional lymphocytes. *Within the inflammation are large irregular foci of collagen fibers and degranulated an degenerating eosinophils (flame figures)* (Fig. 5.120). These foci may be surrounded by macrophages and multinucleated giant cells. The epidermis may be acanthotic or ulcerated.

Indolent ulcer (rodent ulcer) is a common and clinically distinct condition in cats. The cause of these lesions is unknown. In

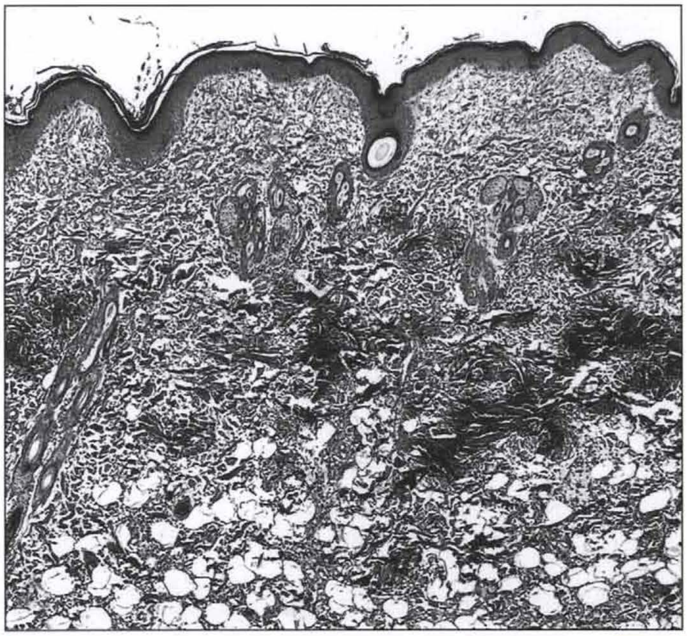

Figure 5.120 Eosinophilic granuloma in a cat. The dermis contains multiple foci of collagen fibers (arrow) surrounded by degranulated and degenerating eosinophils and mononuclear leukocytes (flame figures).

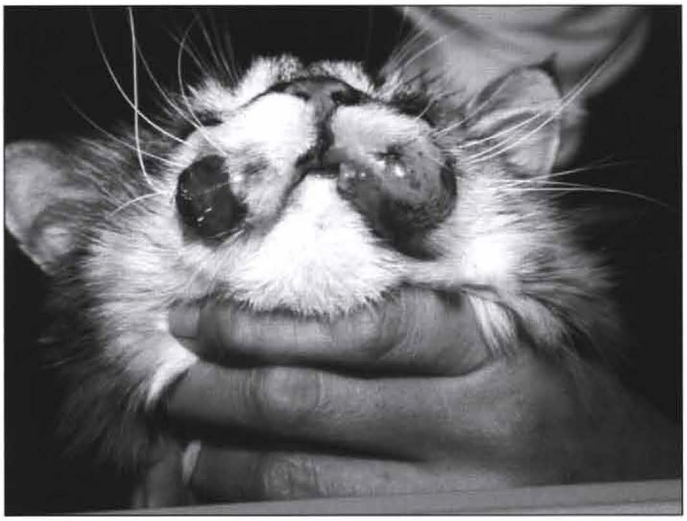

Figure 5.121 Feline indolent ulcer. Ulcerated lesions on the upper lips. (Courtesy of B Dunstan.)

some cats they are reported to be a manifestation of allergic disease, although in other cases an allergic etiology cannot be found. Affected cats can have concurrent eosinophilic granuloma or eosinophilic plaque, increasing the index of suspicion of an allergic etiology. *Clinically the condition is characterized by an ulcerated lesion on the upper lip adjacent to the philtrum that can be unilateral or bilateral* (Fig. 5.121). The ulcers are not pruritic or painful. Histologically the acute lesions are characterized by diffuse infiltrates of eosinophils with neutrophils, mast cells, and macrophages, however the lesions are more often biopsied in the chronic phase when the inflammation is composed almost entirely of lymphocytes, plasma cells, macrophages and neutrophils, together with fibrosis. The numbers of neutrophils vary according to the degree of ulceration.

Canine eosinophilic granuloma

This is a *rare condition in dogs* that histologically has many similarities to feline eosinophilic granuloma. Any breed and age can be affected, however the condition appears to be more common in Siberian Huskies, in dogs under 3 years of age, and males. There may be a genetic basis for the disease in Siberian Huskies and Cavalier King Charles Spaniels. The etiology is unknown although a hypersensitivity has been proposed, due to the fact that the lesions are corticosteroid-responsive, the eosinophilic nature of the lesions, and that there is occasionally circulating eosinophilia. *The lesions can be nodules or plaques, and occur most commonly in the mouth and on the tongue*. Cutaneous lesions can be multiple and there is one report of a single lesion occurring in the external ear canal. *Histologically the lesions are composed of diffuse dermal eosinophilic inflammation within which are foci of degranulating eosinophils and degenerating collagen sometimes surrounded by epithelioid macrophages*. The overlying epithelium or epidermis may be acanthotic or ulcerated.

Equine eosinophilic nodular diseases

Eosinophilic inflammation is a common reaction pattern in the horse, and cutaneous nodules, either single or multiple, are common skin lesions in the horse. Nodular conditions of unknown etiology and pathogenesis include collagenolytic granuloma (nodular necrobiosis), axillary nodular necrosis, and unilateral papular dermatosis. Other eosinophilic nodular conditions with known etiologies, such as cutaneous habronemiasis, can look histologically similar (see Helminth diseases of skin). Cutaneous mast cell tumors in the horse can also be seen clinically as cutaneous nodular lesions, and, as histologically they may contain significant numbers of eosinophils and areas of necrosis, care should be taken to differentiate this tumor from an inflammatory eosinophilic lesion.

Collagenolytic granuloma (nodular necrobiosis, equine eosinophilic granuloma) is the *most common* of the equine cutaneous eosinophilic nodular diseases. The etiology is unknown. Hypersensitivity, especially to insect bites, has been suggested,

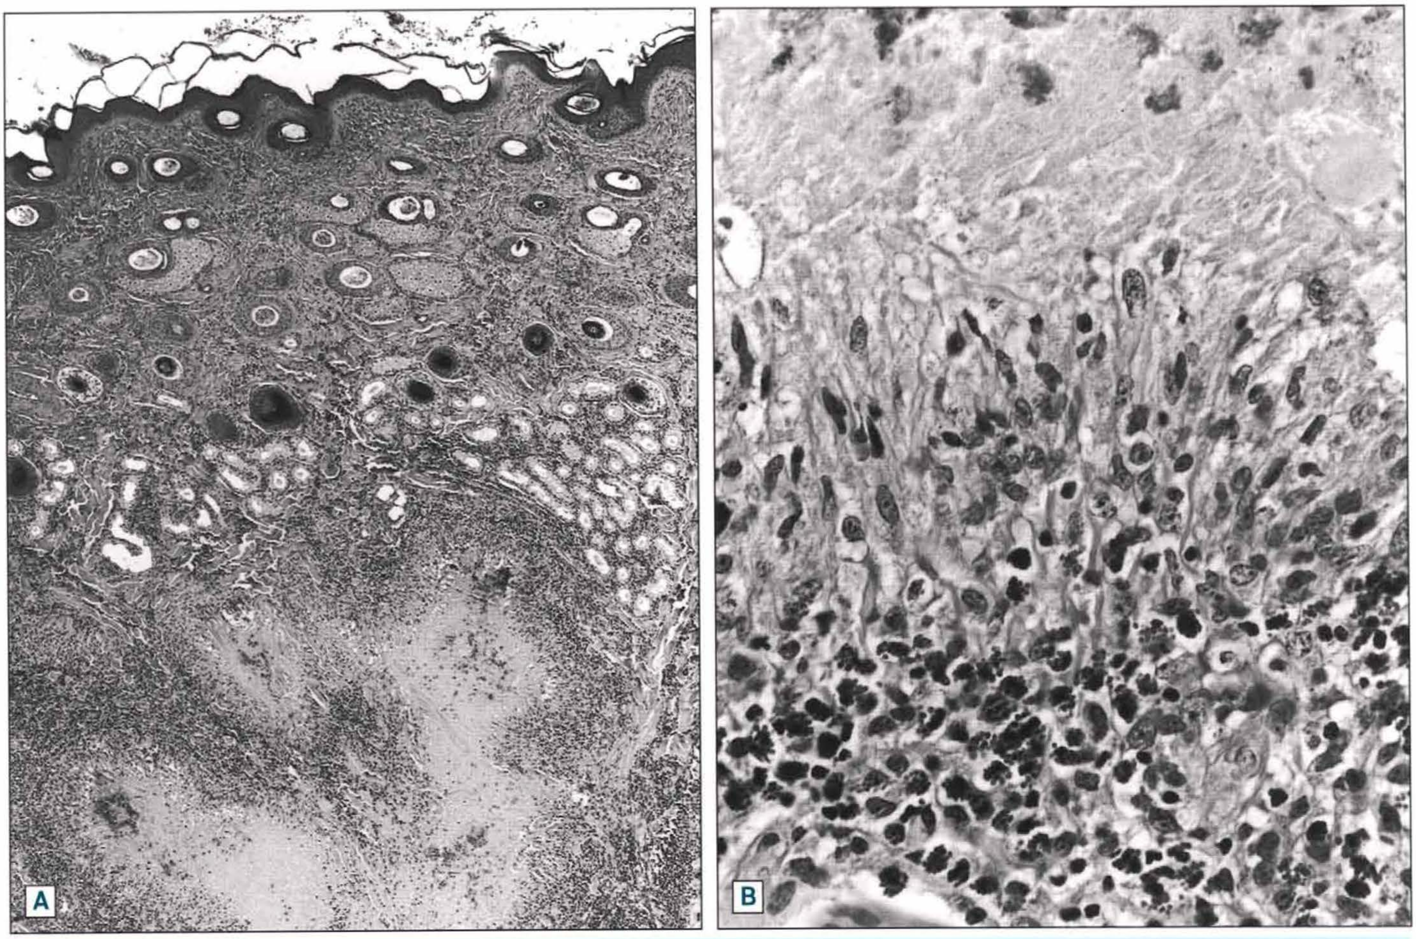

Figure 5.122 Equine nodular collagenolytic granuloma. A. Foci of collagen degeneration deep in the dermis. **B.** Degenerating collagen and degranulating eosinophils are surrounded by epithelioid macrophages and additional eosinophils.

however this has not been fully established. The lesions occur as single or multiple firm nodules measuring 0.5–5 cm in diameter, most commonly on the withers and back but can occur anywhere on the body, and can be generalized. *Histologically the dermal lesions are characterized by foci of dermal collagen degeneration that are surrounded by granulomatous inflammation, sometimes forming a palisading granuloma, and inflammation that is markedly eosinophilic* (Fig. 5.122A, B). Eosinophilic granulomas have also been reported associated with the silicone coating on needles at injection sites, however these lesions are clinically distinct as they tend to be linear, and can usually be documented to be at an injection site.

Axillary nodular necrosis is considerably less common than collagenolytic granuloma. The cutaneous and subcutaneous nodules are 1–5 cm in diameter and can be single or multiple. They are usually unilateral and occur on the trunk behind the axilla, which explains the colloquial term "girth galls." Trauma from tack can explain the ulceration of nodules but is not considered to the cause, which is currently unknown. *Histologically the lesions are characterized by foci of coagulative necrosis that may contain eosinophils, surrounded by eosinophilic and granulomatous inflammation.* Eosinophilic vasculitis can sometimes be found. The collagen degeneration that is a feature of collagenolytic granuloma is not usually a feature of axillary nodular necrosis.

Unilateral papular dermatosis is an uncommon condition in horses seen primarily in the United States, and is more common in spring and summer. It has been seen in many breeds although Quarter Horses appear to be over-represented. *Clinically the lesions are multiple cutaneous nodules and papules, measuring 2–10 mm, which occur in a unilateral distribution, usually on the trunk.* The etiology is unknown, however the seasonality of the lesions together with the eosinophilic nature of the histologic findings *suggests ectoparasite hypersensitivity*. It has further been suggested that the unilateral distribution may indicate direct contact hypersensitivity to an ectoparasite. *The histologic lesions are characterized by small foci of eosinophilic coagulative necrosis that are often folliculocentric, surrounded by eosinophilic dermal inflammation.* Histologic differentiation of this condition from the two preceding nodular diseases in horses, especially in the absence of folliculocentricity, can be problematic without a clinical description of the lesions.

Multisystemic, eosinophilic, epitheliotropic disease in the horse

This rare disease typically occurs in young horses and is characterized by eosinophilic infiltration of many organs, with intestine and skin being most commonly affected. The cause of multisystemic, eosinophilic, epitheliotropic disease is unknown. Proposed etiologies have included viral, bacterial, and toxic mechanisms, however none of these has been confirmed. Recurrent episodes of type I hypersensitivity due to dietary, inhaled or parasitic antigens has been suggested in several reports. There is one report of this condition occurring concurrently with intestinal lymphosarcoma, and several other unpublished cases that appear identical to the case described; the authors suggest that the clonal proliferation of T lymphocytes triggers proliferation of eosinophils by secretion of cytokines such as IL-5. This mechanism has also been proposed in humans who have concurrent abnormal T-lymphocyte proliferations and hypereosinophilic syndrome. Affected horses are presented clinically with weight loss, pitting edema, and often with exudative, exfoliative dermatitis that usually originates at the coronary bands or head and becomes generalized. Eosinophilia is generally absent. Histologically the condition is characterized by *eosinophilic and lymphoplasmacytic infiltration of multiple organs, sometimes with eosinophilic granuloma formation.* Organs most commonly affected include pancreas, gastrointestinal tract, salivary glands, and skin. In the skin the inflammation may be perivascular and interstitial, with epidermal acanthosis and hyperkeratosis, and sometimes with spongiosis and eosinophilic exocytosis into eosinophilic subcorneal pustules.

Sterile eosinophilic folliculitis and furunculosis (eosinophilic furunculosis of the face)

This is an uncommon condition in **dogs** characterized by the sudden onset of painful folliculocentric nodules and papules with erosion or ulceration. The etiology of this condition has not been fully characterized, but *a hypersensitivity reaction to arthropod bites is strongly suspected.* The condition is most common in young, large breed dogs, and lesions are primarily seen on the dorsal muzzle, around the eyes, ears, and less commonly in the axillae, inguinal areas, and ventrum. Histologic lesions are characterized by predominantly folliculocentric eosinophilic inflammation. Eosinophilic luminal inflammation can lead to furunculosis, with free hair shafts surrounded by eosinophils and degranulating eosinophils. The dermal inflammation may be accompanied by edema and mucin deposition, and occasionally dermal collagen necrosis is present.

In **cats**, sterile eosinophilic folliculitis and furunculosis may be seen as a bystander lesion in any allergic dermatitis, however is more commonly seen in mosquito-bite hypersensitivity and feline herpesvirus dermatitis, both of which are most commonly located on the face and head. In **horses**, sterile eosinophilic folliculitis and furunculosis can be seen in any of the eosinophilic nodular conditions or hypersensitivities. However, other than unilateral papular dermatosis, the follicles are affected secondarily and the lesions are not folliculocentric. Sterile eosinophilic folliculitis has been reported in **cattle** and is characterized by multiple crusting or alopecic lesions primarily on the head, neck, and trunk.

Eosinophilic dermatitis with edema

This is a rare condition in dogs. The cause is unknown, although hypersensitivity to drugs, arthropods, or diet is suspected. *It is characterized by erythematous macules and plaques primarily involving the ventral abdomen and ears,* and has been compared to Wells' syndrome (eosinophilic cellulitis) in humans. The histologic lesions are marked perivascular to diffuse eosinophilic dermatitis with edema, and occasional foci of collagen degeneration.

Feline relapsing polychondritis

Feline relapsing polychondritis is a rare condition in the cat characterized by bilateral dorsal or medial curling of the pinnae. The pinnae are discolored purple and markedly edematous. Histologically, lymphoplasmacytic infiltrates surround areas of necrosis of the auricular cartilage. The condition was named after a similar human condition thought to be an immune-mediated attack directed against type II collagen and known to affect other cartilaginous sites such as the nose, trachea, and cardiac valves. The pathogenesis in cats is not defined and despite the name, the condition in cats is not known to be recurrent. Too few cases have been studied to accurately document the clinical course or define association with other diseases.

Follicular lipidosis

Regional alopecia of areas of mahogany-colored points of the hair of the feet and face of young Rottweilers has been reported. Histologically, the lesions are characterized by vacuolation and nuclear pyknosis of the hair matrix cells of primary anagen hair follicles. Matrix cells of the bulb are most severely affected while cells of the internal and external root sheath are affected to a lesser degree. The vacuoles are clear or contain fine granular or clumped melanin. Hair shafts also contain occasional vacuoles and have irregular, thickened, or frayed cuticles. Ultrastructural examination and oil-red-O staining of additional sections confirm the vacuoles to be lipid. *This condition may represent yet another type of color-associated follicular dysplasia.* Too few cases have been recognized to clearly predict the clinical course of the alopecia, or to identify associated abnormalities or the mode of inheritance, if any. The cause has not been determined.

Bibliography

Gross TL, et al. Follicular lipidosis in three Rottweilers. Vet Dermatol 2001;8:33-40.

Follicular mucinosis (alopecia mucinosa)

Follicular mucinosis is characterized by collections of mucin in the outer root sheath of the follicular epithelium and of sebaceous glands. Intraepithelial cysts filled with mucin may form. Grossly, the lesions consist of patchy alopecia and scaling. A disease resembling follicular mucinosis in humans has been described in the **cat** and **dog**. The condition described in 2 cats chiefly affected the head, neck, and shoulders. Histologically, there was mucinous degeneration of the outer root sheath of the follicular infundibulum. Both cats developed epitheliotropic lymphoma within several months of the initial biopsy. Follicular mucinosis has been reported in a 10-year-old male Labrador Retriever. The skin of the head, limbs, and some areas of the trunk were affected. In addition to the histologic lesions described above, there was a perivascular and perifollicular lymphocytic to plasmacytic infiltrate. The epidermis was mildly acanthotic with compact orthokeratosis and multifocal spongiosis with lymphocytic exocytosis. The basal cell layer demonstrated hydropic degeneration, mild apoptosis and prominent pigmentary incontinence. No follow-up information was available. In humans, follicular mucinosis can resolve spontaneously or become a chronic relapsing condition. Some cases are thought to progress to epitheliotropic lymphoma, but this is controversial. It should be noted that epidermal and epithelial mucinosis can be seen in various allergic dermatitides of the cat.

Laminitis

The hoof wall is a complex structure composed of an epidermis and dermis that attaches to the underlying distal phalanx. The distal phalanx is held in place by interdigitation of the epidermal lamina of the inner hoof wall and the dermal lamina of the corium that is attached to the third phalanx. When these laminae fail, the forces of body weight, motion, and tendons lead to sinking and rotation of P3, shearing of vessels that supply these tissues, and damage to the corium of the sole and coronet. *The separation of the distal phalanx (coffin bone, P3) from the inner hoof wall is responsible for the severe clinical signs in laminitis*, rather than a primary inflammatory process. Laminitis occurs in all hoofed species, but particularly affects horses and cattle. *Laminitis is one of the most devastating of equine diseases, often leading to chronic debilitation or euthanasia.*

Precipitating events include trauma and generalized metabolic disturbances. In the horse, laminitis is sporadic, although fat, underexercised ponies are especially predisposed. Colic, sepsis, toxemia, episodes of diarrhea or shock, excessive water (after exercise), or lush pasture intake, carbohydrate overload, drug therapy, and intense training with repeated foot trauma ("road founder") have all been implicated as precipitating events in the horse. Black walnut (*Juglans nigra*) heartwood shavings toxicity causes natural disease in the horse.

Laminitis occurs sporadically in *dairy cows, heifers, fattening cattle, and young bulls*. In cattle, carbohydrate overload is also an important predisposing cause of laminitis. Others include metritis, mastitis, and ketosis. A heritable form has been reported in Jersey cattle in South Africa, the USA, and the UK. *Laminitis, not related to traumatic and metabolic episodes, occurs in all species but is important only in ungulates.* Erysipelas in lambs, the various causative types of footrot in pigs, sheep, and cattle, and bluetongue in sheep are examples of diseases in which degenerative and inflammatory changes occur in the laminae of the hoof.

The *pathogenesis* of metabolic laminitis remains incompletely understood although progress has been made. Past studies suggested that a *primary ischemic event* precipitated laminitis. Recent studies using an equine model of carbohydrate overload-induced laminitis indicate that degeneration of primary epidermal laminae and the basement membrane are responsible for the architectural changes in the hoof wall and the onset of clinical signs. Vascular events leading to ischemia also play an important role in laminitis but are now thought to occur as a consequence of the initial laminar degenerative changes. Events triggering the degeneration are still not completely defined, however bacterial-derived soluble factors generated in the equine large intestine have been shown in vitro to activate laminar enzymes capable of lysing components of the epidermal laminae. Two of these enzymes, metalloproteinase-2 (MMP-2) and metalloproteinase-9 (MMP-9) are present in normal laminar tissues and levels are increased in laminar tissues affected by laminitis. MMP-2, MMP-9, and inhibitors of MMP enzymes are thought to work in concert to regulate epidermal cell-to-cell detachment/attachment and cell-to-basement-membrane attachment during regular growth and maintenance of the laminar tissues. Cultured human keratinocytes increase production of MMP enzymes under the influence of TNF, IL-1 and TFG-1. Factors leading to increased production of MMP-2 and MMP-9 in the epidermal laminae during laminitis are not yet known.

The earliest changes evident in the laminar tissue anatomy during acute laminitis are elongation and disorganization of basal and parabasal keratinocytes and attenuation of the tips of the secondary epidermal laminae. The basement membrane of the secondary laminae detaches first in the region of parabasal cell attachment and subsequently in the region of the basal cells leaving aggregates of degenerating basement membrane components within the connective tissue space between the laminae. *Loss of the basement membrane leads to separation of the dermal and epidermal laminae of the hoof wall and* *is key in loss of structural integrity of the P3/hoof wall attachment.* Collapse of secondary laminae leads to loss of capillaries normally present within the connective tissue between the epidermal laminae. The loss of capillaries leads to increased resistance to blood flow, arteriovenous shunting, and eventual ischemic damage. This early stage is characterized clinically by a bounding digital pulse. Current research suggests that the progression of laminitis in the very early stages prior to degeneration of the epidermal laminae and basement membrane may possibly be slowed or halted by attempts to produce vasoconstriction in the foot (ice-packing). This slowing of circulation would theoretically decrease the delivery of cytokines or other factors responsible for induction of MMP activity.

Acute laminitis is seen as sudden lameness and severe pain affecting most commonly the forefeet but may affect all feet, or just the hind feet. An increase in the hoof wall temperature and a bounding digital pulse indicate marked vascular engorgement in the hoof tissues. In horses, pain is often severe enough to provoke systemic disturbances. A section through an acutely affected hoof reveals little gross alteration beyond congestion of the laminar dermis and occasionally hemorrhage. There is no hoof deformity, although the skin above the coronary band may be swollen. Horses with diffuse swelling and depression along the coronary band are often found to have acute separation and displacement of P3 and are referred to as "sinkers," a manifestation of acute laminitis. Microscopic changes are as described above. In addition, the dermis may be congested, edematous, and have mild hemorrhage and mild infiltrates of mononuclear cells. In time, coagulative necrosis of the secondary laminae may be evident.

Chronic laminitis is defined clinically as the phase commencing after several days of lameness or when *rotation of the third phalanx is first radiographically evident.* The rotation has been attributed to loss of the interlocking force normally supplied by the epidermal laminae. In chronic cases, the ventral deviation is caused also by irregular hyperplasia of epidermal laminae placing a wedge of epidermis between the phalanx and the immovable hoof wall. The weight of the animal, the leverage forces placed on the toe and the pulling forces of the deep digital flexor tendon contribute mechanically to the rotation. *In severely affected animals, the third phalanx may penetrate the sole*, which becomes convex. A mid-sagittal section through the hoof wall at this point will show obvious separation of P3 from the dorsal hoof wall, sinking and various degrees of rotation of P3. The corium at the coronary band and sole may be edematous or hemorrhagic. In long-standing cases, the space between the dorsal hoof wall and P3 is filled with firm white tissue (proliferative epidermis). The toe usually turns up and the cranial aspect of the hoof becomes concave and wrinkled by encircling horizontal ridges.

The chief microscopic lesion in chronic equine laminitis is marked irregular hyperplasia of the epidermal laminae. The regenerating secondary laminae may not regain their orderly arrangement and instead form irregular and anastomosing epidermal cords. The epidermal laminae, both primary and secondary, become markedly hyperkeratotic. The reason for the hyperkeratosis is not known. Both physical and physiologic influences on keratogenesis are likely altered in chronic laminitis. Similar epidermal lesions occur in chronic bovine laminitis, although parakeratotic hyperkeratosis develops in addition to the orthokeratotic hyperkeratosis. Alterations in the dermal vasculature are most prominent in cattle. Moderate-to-marked arteriolosclerosis and arteriosclerosis occur in chronic bovine laminitis, especially in the solar dermis. Other changes in laminitis in cattle include chronic dermal granulation tissue, organized and recanalized vascular thrombi, perineural fibrosis and perivascular accumulations of macrophages, often containing hemosiderin.

Localized scleroderma

Localized scleroderma (morphea) is a rare disease of dogs and cats. *Asymptomatic, well-demarcated, sclerotic plaques that are alopecic, smooth and shiny characterize the condition.* Lesions tend to be linear and occur on the trunk, limbs, and head. Diffuse fibrosing dermatitis is seen histologically. Dense collagen bundles replace the entire dermis and subcutis. Pilosebaceous units are essentially absent. A mild superficial and deep perivascular accumulation of lymphohistiocytic cells is present. The pathogenesis is not defined. Affected animals are otherwise healthy and lesions have been reported to regress spontaneously in some cases.

Porcine juvenile pustular psoriasiform dermatitis

This disease of weanling pigs was originally named **pityriasis rosea**. Because the clinical signs and gross lesions bear little relationship to those of the human disease for which it was originally named, the new designation, porcine juvenile pustular psoriasiform dermatitis, has been suggested. *The disease is of no significance, except esthetic. The cause is not known.* A hereditary predisposition has been suggested but not proven, particularly in Landrace pigs. Lesions develop most often in weaned pigs 3–14 weeks of age. Entire litters or just a few piglets may be affected.

The disease begins with nonpruritic, small scaly, erythematous papules on the skin of the abdomen and inner thighs. The papules expand centrifugally to produce at first scaly plaques and later, when the central areas return to normal, ring-shaped, erythematous lesions (Fig. 5.123). As the rings expand, they coalesce to produce mosaic patterns and may extend to the sides and perineum. *The clinical differential diagnoses include swinepox, dermatosis vegetans, and ringworm.* The acute histologic lesion is superficial and deep perivascular dermatitis with eosinophils, neutrophils and mononuclear cells. Spongiosis and leukocytic exocytosis lead to the formation of spongiform pustules, and there is superficial dermal mucinous degeneration. Superficial epidermal necrosis may extend into the ostia of the hair follicles. As the lesions heal, marked psoriasiform hyperplasia and parakeratotic scale-crusts are predominant. The condition spontaneously resolves within about 4 wk.

Spiculosis

Spiculosis is a dysplastic and dyskeratotic condition of the hair follicle that results in 1–2 mm diameter and 0.5–2.0 cm long brittle spicules (hair shafts) protruding from hair follicles. The condition has been reported in humans and Kerry Blue Terriers. Clinically, the condition is characterized by coarse, brittle, and long hair shafts and pruritus, scaling, and alopecia of the skin of various areas of the body. Histologically, hair follicles have enlarged hair bulbs that may have two dermal papilla. Enlargement of the hair bulb is due to collections of heavily pigmented matrix cells that keratinize prematurely to form hyperpigmented keratinized amorphous masses or columns of unpigmented keratin in place of normal hairs.

Sterile granulomas and pyogranulomas

Sterile granulomatous or pyogranulomatous dermatoses have been reported in dogs, cats, and less commonly in horses. Absence of microbial agents and foreign material and good response to glucocorticoid therapy has suggested an *immune-mediated pathogenesis.*

Sterile pyogranuloma syndrome

The sterile granuloma/pyogranuloma syndrome (idiopathic periadnexal multinodular granulomatous dermatitis) occurs in **dogs** of all ages and sexes but Collies, Boxers, Great Danes, Weimaraners, English Bulldogs, Doberman Pinschers, Dachshunds, and Golden Retrievers appear to be predisposed. The condition is clinically and, in many respects, histologically very similar to cutaneous reactive histiocytosis as described in dogs (see Histiocytic proliferative disorders). Future studies may indicate that these two entities are a single disorder. Most

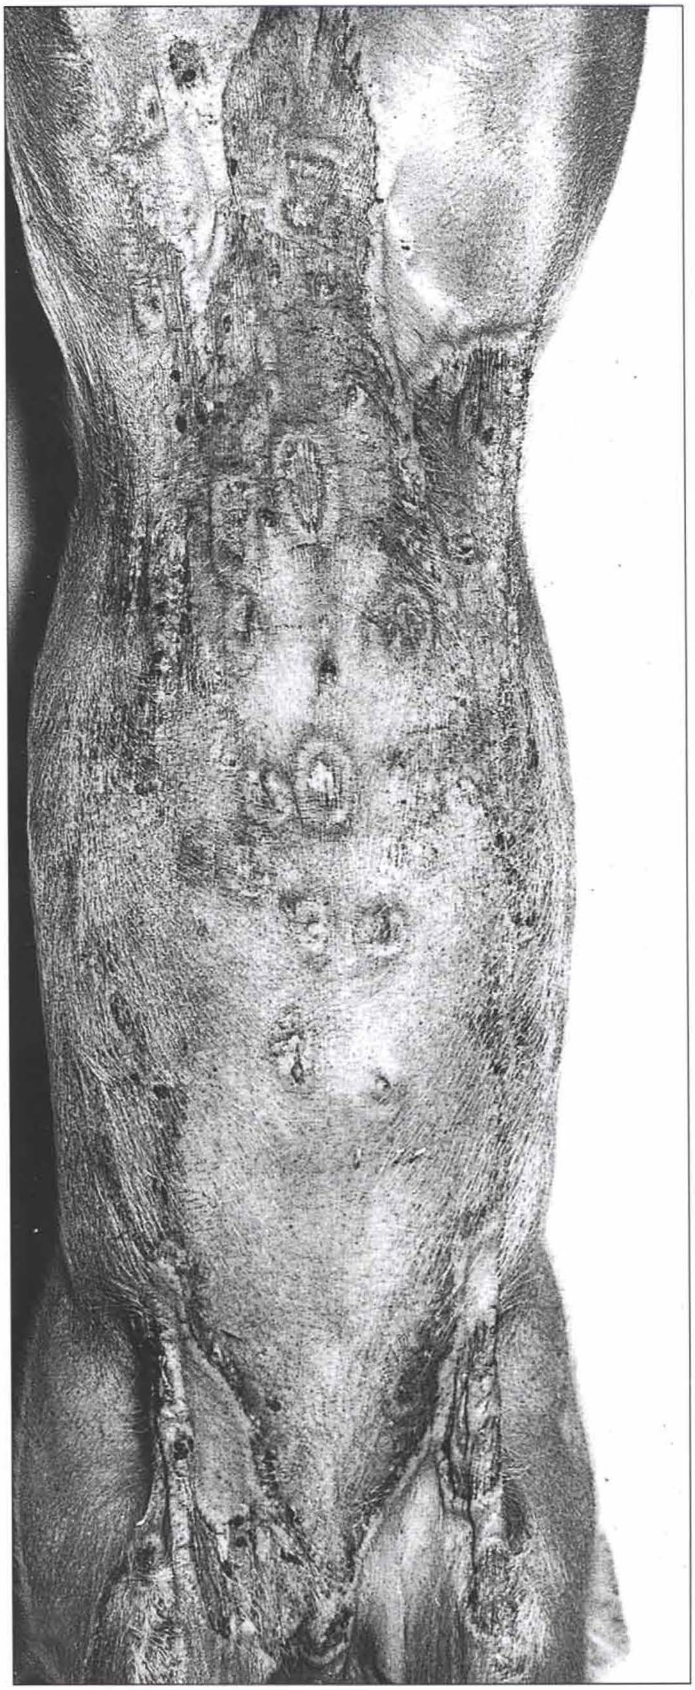

Figure 5.123 Porcine juvenile pustular dermatitis. Circular, ring, and coalescing lesions of the ventral abdomen and proximal limbs. (Courtesy of JA Flatla.)

dogs have multiple asymptomatic haired to partially alopecic papules, nodules or plaques on the face and/or feet. Pedal lesions are frequently secondarily infected, ulcerative and fistulous. The pinnae, periocular region, trunk and abdomen may also be affected and lymphadenopathy may be present. Dogs are not systemically ill and the condition may spontaneously resolve or wax and wane. Histologic findings include *large perifollicular granulomas or pyogranulomas* that are elongated and vertically oriented that track hair follicles but do not invade them. Older lesions may become diffuse; obliterating adnexal structures and extending extend into the subcutis. Histiocytes, lymphocytes and neutrophils predominate, with occasional plasma cells or multinucleated giant cells.

Sterile granulomatous or pyogranulomatous dermatitis has also been reported in **cats**. Older male cats had multiple, pruritic, erythematous-to-violaceous papules, nodules and plaques, especially on the head and pinnae. Histologically these lesions were characterized by perifollicular pyogranulomatous dermatitis. Middle-aged female cats had pruritic, bilaterally symmetric, erythematous-to-purpuric plaques in the temporal regions. Histologically these lesions were characterized by nodular-to-diffuse granulomatous inflammation wherein multinucleated histiocytic giant cells, unexplained purpura and erythrophagocytosis, and a superficial dermal Grenz zone were prominent features.

The histologic differential diagnoses includes inflammation due to the presence of infectious agents or foreign material, sarcoidosis, sebaceous adenitis, and cutaneous reactive histiocytosis. Negative special stains for bacterial and fungal organisms, negative cultures, lack of polarization of foreign material on microscopic examination and failure to respond to antibiotics are supportive. Sebaceous glands are clearly the target of inflammation in sebaceous adenitis leading to somewhat regular and mid-dermal perifollicular location of inflammatory nodules. Lesions of cutaneous histiocytosis may be difficult to distinguish and both conditions may have a waxing and waning course. Distinct, organized granulomas are typically not present in cutaneous reactive histiocytosis whereas they may be present in sterile nodular pyogranuloma syndrome. Histiocytes are often larger, possibly atypical and may have numerous mitotic figures in cutaneous reactive histiocytosis.

"Sarcoidal" granulomatous disease

Sarcoidosis in humans is a systemic granulomatous disease of undetermined etiology. The granulomas are characteristic, being composed predominantly of epithelioid macrophages with few lymphocytes ("naked" granulomas).

A sterile "sarcoidal" granulomatous dermatitis has been described in **dogs** and **horses**. Dogs develop multiple erythematous papules, nodules and plaques that were neither pruritic nor painful. The lesions most commonly affected the neck and trunk. Nodular-to-diffuse sarcoidal granulomatous inflammation was present histologically.

Equine generalized granulomatous disease is characterized by exfoliative dermatitis, wasting, and sarcoidal granulomatous inflammation in multiple organ systems and is discussed in more detail in Vetch toxicosis and vetch-like diseases.

Sterile nodular panniculitis

Panniculitis refers to inflammation of the subcutaneous adipose tissue. Panniculitis has many causes, most of which have been discussed in previous sections (bacteria, fungi, immune-mediated disease, trauma, injection of irritant substances, foreign bodies, nutritional disorders, adverse reactions to vaccines or other injections, pancreatic disease). *The syndrome of sterile nodular panniculitis currently is considered to be idiopathic and the diagnosis is largely based on elimination of known causes of panniculitis, particularly panniculitis due to infectious agents.* It is likely that future studies will provide insight into the pathogenesis of lesion formation and define specific diseases now grouped within this syndrome.

In sterile nodular panniculitis, adipose tissue is the primary target of inflammation. Excisional biopsy is necessary to establish the diagnosis as the lesions are often confined to the subcutis and deep dermis. It is a rare condition affecting **dogs, cats**, and **horses**. There is no age or breed predisposition in cats or horses but, in dogs, affected animals are usually young (<1 yr) and Dachshunds and Poodles are over-represented.

The gross lesions are subcutaneous nodules that may become cystic, ulcerate or develop fistulous tracts. The exudate may be oily, serosanguineous, or hemorrhagic. Lesions are often multiple, 0.5 to several centimeters in diameter and may be grouped or distributed widely (Fig. 5.124). There is a tendency for the canine lesions to affect the trunk. Lesions in the horse are most often found on the neck, thorax, abdomen, and proximal limbs and may elicit pain upon palpation. *The microscopic lesion is lobular panniculitis that varies from necrotizing, to pyogranulomatous or granulomatous, to fibrotic, depending on the stage of the lesion.* Lipid released from damaged

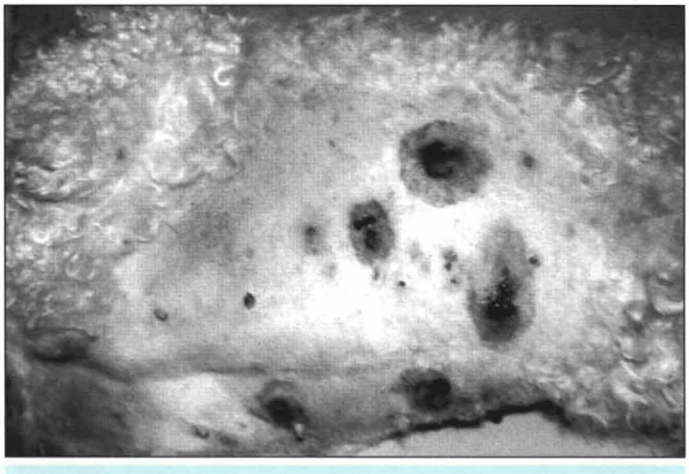

Figure 5.124 Sterile nodular panniculitis. Note multiple draining lesions on the trunk.

lipocytes hydrolyzes to glycerol and fatty acids. Fatty acids incite further inflammation that perpetuates the lesions. Affected animals with single lesions may be asymptomatic while animals with multiple lesions often have pyrexia, lethargy, and anorexia. A normochromic, normocytic nonregenerative anemia is seen in chronically affected animals with multiple extensive lesions. *Sterile panniculitis is indistinguishable histologically from the panniculitides of infectious cause.* The lesions fail to respond to antibiotics but resolve with corticosteroid therapy, sometime leaving residual scars. Some cases spontaneously regress. The condition can be recurrent.

Necrotizing panniculitis

Panniculitis secondary to pancreatitis and pancreatic neoplasia is well-recognized in humans. *Necrotizing cutaneous lesions are rare complications of pancreatic disease in the dog.* Cases have been reported in a dog with pancreatic carcinoma and one with pancreatic nodular hyperplasia. The pathogenesis likely pertains to the release of pancreatic lipases.

The lesions are multifocal, erythematous, nonpruritic cutaneous nodules, which may ulcerate centrally and discharge seropurulent exudate. Histologically, the lesion is necrotizing panniculitis in which mineralization of the lipocytes is a predominant feature. The initial inflammatory reaction is neutrophilic but may become granulomatous with time.

Symmetrical lupoid onychodystrophy

Symmetrical lupoid onychodystrophy (SLO) is a degenerative disease of the nailbed in **dogs**. A wide variety of breeds and both male and females are affected. Dogs between 1–8 years are more commonly affected. German Shepherd Dogs, Rottweilers, Miniature Schnauzers, Golden and Labrador Retrievers, Boxers, and Greyhounds may be predisposed. The condition is characterized initially by brown discoloration of the proximal nailbed followed by separation and sloughing of one or more of the claws of multiple feet in otherwise healthy dogs. The condition is painful and often leads to lameness. Amputation of the third phalanx of affected digits to include nailbed epithelium is often needed to establish the diagnosis. Histologic lesions are most pronounced on the dorsal aspect of the claw. *The most common changes are a lichenoid interface dermatitis with lymphocytic exocytosis and spongiosis and multifocal hydropic degeneration of the basal epidermis.* Pigmentary incontinence may be severe and there may be dermal hemorrhage or fibrosis and mucinosis of the deep dermis. Direct immunofluorescence for deposits of immunoglobulin have not revealed specific labeling. Nails regrow but are misshapen, dry, soft or brittle and discolored. Secondary bacterial infection may occur. *The pathogenesis of SLO is not known* and, in fact, the possibility that SLO is not a specific disease entity but merely an inflammatory reaction typical for the nailbed has not been ruled out. Amputation of the third phalanx and histopathological evaluation of this tissue is a relatively new procedure. *The clinical differential diagnoses includes pemphigus, lupus erythematosus, vasculitis, keratinization disorders, and bacterial or fungal infection.*

NEOPLASTIC AND REACTIVE DISEASES OF THE SKIN AND MAMMARY GLANDS

Epithelial tumors of the skin

Epithelial tumors of the skin are classified according to the predominant pattern of differentiation and the biological behavior. Recent refinements of the classification of a number of these tumors according to the World Health Organization International Histological Classification of Tumors of Domestic Animals have led to changes in nomenclature. These changes may not be widely accepted, as justification for reclassification based on prognosis or response to therapy has not been forthcoming. The decision to classify a given tumor as one or another of the epidermal or adnexal tumors is often quite arbitrary. A neoplasm of the multipotential germinal cells of the epidermis may differentiate into a number of types of epithelial cells characteristic of mature cells of the various components of the epidermis or adnexa. Sometimes the differentiation results in a distinctive group of tumor cells, making precise identification unequivocal. At other times, the tumor cells may differentiate toward several skin structures forming squamous cells, sebaceous cells or components of the hair follicle. The tumor can then be named according to the most aggressive or dominant cell type within the tumor. Other than squamous cell carcinomas, the majority of tumors derived from the epidermis or adnexa exhibit benign behavior.

Tumors of the epidermis include squamous papilloma, squamous cell carcinoma, and basal cell tumors. *Adnexal tumors of follicular origin* include infundibular keratinizing acanthoma (intracutaneous cornifying epithelioma, keratoacanthoma), tricholemmoma, trichoblastoma, trichoepithelioma, and pilomatricoma. *Adnexal tumors arising from glandular structures* include sebaceous gland tumors, apocrine gland tumors, and eccrine gland tumors. Also included in this section are varieties of tumor-like or keratin-filled cystic lesions that can be confused with true neoplasms. Mention will be made also of tumors that metastasize to the skin.

Cysts, hamartomas, and tumor-like lesions

Cysts

Infundibular cysts (epidermoid cyst, epidermal cyst, epidermal inclusion cyst) are seen as single or multiple, smooth, most often unilocular, spherical dermal nodules seldom larger than 1 cm in diameter. *Each nodule consists of an orderly wall of stratified squamous epithelium identical to epidermis, with gradual keratinization at its luminal surface* (Fig. 5.125A, B). *The cyst lumen is filled with concentric laminations of keratin.* There is usually neither mineralization nor inflammation within the cyst. The basal layer of the cyst wall abuts dermal collagen in a smooth line analogous to the normal dermal–epidermal junction. In longstanding lesions, the epithelial wall may become very thin, and *rupture may release entrapped keratin to stimulate pyogranulomatous dermal inflammation.* Infundibular cysts may arise from dilatation of the infundibulum of occluded hair follicles, and indeed occasionally one can detect superficial dermal scarring that may support this hypothesis. As well, such cysts may contain fragments of mature hair shafts. Other cysts arise from traumatic, developmental or surgical implantation of epidermal fragments into dermis or subcutis. Penetrating grass seeds cause implantation of epidermal fragments in **sheep**. Occasionally, an epidermal inclusion cyst (*subungual epidermal inclusion cyst*) can be found within the bone of the third phalanx of the **dog**. One report in the dog documents multiple squamous cell carcinomas arising from multiple infundibular cysts in a dog. In the **horse**, epidermal inclusion cysts are most commonly reported to occur in the nasal diverticulum (*atheromas*) or at the base of the ear (*dentigerous cysts*).

Isthmus cyst is a cyst lined by a keratinizing epithelium that lacks a granular layer. The inner layers of the epidermis lining the cyst have large amounts of pale eosinophilic cytoplasm and inconspicuous intercellular bridges.

Panfollicular cyst (trichoepitheliomatous cyst, hybrid cyst) is lined by stratified squamous epithelium that includes areas resembling both the infundibular cyst and isthmus cyst. In addition, areas of squamous epithelium comprised of primitive basal cells with abrupt keratinization to shadow cells may be present.

Dilated pore of Winer is a flask-shaped epidermal cyst on the head or neck of middle-aged or old cats and rarely, dogs. It is connected to the skin surface by a pore. It differs from the infundibular cyst in that the stratified keratinizing epithelium of the cyst wall near its base is hyperplastic with very regular rete ridges in parallel columns. For practical purposes, *it is yet another variant of epidermal/follicular cyst.*

Keratoma (horn cyst, horn tumor, keratin cyst) is a keratin-filled cyst arising from the coronary band. They are seen in cloven-hoofed animals and have been most often reported in the **horse**. The cysts are 1–5 cm in diameter and grow distally, between the third phalanx and the hoof wall. Keratomas are painful, causing lameness and bulging of the affected area of the hoof wall. *Histologically, the cyst is lined by squamous epithelium of the primary epidermal lamellae and filled with laminated keratin that in some cases may mineralize.* Trauma to the hoof wall and infection have been suggested, though not proven, causes of keratomas.

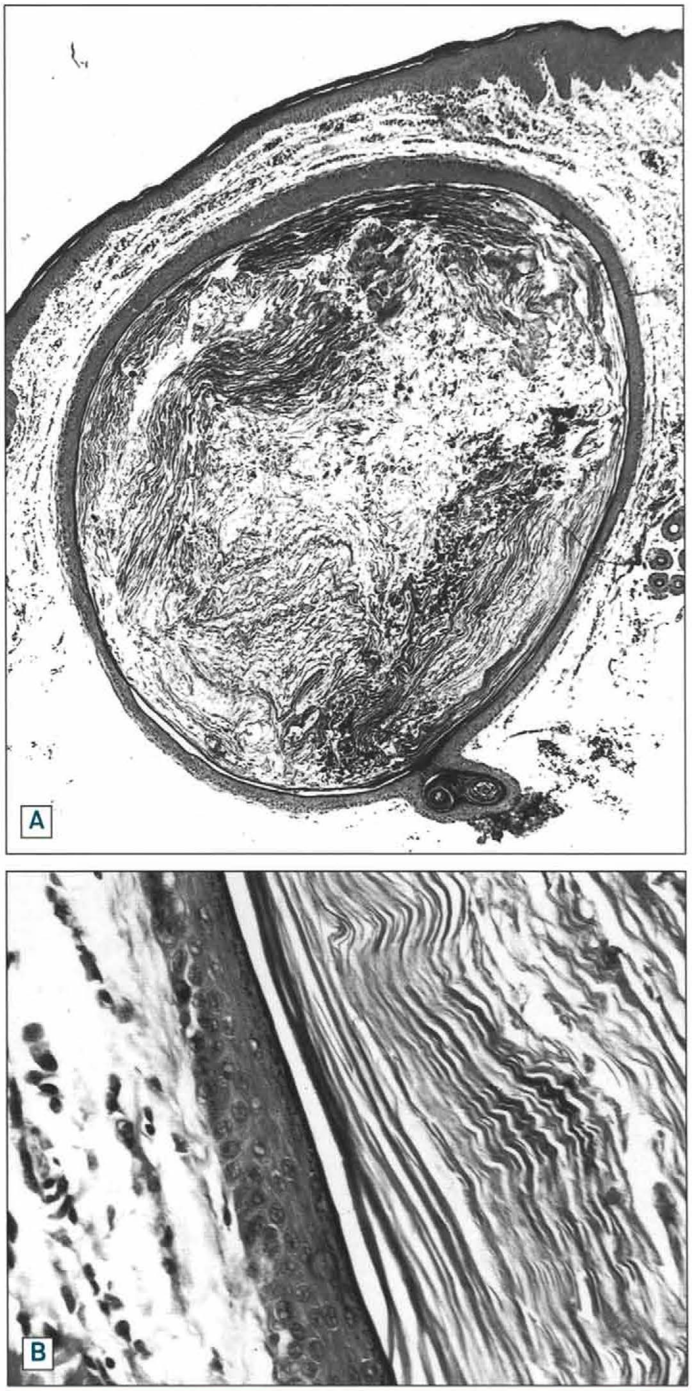

Figure 5.125 Infundibular cyst. A. Cyst filled with laminated keratin. **B.** Simple wall formed by an epidermis with gradual keratinization.

Dermoid cysts (dermoid sinus) are congenital lesions found in young animals along the dorsal midline. They arise by developmental failure of epidermal closure along embryonic fissures that maroons an island of multipotential ectoderm within the subcutis. Some dermoid cysts may extend deep into the tissue and be connected to the dura mater of the spinal cord. Some, such as those occurring in Rhodesian Ridgeback **dogs**, actually retain a sinus pore to the skin surface (see Congenital and hereditary diseases of skin). Dermoid cysts are common in some families of Boxer dogs and affected animals have multiple cysts along the midline of the skin over the forehead. In the **horse**, dermoid cysts occur most often on the midline between the withers and the rump. Dermoid cysts contain keratin and hair fragments and sometimes sebaceous secretions. The dermis abutting the cyst wall has numerous hair follicles, sebaceous glands and occasionally, apocrine glands. Specimens with only hair follicle differentiation may be confused with unilocular trichoepitheliomas, but the dermoid cyst has gradual keratinization rather than abrupt trichilemmal keratinization.

Apocrine cysts may be single or multiple and are filled with clear secretions and lined by a single layer of apocrine cells. The lining may form intraluminal papillary projections. In some animals, particularly dogs, apocrine cysts can be multiple and numerous. The observation of very orderly proliferation, especially if in multiple sites, should lead to a diagnosis of hyperplasia. This condition is referred to as *apocrine gland cystomatosis* (cystic hyperplasia of apocrine glands) and currently is of undetermined etiology. It is most common in middle aged to older male dogs. Expression of epidermal growth factor was detected in the epithelial cyst lining in one case of apocrine gland cystomatosis in an Old English Sheepdog.

Hamartomas

Hamartomas are *disorganized and excessive amounts, or enlarged components, of mature tissue elements indigenous to the site in which they arise.* Most hamartomas are congenital. Hamartomas grow independent of the growth of the animal and hence may enlarge later in life and become a problem. **Epidermal hamartomas** (pigmented epidermal nevus) grossly appear as focal hyperkeratotic and hyperpigmented plaques. Histologically, there is epidermal papillary hyperplasia and hyperpigmentation of the lower epidermis. The stratum granulosa has enlarged keratohyaline granules. In the dog, an association with papilloma virus infection has been documented in some cases. **Follicular hamartomas** have been reported in the dog and consist of collections of very large primary hair follicles and associated glands surrounded by variable amounts of collagen. The hair follicles extend into the subcutis. Clinically, the lesions may be focal or form rugose, disfiguring nodular to plaque-like lesions with large protruding hairs. **Fibroadnexal hamartomas** (adnexal nevus, focal adnexal dysplasia, folliculosebaceous hamartoma) consist of aggregates of markedly distorted and variably inflamed folliculosebaceous units surrounded by dense collagen and lacking a connection to the skin surface. Some pathologists believe this type of lesion is a result of trauma and is not a true hamartoma.

Tumor-like lesions

Idiopathic squamous papillomas *(warts) are 1–5 mm papillary masses comprised of hyperplastic stratified squamous epithelium supported by dermal projections.* The maturation of the epidermis is orderly and does not show viral-induced cytopathic effects as seen in viral papillomas. These lesions are most often seen on the eyelids, face, conjunctiva, or footpads of older dogs and occasionally cats.

Cutaneous horns *are exophytic cylindrical formations of compact keratin* a few millimeters in diameter and 1–2 cm in length formed by an underlying markedly hyperplastic epithelium. Orthokeratotic hyperkeratosis predominates. Cutaneous horns may arise from squamous papillomas, infundibular keratinizing acanthomas, or dilated pores of Winer. Cutaneous horns of the footpad of cats have been associated with feline leukemia virus infection. One report in a cat cites a concurrent cutaneous horn and multiple squamous cell carcinoma in situ.

Warty dyskeratoma is an endophytic growth comprised of a markedly hyperplastic epidermis demonstrating extensive dyskeratosis and suprabasilar acantholysis.

Xanthomas (*xanthogranulomas*) are single to multiple nodular lesions occurring most often in the cat and occasionally in the dog. Clinically, the lesions are *asymptomatic yellow to white nodules, plaques or dermal papules.* In cats, xanthogranulomas are most often found on the face, legs, trunk, or footpads while in the dog the lesions appear on the face, ears, and ventrum. Histologically, the xanthogranulomas are dermal to subcutaneous collections of large foamy macrophages and multinucleated giant cells interspersed among deposits of cholesterol and triglycerides that appear as arrays of clear lenticular clefts and lakes of extracellular pale staining material. Disorders of metabolism such as hyperlipidemia, diabetes mellitus, or high cholesterol diets lead to the formation of xanthogranulomas in most cases, while other cases, particularly solitary xanthomas, are idiopathic. *The histologic differential diagnosis includes granulomatous inflammation associated with infectious agents, such as feline leprosy.* The presence of cholesterol clefts and free lipid and lack of detection of infectious agents should lead to the diagnosis of xanthogranuloma.

Tumors of the epidermis

Papilloma and fibropapilloma

Cutaneous papillomas are benign proliferative epithelial neoplasms that have a complex etiology and pathogenesis. The differences in site preference, clinical course and histology of such lesions have been made more understandable by the discovery that *most papillomas are caused by infection with a host- and often site-specific papillomavirus* of the family Papovaviridae.

Not all papillomas are caused by or contain viruses. The nonviral lesion is considered to be an idiopathic squamous papilloma and is described in tumor-like lesions. Papillomaviruses are associated with skin papillomas in all domestic and many nondomestic species. Immunocompromised animals have increased susceptibility to papillomavirus infection. Cattle, horses and dogs are most frequently affected. In each species, there are several viruses distinguishable by gene sequencing, and in most instances each identified virus type has a preferred site for replication and, except for bovine papillomaviruses, seems highly species-specific. *In general, papillomaviruses induce two types of cutaneous lesions – squamous papilloma and fibropapilloma* – but lesions of intermediate type are common. While some of the variation in anatomic localization or histologic pattern appears to result from management practices and routes of inoculation, the different viral strains themselves seem to have site preferences and typically induce one or the other histologic reaction (papilloma or fibropapilloma).

Advances in immunohistochemical localization of the viral antigens or detection via gene probes has greatly increased the sensitivity of viral detection, permitting retrospective studies on fixed tissues for the presence of the viral genome. Viral papillomas may regress due to cell-mediated immune attack, may persist, or may progress to squamous cell carcinomas. While some viral and host factors are known to influence the behavior of viral-induced papillomas and fibropapillomas, many other factors are not yet defined.

The typical papilloma is a 1–2 cm wart-like, filiform, exophytic, and hyperkeratotic mass composed of hyperplastic epidermis supported by thin, inconspicuous dermal stalks with dilated capillaries. Lesions can be anatomically extensive and multiple (Fig. 5.126A). The stratum corneum exhibits variable degrees of ortho- to parakeratotic hyperkeratosis. Most of the hyperplasia is due to marked expansion of stratum spinosum cells, which have pale basophilic cytoplasm (Fig. 5.126B). Cells of the spinous and/or granular layer have ballooning degeneration of their cytoplasm and eccentric pyknotic nuclei (*koilocytes*). Degenerating keratinocytes may have condensed *eosinophilic cytoplasmic inclusions that represent aggregates of keratin*, a result of the viral cytopathic effect. These inclusions should not be confused with the cytoplasmic inclusions associated with poxvirus infections. The stratum granulosum has large, irregularly shaped eosinophilic keratohyalin granules. Cells of the stratum spinosum and granulosum may have vesicular nuclei with intranuclear pale basophilic viral inclusions that contain virus particles visible with electron microscopy and viral antigen detectable by immunohistochemistry, but these may not be numerous. A variant of the typical squamous papilloma is the **inverted papilloma** that shares the same morphological features, as the typical squamous papilloma except the lesion is endophytic, residing in an invagination of the epidermis. Inverted papillomas have been described as arising in the nailbed of dogs as well as on the skin.

Fibropapillomas *appear as nodules or plaques covered by a variably hyperplastic and hyperkeratotic epidermis*. Classic examples of fibropapillomas are the *equine sarcoid* and *feline fibropapilloma* (see Spindle cell tumors). Microscopic lesions typical of fibropapillomas include the features of acanthosis, hyperkeratosis and downgrowth of rete ridges, but the dermal proliferation predominates. The proliferating cell is a large, plump fibroblast. The cells are arranged in haphazard whorls and fascicles rather than in perpendicular sheets as in granulation tissue. In some the epidermal proliferation is minimal and is seen only as slight acanthosis and accentuation of rete pegs, while in others the hyperplasia resembles full-fledged papillomas.

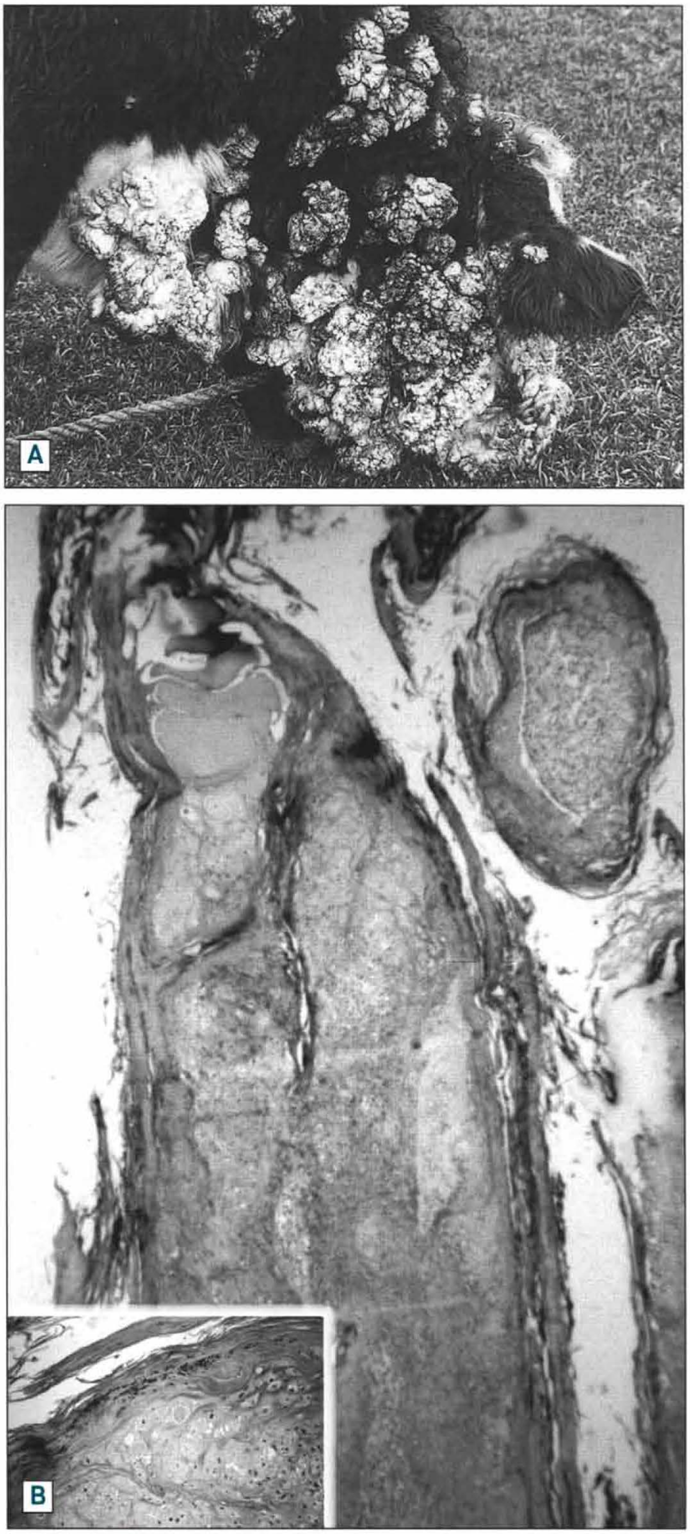

Figure 5.126 A. Multiple **papillomas (warts)** in a steer. **B. Papilloma** in a puppy. Marked hyperplasia is due to marked expansion of stratum spinosum cells. Cells of the spinous and/or granular layer have ballooning degeneration of their cytoplasm (see inset).

Cattle

Six different papillomaviruses occur in cattle. Three (*Bovine papillomavirus* (BPV) types 1, 2, and 5) cause cutaneous fibropapillomas, whereas the other three (BPV-3, -4, -6) cause papillomas of skin (BPV-3, -6) or alimentary tract (BPV-4). For both lesion types, affected cattle are less than 2 years of age and have single or multiple lesions that usually spontaneously regress within a year of appearance. Bovine papillomatosis may be a herd problem in that the virus is easily transmitted by animal-to-animal contact and by fomites. *BPV-1, -2, and -5 cause "teat frond" warts, common cutaneous warts, and "rice grain" fibropapillomas.* These three conditions are characterized by a fibrous core with an overlying variably hyperplastic stratified squamous epithelial lining and occur most often on the udder, teats, head, neck, shoulders and to a lesser extent on the omasum, vagina, vulva, penis, and anus. Lesions may be small nodules or large cauliflower-like lesions subject to trauma and possibly fly strike. Teat papillomas that appear during lactation and regress during the nonlactating period are not uncommon. Interdigital papillomas can lead to lameness. *BPV-3, -4, and -6 cause lesions that are grossly flattened and sessile.* Histologically there is epithelial hyperplasia but not fibroblast proliferation. These lesions tend to be more persistent. In some parts of Scotland and England, BPV-4 causes lesions in the alimentary tract and urinary bladder that may progress to squamous papillomas. Ingested bracken fern (*Pteridium aquilinum*) acts as a co-carcinogen in the progression from benign papilloma of the bladder mucosa to an invasive squamous cell carcinoma. Infection with papillomavirus and repeated exposure to strong sunlight appears to accelerate the development of squamous carcinomas arising in the sclera and lid margins of cattle, particularly those with poorly pigmented periocular skin such as Simmental and Hereford cattle. Papilloma viral infection is therefore one of the contributing factors in the development of the condition known as *cancer-eye*. BPV-1 and BPV-2 have a broader host range and tissue tropism than other papillomaviruses in that they are responsible for both bovine cutaneous fibropapillomas and equine sarcoids.

Horses

Horses develop *typical viral squamous papillomas*. They occur as single or multiple masses in young horses and usually regress within a year (Fig. 5.127). *Muzzle* is the most prevalent site, but tumors may occur anywhere including genital mucous membranes. They are histologically identical to squamous papillomas in calves. Two different viral genome sequences have been described in horses. Unlike the bovine viral strains, however, *the equine virus appears to be species specific. Congenital papillomas* have been reported in foals, and may be hamartomatous rather than viral induced.

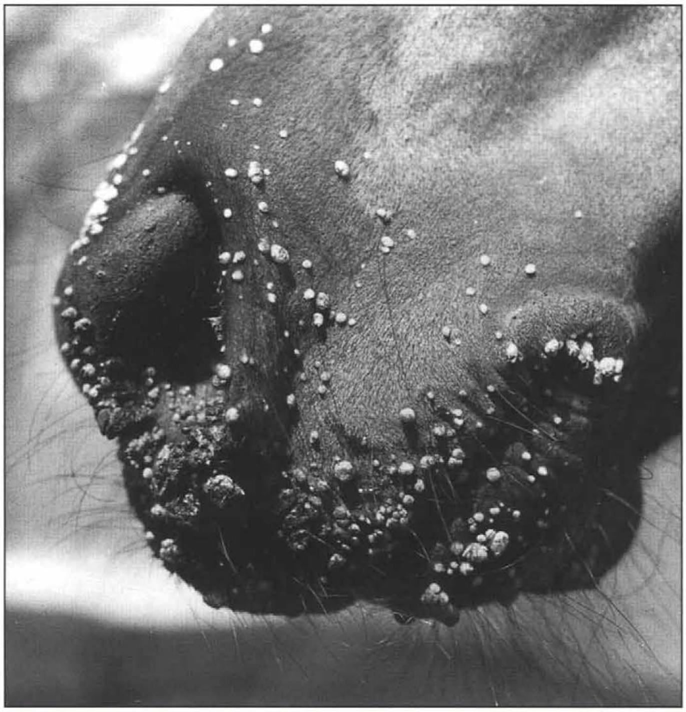

Figure 5.127 Multiple viral papillomas on an equine muzzle.

The most important papillomavirus-induced lesion in the horse is the *sarcoid*, known to be caused by BPV-1 and BPV-2. The lesions are primarily fibroblastic (see Spindle cell tumors) and have not been shown to be transmissible by direct contact.

Sheep and goats

Ovine papillomavirus 1 causes *fibropapillomas* in sheep. There is one report of multiple cutaneous papillomas in a sheep in England in which papilloma-like virus was observed and subsequently transmitted to other sheep. Multiple cutaneous papillomas have been described in goats but circumstantial evidence points towards an actinic rather than viral cause. No virus has been demonstrated by immunofluorescence, electron microscopy or in situ hybridization.

Dogs

Papillomaviruses in dogs cause papillomas of the oral, ocular and genital mucous membranes and of haired skin. Studies indicate that more than one papillomavirus infects the dog and that each virus is responsible for papillomas at a specific body site. *Canine oral papillomavirus* (COPV) has been cloned and characterized and is known to be responsible for canine oral papillomatosis, a contagious and self-limiting condition of young dogs. Occasionally, young dogs with this condition will also develop papillomas on the esophagus, conjunctiva or cornea. Idiopathic sporadic and solitary papillomas can occur on the haired skin of dogs of any age. Eyelid papillomas may appear as part of juvenile papillomatosis or as solitary lesions in older dogs. A report documenting COPV as the cause of multiple papillomas of the haired skin and oral cavity of a dog with corticosteroid-induced immunosuppression suggests that the tissue tropism of the various papillomaviruses is influenced by the immune system. Generalized cutaneous papillomatosis has also been reported in a dog with chemotherapy-induced immunosuppression. A novel papillomavirus was also documented as the cause of multiple foci of endophytic epidermal hyperplasia in a dog on long-term corticosteroid therapy. The lesions resolved with cessation of corticosteroid therapy. Only the oral papillomatosis has been well studied. *The typical transient squamous papillomas contain virus-like basophilic intranuclear inclusions* that are typical of papillomavirus with electron microscopy and immunohistochemistry. The virus is similar to *Bovine papillomavirus 1*. Evidence of viral pathogenesis for the other papilloma-like lesions is not as strong. Some solitary cutaneous papillomas and venereal papillomas contain papillomaviral genome, but the relationship of the viral genetic material to lesion development or to the virus of oral papillomatosis are unknown. Oral or ocular papillomas in young dogs have been reported to progress to squamous cell carcinoma in situ or to invasive squamous cell carcinomas upon rare occasion. A variant of the typical papilloma, the **inverted papilloma** has been reported in the dog. The tumors were single-to-multiple and grossly resembled intracutaneous cornifying epitheliomas (keratoacanthomas). They were keratin-filled cyst-like structures lined by stratified squamous epithelium. The epithelium, however, had intraluminal papillary projections and typical keratinocyte viral cytopathic effects, intranuclear inclusions, and papillomavirus virions present ultrastructurally. Molecular studies suggested the virus was different from COPV.

Cats

Feline fibropapillomas with features virtually identical to the equine sarcoid have been described and found to be associated with papillomavirus DNA via PCR. The implicated virus is most similar to *Bovine papillomavirus* (see Spindle cell tumors). Papillomavirus antigens have also been detected in a large number of cases of multicentric squamous cell carcinoma in situ in cats and in non-neoplastic, proliferative lesions of the epidermis and outer root sheath of hair follicles in immunosuppressed cats. One cat with the non-neoplastic proliferative lesions was infected with FIV and the others were Persians with coat color characteristics suggestive of Chediak–Higashi syndrome. Progression to overt neoplasia and malignancy of these lesions has not been established. At least eight feline papillomaviruses infect the oral cavity and skin of domestic and wild felids.

Rabbits

Domestic **rabbits** develop oral papillomatosis due to infection with *Rabbit oral papillomavirus*. Papillomas, which are multiple and found most often under the tongue, are grossly and histologically typical of viral-induced squamous papillomas.

Squamous cell carcinoma

Squamous cell carcinoma *is a relatively common, locally invasive and occasionally metastatic neoplasm of most domestic species.* The behavior of squamous cell carcinoma of the skin is usually that of locally destructive spread. Its metastatic potential is low, with certain qualifications depending on location. Those initiated by sunlight are slow to metastasize, then usually only to local lymph nodes. In contrast, those originating on the canine digit may be more prone to metastasize, but even these are cured by amputation in virtually all but the most neglected cases.

Sunlight is probably the most important carcinogenic stimulus for these tumors and accounts for the preference of squamous cell carcinoma for the eyelid and conjunctiva of cattle and horses, the ear pinna of cats and sheep, and the vulva of cattle, goats, and recently sheared sheep (Fig. 5.128A, B). Chronic exposure to sunlight has also been proven to cause squamous cell carcinoma of the relatively hairless, poorly pigmented abdominal and juxtanasal skin of dogs (see Actinic diseases of skin). The progression from solar keratosis to carcinoma occurs over several years and in many instances never attains the full status of carcinoma. The action of sunlight may be related to overexpression of p53 protein as a result of UV-induced mutations of the *p53* tumor suppressor gene.

In addition to sunlight, *carcinogens* contained in tobacco, coal tar and soot, arsenic, and smegma have been shown experimentally or by epidemiologic inference to cause squamous cell carcinoma of skin and other tissues. *Genetic factors and papillomaviruses* also influence the occurrence of squamous cell carcinomas. The influence of *epidermal injury* per se in the initiation of cancer is still unsettled, but there is support for this theory in the greater risk of squamous carcinoma at sites of ear notching, branding, burns, and chronic inflammation. Squamous cell carcinomas of the nasal planum arising in chronic cutaneous lesions of discoid lupus erythematosus have been reported in dogs.

Squamous cell carcinomas are usually firm, white, poorly demarcated dermal masses that are ulcerated and streaked with red. In some locations (eye, penis) they are raised and papillary even though the surface is ulcerated. Chronic inflammation accompanies many of these tumors, particularly those of the ear pinna and nail bed. In these instances, the reddening, crusting and ulceration of the inflammatory lesion may hide the tumor. Microscopic examination of such lesions is often dominated by hyperkeratosis, parakeratosis, ulceration, acanthosis and superficial dermal scarring, with only a few foci of unequivocal neoplasia in which atypical squamous cells have invaded across the basal lamina of the hyperplastic rete pegs. The precancerous plaque and papilloma lesions of ocular squamous cell carcinoma are described under Ocular neoplasia (Vol. 1, Eye and ear).

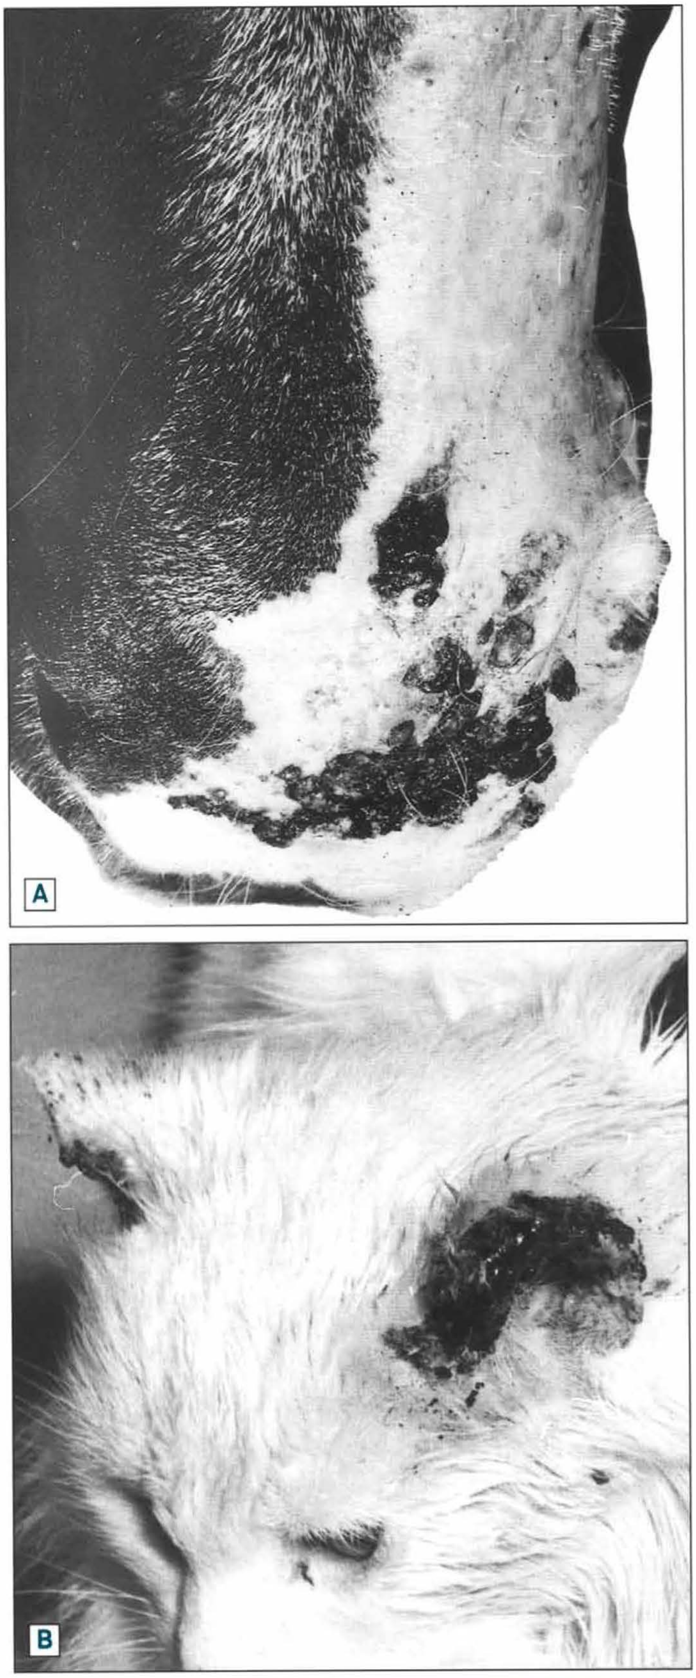

Figure 5.128 Squamous cell carcinoma. A. Involving the unpigmented skin of a horse's nose. **B.** Involving the unpigmented skin of a cat's ears.

Squamous cell carcinomas are recognized microscopically by identifying malignant epithelial cells demonstrating various degrees of differentiation towards keratinocytes. **Squamous cell carcinoma in situ** refers to a malignant tumor of cells with squamous differentiation that is *confined by the basement membrane.* These tumors are often seen in association with ultraviolet light exposure and are interpreted by some pathologists as marked dysplasia (solar keratosis, actinic keratosis), a precancerous stage in the process of malignant transformation of cells. In **invasive squamous cell carcinomas**, *tumor cells breach the basement membrane* to form trabeculae, nests and cords within the dermis that are usually contiguous with the epidermis in at least one area. The tumor cells most resemble those of normal stratum spinosum but have vesicular nuclei with one or multiple very prominent nucleoli. Cytoplasm is usually abundant and eosinophilic. Keratinization within such cords or islands results in laminated keratin "pearls" surrounded by tumor cells. With increasing anaplasia, tumors exhibit wide variation in nuclear size, decreasing cytoplasmic mass, increased basophilia, and disappearance of intercellular bridges. Keratinization may be limited to only individual tumor cells and mononuclear or even multinucleated giant tumor cells may be present. In the typical squamous cell carcinoma, the tumor cells spread through the dermis as slender anastomosing cords, with some cells falling off the cords to remain as apparently isolated islands in the dermal stroma. Tumor cell invasion is usually associated with marked desmoplasia. Mitotic figures are usually numerous and are in proportion to the degree of anaplasia. Some tumors, especially those of actinic origin with a long precancerous phase, are accompanied by abundant mononuclear leukocytic inflammation. Others, such as those of the digit, are both inflamed and very scirrhous. In such tumors, the neoplastic cells may be obscured by inflammatory cell influx, difficult to distinguish from the reactive fibroblasts, or largely destroyed by the ulceration of the inflamed mass.

Acantholytic squamous cell carcinomas are histologic variants demonstrating marked dyscohesion and degeneration of neoplastic keratinocytes resulting in pseudocyst formation within the tumor. This type of tumor must be carefully distinguished from an adenocarcinoma by identifying tumor cell keratinization. **Spindle cell squamous cell carcinomas**, in which the neoplastic epithelium is distinguishable from the desmoplastic stroma only by immunohistochemistry, have been reported. **Basosquamous carcinomas** are low-grade malignant tumors comprised primarily of dermal lobules of basaloid cells with centralized foci of atypical abruptly keratinized cells. The basaloid population may have foci of dyskeratosis or melanization. Tumor lobules may or may not be connected with the epidermis.

Subungual squamous cell carcinomas in **dogs** may be multiple and are seen most often in black dogs, particularly, Labrador Retrievers and Standard Poodles. **Carcinoma of the horn of cattle** is almost exclusive to castrated male adult cattle in India and neighboring countries. The tumor gradually infiltrates and destroys the horn core and may invade adjacent sinuses and cranial bone. The histology is of well-differentiated squamous cell carcinoma but neither the site of origin nor the reason for its peculiar site and sex preference is understood. Theories about chronic trauma to the huge horns are not now in vogue.

Multicentric squamous cell carcinoma in situ (Bowen-like disease) is a type of squamous cell carcinoma confined by the basement membrane. These lesions may progress to invasive squamous cell carcinomas. This tumor is not associated with exposure to ultraviolet light but instead has been associated with papillomavirus infection. The condition has been described in middle-aged to older mixed-breed **cats**. One case reports an association with a cutaneous horn in a cat with no evidence of a viral infection. Tumors appear as 0.5–5 cm in diameter, single to multiple irregular, slightly elevated plaque or papillary lesions of haired pigmented skin. Microscopically, sharply demarcated areas of the epidermis and follicular outer root sheath are irregularly thickened and disorganized by neoplastic keratinocytes. The basal and spinous layers are most affected. Mitotic activity is present in all layers of the epidermis and keratin pearl formation may be present. Tumor cells often have large hyperchromatic nuclei and may have vacuolated cytoplasm, cytoplasmic pallor, or occasionally are multinucleated. The tumors are often pigmented and may have papillomatous epidermal projections with marked hyperkeratosis.

Basal cell tumor

Basal cell tumors are *common in dogs and cats but are rare in other domestic species. They are the most common skin tumor of cats.* Current classification schemes limit the category of basal cell tumors to tumors *comprised only of proliferations of undifferentiated basaloid cells.* Those that exhibit differentiation towards basal cell-derived structures such as sebaceous glands, hair follicles or even keratinized epidermis are given a wide variety of names depending on the predominant direction of such differentiation. This new reclassification of cutaneous tumors has now placed some of the tumors that used to be considered basal cell tumors in the category of trichoblastomas (see Tumors with adnexal differentiation). Human basal cell tumors most frequently occur in lightly pigmented skin exposed to sunlight, the latter known to favor the development of the tumor. No such predilection is proven for dogs and cats.

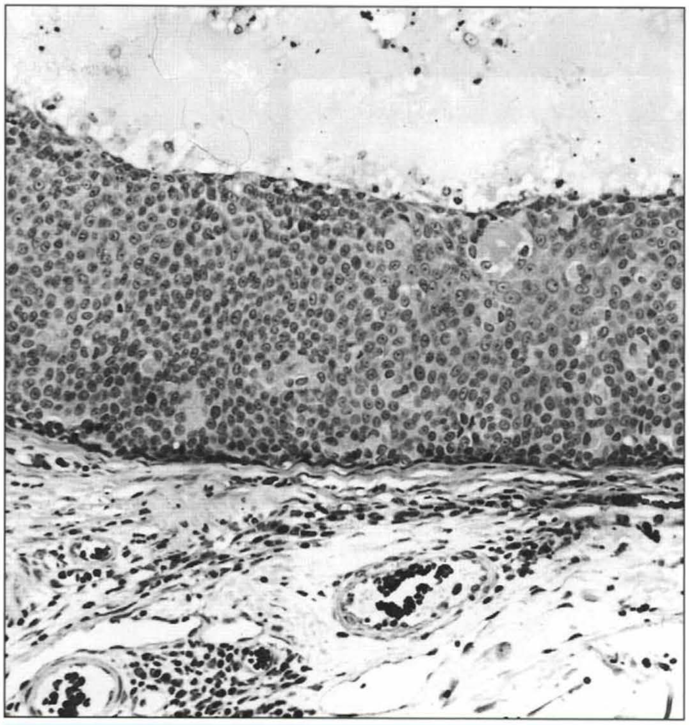

Figure 5.129 Cystic basal cell tumor.

Histologically, basal cell tumors are composed of cords or nests of cells resembling those of normal stratum germinativum. Each has an oval, deeply basophilic nucleus, a single nucleolus, and scant, eosinophilic cytoplasm with indistinct cell boundaries. In contrast to normal stratum germinativum, there are no intercellular bridges. The cells extend into the dermis as islands, or grow expansively as solid sheets, multiple small cysts lined by basal cells, or less frequently as a single large cyst (Fig. 5.129). The latter form is most common in the cat. Several layers of undifferentiated basal cells with no inner limiting membrane and no adnexal or squamous differentiation form each cyst. The cysts are usually filled with eosinophilic debris, and most probably form by central necrosis of an initially solid mass of basal cells. The islands of tumor cells may or may not connect with the overlying epidermis. Mitotic figures and nuclear pleomorphism are variable. Benign tumors have no stromal invasion or associated desmoplasia. Tumor cells may contain melanin, and melanophages may be present in the intervening stroma.

Basal cell carcinomas have two subtypes. **Infiltrative basal cell carcinomas** are comprised of cords of primitive basaloid cells that penetrate the surrounding dermis and possibly subcutis. Mitotic figures may be numerous. The tumor is usually associated with desmoplasia. **Clear cell basal carcinomas** are more rare and consist of large, polygonal cells with clear or finely granular cytoplasm. Nuclei lack pleomorphism and mitoses may be variable.

Tumors with adnexal differentiation

Tumors arising from hair follicles

Hair follicle (pilar) neoplasms are common in dogs but apparently are very rare in other domestic species. Their classification is rather complex; however, the majority of tumors arising in animals share a benign biological behavior. Exceptions exist as described below.

Intracutaneous cornifying epithelioma (*infundibular keratinizing acanthoma*) is a benign cystic tumor of the skin of dogs. Common sites are the dorsum of the neck and back. Usually there is only a single tumor, but in Norwegian Elkhounds, a breed predisposed to these tumors, they may be multiple or occur in succession. Tumors of this description arising in the subungual region are called **keratoacanthomas**.

The gross lesion is a slightly raised firm 1–3 cm nodule that may have a central craterous pore representing the follicular isthmus or infundibulum from which keratin can be expressed. *The histologic lesion is a simple or multiloculated cavity filled with keratin and lined by squamous epithelium with large, pale eosinophilic squamous cells multifocally containing keratohyaline granules.* The periphery of the cyst wall consists of basal cells (Fig. 5.130A, B). The basal cells have gradual and complete maturation to stratum corneum, but may become somewhat disoriented and form keratin pearls within the cyst wall as well as shedding keratin into the lumen. The basilar layer is orderly, and while it may show blunt cord-like expansion into surrounding compressed dermis and anastomosing cords of epithelial cells forming small horn cysts in the wall of the central cyst, there is no breach of the basement membrane by tumor cells. Focal rupture is common, inciting a granulomatous or pyogranulomatous reaction in surrounding dermis.

Trichoepithelioma is *a tumor of primitive hair germ that exhibits rudimentary differentiation towards all three segments of the follicle: the infundibulum, isthmus, and the inferior segment.* Trichoepitheliomas are single or multiple skin tumors occurring anywhere on the body with a slight preference for the back. The typical macroscopic appearance is of a very firm, white, multilobulated and encapsulated tumor that may infrequently be mineralized. Histologically, the usual pattern consists of multiple islands of basal cells with differentiation into the external or internal sheath surrounded by a thickened basement membrane; the center of each island undergoes abrupt keratinization without interposition of a granular layer (Fig. 5.131A, B). Occasional tumor cells containing trichohyaline granules and foci of matrical keratinization are present.

The outer layer of basal cells may abut the fibrous stroma or send out basal cell ribbons into a mucinous stroma. Some trichoepitheliomas have several large primary cystic areas surrounded by many smaller cysts. Rupture of some of the keratinaceous cysts stimulates pyogranulomatous inflammation within the stroma and even within the cyst, sometimes accompanied by mineralization and foreign-body giant cells. Mineralization and inflammation are more typical of the closely related pilomatricoma. **Malignant trichoepitheliomas** have the additional features of mitotic activity, cystic degeneration and necrosis, and invasion of subcutis sometimes accompanied by desmoplasia. Lymphatic invasion is considered an essential finding to confirm malignancy by some pathologists. Regional and pulmonary metastasis is possible. *Trichoepitheliomas are distinguished from all other epidermal or appendage tumors by the abrupt (matrical) keratinization and the follicle-like basal cell nests that surround it.* Other tumors or cysts simulating trichoepithelioma lack one or both of these features.

Tricholemmoma (also trichilemmoma) is a rare, *benign and nonrecurring,* pilar tumor of dogs in which tumor cells differentiate into cells characteristic of either the inferior segment of the hair follicle (**inferior tricholemmoma**), external root sheath, or the isthmic (**isthmic tricholemmoma**) section of the external root sheath. In *inferior tricholemmomas,* tumor cells form nests separated by a fine collagenous stroma. The tumor cells have abundant eosinophilic cytoplasm that is pale (clear cells) peripherally and more intensely eosinophilic toward the center of the nests (Fig. 5.132). Pallor of the outermost layer of cells is due to marked cytoplasmic glycogen storage, seen in histologic section as cytoplasmic clearing. These are thought to represent differentiation toward
